January 12, 2005

## Abstract

This paper presents strong evidence for a systematic concave relation between wages on the one hand and job and worker characteristics on the other hand by adding second order terms to a Mincerian earnings function for 6 OECD countries. An assignment model with search frictions provides a parsimonious explanation for our findings. This model yields two restrictions on the coefficients which fit the data very well. The impact of search frictions on wages is large. We find that reservation wages are 25% lower than they would be in a frictionless world. We argue that it is unlikely that our findings are caused by unobserved components in worker and job characteristics. Our results relate to the literature on industry wage differentials, and on structural identification in hedonic models.

Keywords: wages, search, assignment

# 1 Introduction

How much output is lost due to search frictions? To what extent do wages deviate from the simple Walrasian rule of "one good, one price", implying that workers with equal human capital should earn equal wages? Labor economists have been struggling with these questions for ages. Empirical inference is troubled by the fact that residuals in simple Mincer type earnings regressions can be due to at least three factors: (1) imperfect measurement of the relevant human capital variables, (2) measurement error in wages, and (3) non-Walrasian features of the labor market like search frictions, resulting in wage dispersion between otherwise homogeneous workers. A simple way to decompose the error term in these three components is not available.

This paper shows that an estimate of the effect of search frictions on workers with equal human capital can be derived from a non-linearity in the earnings function. In fact, simply adding second order terms in human capital variables and job characteristics suffices for our approach. At first sight, the identification of the effect of frictions from these non-linearities seems to put the full burden of proof on functional form assumptions. We show that this is not the case. The only assumption required for our approach is that the third moments of the distributions of observable and non-observable worker and job characteristics are approximately equal to zero, as holds for the normal distribution. Even if this condition is not satisfied, only strange assumptions on these distributions can rationalize our empirical results. The empirical evidence, and the regularity of our results across countries, provides strong support for the relevance of search frictions above unobserved heterogeneity. Our methodology allows a back-of-the-envelope calculation of the size of the *cost of search*, which is defined as the relative gap between the worker's reservation wage and the wage she would receive in a hypothetical Walrasian world. This cost of search is estimated to be between 15 and 30 %.<sup>1</sup> The output losses due to non-Walrasian features of the labor market are therefore substantial.

The seminal papers by Dickens and Katz (1987) and Krueger and Summers (1988) started a debate on the nature of inter-industry wage differentials. Some contributors claimed that the industry effects in simple OLS earnings regressions are the reflection of genuine wage differentials between workers with equal human capital in different industries. These differentials might be driven by efficiency wages or rent sharing. Others

---

<sup>1</sup>In a previous version of the paper we reported higher estimates but those were based on a mistake.

took a more sceptical position, claiming that industry differentials might very well be attributed to unobserved worker characteristics which are correlated with industry choice, see Murphy and Topel (1987). The large literature on the measurement error in schooling variables, see Angrist and Krueger (1991), reveals that the importance of these unobserved characteristics should not be underestimated. Recent contributions apply matched worker-firm data to resolve the issue, see Abowd, Kramarz, and Margolis (1998).

Another strand in this literature starts from Burdett and Mortensen's (1998) model of monopsonistic wage setting in a world with on the job search. A high wage raises the inflow and reduces the outflow of workers, but it also reduces profits by increasing the wage bill. This trade-off results in a non-degenerate equilibrium wage distribution. Larger firms pay higher wages and have longer average tenures. These correlations allow for inference on the dispersion of wages, holding constant the human capital of the worker, see Van den Berg and Ridder (1998) and Postel Vinay and Robin (2002).

This paper applies the search model of Teulings and Gautier (2004), that is based on the assignment models analyzed by Sattinger (1975) and Teulings (1995). Workers vary by their level of skill (or human capital) and jobs by their level of complexity. Both the skill and the complexity index vary continuously, so that there is an infinitum of job and worker types. Highly skilled workers are assumed to have an absolute advantage in all jobs and a comparative advantage in complex jobs. In the Walrasian version of this model, each worker type is assigned to a unique job type, where output reaches its maximum. Both this optimal complexity level and log wages are increasing in the skill type of the worker, the former due to comparative advantage, the latter due to absolute advantage. In the presence of search frictions, workers will not wait for ever till this unique first best job type comes along. When a contact occurs between a worker and a job, both face a trade off between either the pay off of matching with the partner that is available now or waiting for a more suitable partner. Hence, workers accept a range of job types, instead of a single job type as in the Walrasian equilibrium. Suppose that wages are set by Nash bargaining between the worker and the firm. Then, both sides share the loss in output relative to what it would be in the optimal assignment. Wages for a particular type of worker are concave in the job type: the wage reaches a maximum for the level of job complexity that maximizes output; it is lower for less or for more complex jobs. The basic idea of this paper is to capture this concavity empirically by simply adding second order

terms in the skill and complexity levels to Mincerian earnings functions.

We can construct a proxy for the skill index. Using standard human capital variables, we construct this index such that it is linearly related to wages. Similarly, we can construct a complexity index linearly related to wages, using industry and occupation dummies. When both indices enter jointly in a wage regression, their coefficients have no structural interpretation, since both indices are perfectly collinear in the Walrasian case, due to the comparative advantage assumption. Hence, the size of both coefficients is determined by the share of unobserved heterogeneity in the variance of both indices, and not by the underlying structure of the economy.<sup>2</sup> We show, however, that it is difficult to justify the second order terms on these grounds. If we apply a standard normality assumption on the distribution of both observed and unobserved job and worker characteristics, then second order terms cannot be explained by unobserved heterogeneity. In fact, any distribution with a zero third moment yields this conclusion.

The estimation results can be used to quantify the size of search frictions. We derive a simple relation for the cost of search from our theoretical model. For the empirical implementation, we allow the skill and complexity index to be only partially observed, but we assume the third moments of the distribution of observed and unobserved characteristics to be zero. Using this assumption, we are able to derive a simple relation between the regression coefficients of the Mincer equation and the size of search frictions. The model yields two testable predictions regarding the sign and relative magnitude of the coefficients for the second order terms.

We cannot test the normality assumption for unobserved characteristics, but we can test this assumption for the observed part of the skill and complexity indexes. Obviously, these assumptions are not exactly satisfied, but they come close to the data. More importantly, these deviations from normality differ widely between the six countries that we investigate. For some countries, the skill distribution is skewed to the left, for others it is skewed to the right, and *mutatis mutandis* the same for the complexity distribution. However, the estimated coefficients for the second order terms have no relation to these differences in the skewness of the skill and complexity distribution, while they fit the restrictions on their sign and relative magnitude derived from the search model very well

---

<sup>2</sup>For the purpose of this paper, it is irrelevant whether there is measurement error in observed characteristics or unobserved heterogeneity, because the former can always be respecified in terms of the latter. Hence, we discuss our results in terms of unobserved heterogeneity.

for all six countries. Hence, search frictions are a far more parsimonious explanation for these terms than asymmetric unobserved heterogeneity.

The paper is organized as follows. Section 2 derives a theoretical relation between wages and worker and job characteristics in the presence of search frictions. This relation is used in Section 3 to explain why in a simple Mincerian type of wage equation, second order terms of worker skills and job characteristics are significant. We also discuss whether or not these second order terms can be interpreted in terms of unobserved characteristics. Section 4 concludes by relating our results to the literature on industry wage differentials and on structural identification of hedonic models.

## 2 Wage formation in a world with search frictions

### 2.1 The Walrasian point of reference

Consider a Walrasian world where workers and jobs are heterogeneous. Workers differ by their level of skill, denoted  $s$ , and jobs by their level of complexity, denoted  $c$ . Both indexes vary continuously on the real domain. Highly skilled workers have an *absolute advantage* in all jobs and a *comparative advantage* in complex jobs. The main features of this type of world are discussed extensively in Teulings (1995, 2005), so we state the characteristics of market equilibrium without proof. Let  $y(s, c)$  denote the log market value of output of worker type  $s$  at job type  $c$ . We assume  $y(\cdot)$  to be twice differentiable in both its arguments. Absolute advantage implies that better skilled workers are more productive than their colleagues with less skills in any job,  $y_s(s, c) > 0$ . Hence, better skilled workers earn higher wages in equilibrium. The Ricardian concept of comparative advantage implies that better skilled workers are *relatively* more productive in more complex jobs. This requires productivity to be *log* supermodular in  $s$  and  $c$ :  $y_{sc}(s, c) > 0$ .<sup>3</sup> Furthermore, we assume that  $y(s, c)$  has a unique interior maximum in  $c$  for each  $s$  and that a free entry-zero profit condition for firms applies. Hence, log wages are equal to the value of output. Finally, the value of leisure is zero, so that workers are willing to work for any positive wage above non-employment.

---

<sup>3</sup>Since Becker's (1973) seminal paper on marriage markets, it has been standard to associate comparative advantage with supermodularity. However, the Ricardian concept of comparative advantage, where the output of a match is tradable and there is free entry, requires *log* supermodularity, see Teulings and Gautier (2004) for a further analysis.

In this Walrasian equilibrium, workers of type  $s$  are assigned to that job type,  $c(s)$ , where they produce the highest value of output, and by implication, where they earn the highest wage. By construction,  $y[s, c(s)]$  satisfies the first and second order condition for a maximum:

$$\begin{aligned} y_c[s, c(s)] &= 0 \\ y_{cc}[s, c(s)] &< 0 \end{aligned}$$

since  $y(s, c)$  is differentiable and since there is an interior maximum of  $y(s, c)$  in  $c$  for each  $s$ . Under the assumptions above, this equilibrium assignment  $c(s)$  is a differentiable function. It is strictly increasing,  $c'(s) > 0$ , due to comparative advantage of better skilled workers in more complex jobs.<sup>4</sup> Since  $c(s)$  is strictly increasing, it has a well defined inverse function,  $s = s(c)$ ,  $s'(c) > 0$ , with  $s[c(s)] = s$ . Hence, the equilibrium assignment is described by a one-to-one correspondence between  $s$  and  $c$ . Each skill type is assigned to a unique job type and vice versa. The equilibrium locus of log wages  $w$  is a twice differentiable function of the skill level  $s$ . It is strictly increasing,  $w = w^*(s) = y^*(s)$ ,  $w^{*'}(s) > 0$ , due to absolute advantage of better skilled workers in any job type. The superscript  $*$  indicates that  $w^*(s)$  is the log wage for worker type  $s$  when assigned to her optimal job type  $c(s)$ , and mutatis mutandis the same for  $y^*(s) \equiv y[s, c(s)]$ . Combining these results yields  $dw^*[s(c)]/dc = w^{*'}[s(c)]s'(c) > 0$ : log wages can also be written as an increasing function of job complexity  $c$ . To summarize, log wages are an increasing function of both the skill level  $s$  and the level of job complexity  $c$ , while the skill level  $s$  is an increasing function of the complexity level  $c$  (and vice versa).

We have not yet defined the units of measurement of  $s$  and  $c$ . For the subsequent analysis, it is useful to apply a convenient normalization of both indexes. First, without loss of generality we can choose the unit of measurement of wages such that  $E[w] = 0$ . Next, we can apply any increasing twice differentiable transformations to  $s$  and  $c$  without losing any features of the equilibrium that we discussed above. Absolute and comparative advantage of better skilled workers, the one-to-one correspondence between

---

<sup>4</sup>Differentiating the identity:  $y_c[s, c(s)] = 0$  with respect to  $s$  yields:

$$y_{sc}[s, c(s)] + y_{cc}[s, c(s)]c'(s) = 0$$

Comparative advantage implies  $y_{sc}[s, c(s)] > 0$ , the second order condition for a maximum implies  $y_{cc}[s, c(s)] < 0$ . Hence:  $c'(s) > 0$ .

$s$  and  $c$ , and the twice differentiability of the log wage function, all these features are invariant to such transformations. A convenient transformation of  $s$  is  $w^*(s)$ . After this transformation, the log wage in the optimal assignment is a linear function of the transformed skill variable, with a unit slope:  $w^*(s) = s$ . Since  $E[w] = 0$ , we have:  $E[s] = 0$ . Likewise, a convenient transformation of  $c$  is  $w^*[s(c)]$ . Then, log wages in the optimal assignment are also a linear function of the transformed complexity variable, also with a unit slope,  $w^*[s(c)] = c$ , and hence:  $E[c] = 0$ . As a further consequence, the assignment of workers to jobs is linear with unit slope:  $c(s) = s$  (or equivalently:  $s(c) = c$ ). Due to this linear one-to-one correspondence between  $s$  and  $c$ , both variables are perfectly correlated in equilibrium. Throughout this paper,  $s$  and  $c$  refer to the skill and complexity indexes that are transformed in this way. This makes them equal to the log wages associated with their respective optimal job type  $c(s)$ , or worker type  $s(c)$ . It is important to note that these normalizations can be imposed without loss of generality. Note furthermore that apart from the assumptions on the differentiability of the output function  $y(\cdot)$ , and on absolute and comparative advantage, we do not make any other functional form assumption.

## 2.2 Adding search frictions

The Walrasian assignment model of the previous section can be extended with search frictions, following the analysis of Teulings and Gautier (2004). The idea is that now workers meet only a limited number of job types per period and vice versa. For simplicity, we rule out on the job search: workers can only search while being unemployed. In the Walrasian equilibrium, a worker of skill type  $s$  was assigned to the unique job type  $c(s)$  that maximized the value of her output, yielding a one-to-one correspondence between  $s$  and  $c$ . Hence, both variables were perfectly correlated. In the presence of search frictions, this one-to-one correspondence breaks down, so that the correlation between  $s$  and  $c$  is no longer perfect. Workers cannot afford to wait for ever till the optimal job type  $c(s)$  comes along, and mutatis mutandis the same for firms. Hence, they accept a set of job types instead of just the optimal job. Let  $r(s)$  be the log reservation wage of the worker. Workers accept only jobs that pay a log wage of at least  $r(s)$ . In the Walrasian equilibrium, this reservation wage is equal to the log wage and to log output:  $y^*(s) = w^*(s) = r(s)$ , since workers will not accept any wage offer that pays less than

what they can get in the optimal assignment. Search frictions make workers less choosy, since they cannot afford to search forever till they find the optimal job type. This reduces log reservations wages  $r(s)$  below  $y^*(s)$ :

$$r(s) \equiv y^*(s) - x(s) = y[s, c(s)] - x(s) \quad (1)$$

$x(s)$  is the ratio between the maximum output and the reservation wage or the relative loss in reservation wage due to search frictions. Hence, we refer to  $x(s)$  as the *cost of search*. Search models imply that a match between a worker and a firm is characterized by a positive surplus  $y(s, c) - r(s)$ . Wage setting distributes this surplus between the worker and the firm. We assume wages to be set by Nash bargaining over this surplus.<sup>5</sup> Let  $\beta$  be the worker's bargaining power parameter. Then, the log wage of an  $s$ -type worker in a  $c$ -type job satisfies approximately:<sup>6</sup>

$$w(s, c) \cong r(s) + \beta [y(s, c) - r(s)] \quad (2)$$

Hence,  $w(s, c)$  is an increasing function of  $y(s, c)$  for a fixed  $s$ . Therefore,  $c(s)$  is also the value of  $c$  that maximizes  $w(s, c)$  for a fixed  $s$ :  $w[s, c(s)] \equiv w^*(s)$ .<sup>7</sup> The situation is depicted in Figure E. Panel A represents the Walrasian case, where  $r(s) = w^*(s) = y^*(s)$ , and hence  $x(s) = 0$ . All workers of type  $s$  are assigned to the job type  $c(s)$  that maximizes their output. Panel B represents the case with search frictions:  $r(s)$  is less than  $y^*(s)$ ,

---

<sup>5</sup>Like in the Walrasian case, there are no other factors of production than labor. Firms have to pay a per period cost of maintaining a vacancy, which limits the supply of vacancies. Firms' expected share in the surplus compensates them for the cost of maintaining vacancies, see Teulings and Gautier (2004) for details.

<sup>6</sup>Strictly speaking, this relation applies in levels:

$$W = R + \beta X$$

However, for a small relative difference  $x$ , the difference is of higher order:

$$w = r + \beta x + O[x^2]$$

since  $\ln(1 + \beta x) = \beta x + O(x^2)$ . Close to the Walrasian equilibrium,  $x$  is small.

<sup>7</sup>There is an important difference between this model and Shimer and Smith (2000). They treat both side of the market symmetrically, so that their wage equation reads:

$$w(s \text{ when matched to } c) = r(s) + \beta [y(s, c) - r(s) - r(c)]$$

where by symmetry  $\beta = \frac{1}{2}$ . Since there are no other factors of production than labor, the firm's outside option is zero in our model, so  $r(c)$  drops out. Hence, contrary to Shimer and Smith's model, the maximum of  $y(s, c)$  and  $w(s, c)$  for a given  $s$  coincide.

the difference being  $x(s)$ . An  $s$ -type job seeker is less choosy than in a Walrasian world and accepts all  $c$ -type tasks for which  $y(s, c) \geq r(s)$ . Low wages  $w(s, c)$  are a weighted average of  $r(s)$  and  $y(s, c)$ . Figure 1 depicts both situations in  $s, c$ -space: the Walrasian equilibrium is represented by the solid diagonal, the search equilibrium by the band around it.

Like in the Walrasian equilibrium, we choose suitable normalizations of  $s, c$  and  $w$ . We maintain the normalization  $E[w] = 0$ . The normalization of  $s$  and  $c$  is more involved in this case, since the one-to-one correspondence between  $s$  and  $c$  that applied in the Walrasian equilibrium does not carry over to the search equilibrium. Hence, wages depend on both  $s$  and  $c$ . For the empirical exercise discussed in Section 3, it is most convenient to normalize  $s$  and  $c$  as the conditional expectations of log wage:

$$\begin{aligned} E[w(s, c) | s] &= s \\ E[w(s, c) | c] &= c \end{aligned}$$

The Walrasian equilibrium is a special case of this rule. Then:  $E[c|s] = c(s)$ , so that  $E[w(s, c) | s] = w[s, c(s)] = w^*(s) = s$ . A similar argument applies to  $E[w(s, c) | c]$ . The idea behind the normalization is similar to inference based on revealed preference. There, we have no direct observations of the utility function, but we infer it from observed behavior. We can normalize utility by any monotonic transformation without loss of generality. Here, we have no direct observations on  $s$  and  $c$ , but we infer them from log wages. Again, we can normalize them by any increasing transformation without loss of generality.<sup>8</sup>

We simplify the analysis by the following assumption:

**Assumption 1:** The cost of search are equal for all skill types:  $x(s) = x$

By this assumption the cost of search is equal for all skill types, so that  $x$  is the fraction of foregone output due to search frictions, i.e. the difference between output in a Walrasian economy and an economy with search frictions. In a more general model, Assumption 1 is likely to be violated. Here our aim is more modest. We are only interested in a first order approximation of  $x(s)$ . For that purpose, we can ignore variations in  $x(s)$  along

---

<sup>8</sup>The usual approach of a theorist is to make assumptions on primitives and derive the implications for endogenous variables. Here we work the other way around. That is most convenient for the empirical part of this paper. The analogy with revealed preference shows why this is a legitimate approach.

the support of  $s$ . Teulings and Gautier (2004) derive an expression for  $x(s)$  in terms of the primitives of the model. A suitable combination of the density of skill supply and the cost of maintaining vacancies, generates Assumption 1 as a result. Furthermore, we show that  $x(s)$  is almost constant in simulations of the model for quite standard assumptions on these primitives, except for extreme values of  $s$ .

We apply a Taylor expansion around the Walrasian equilibrium, where the cost of search are zero,  $x = 0$ . Let  $\Delta c \equiv c - c(s)$  denote the deviation from the optimal allocation for type  $s$  and let  $\Delta c^* \equiv c^+(s) - c(s)$ , where  $c^+(s)$  is the most complex job that a worker of type  $s$  is willing to accept, that is, for which  $y(s, c) \geq r(s)$ . In the Walrasian equilibrium,  $\Delta c^* = 0$ . A worker of type  $s$  turns down more complex jobs because too much output would go to the firm. Nash bargaining implies that output is equal to the reservation wage at the boundary of the matching set. Hence:

$$y[s, c(s) + \Delta c^*] = r(s)$$

By a second order Taylor expansion of equation (1) with respect to  $c$  around  $c = c(s)$  and using  $y_c[s, c(s)] = 0$ , we have:

$$x \cong -\frac{1}{2}y_{cc}\Delta c^{*2} \quad (3)$$

We can make exactly the same argument for the least complex job that a worker of type  $s$  is willing to accept. Hence, job offers with  $|\Delta c| > \Delta c^*$  are rejected.

**Lemma 1:**

*Up to a second order Taylor expansion, the matching set of a type  $s$  worker is symmetric around the midpoint  $c(s)$ , its upper bound being  $c(s) + \Delta c^*$  and its lower bound being  $c(s) - \Delta c^*$ .*

This lemma can be used for the derivation of the expectation of  $\Delta c^2$  in the matching set, again using a Taylor expansion:<sup>9</sup>

$$\begin{aligned} \text{E}[\Delta c|s] &\cong 0 \\ \text{E}[\Delta c^2|s] &\cong \frac{1}{3}\Delta c^{*2} \cong -\frac{2}{3}y_{cc}^{-1}x \end{aligned} \quad (4)$$

---

<sup>9</sup>Let  $f(\Delta c) = f_0 + f_1\Delta c + O(\Delta c^2)$  be a second order Taylor expansion of the density function  $\Delta c$  in the pool of vacancies. Then:

The parameter  $|y_{cc}|$  has a special interpretation. It is the curvature of the log cost function of a firm producing task type  $c$ , or, the *complexity dispersion parameter*, see Teulings (2005), measuring the productivity loss due to suboptimal assignments:

$$\text{Loss}(\Delta c) = y^*(s) - y[s, c(s) + \Delta c] \cong -\frac{1}{2}y_{cc}\Delta c^2$$

where the second equality follows from the same Taylor expansion as in equation (3). Since the wage of the least attractive job type in the matching set of a worker of type  $s$  is equal to her reservation wage,  $\text{Loss}(\Delta c^*)$  is equal to  $x$ . Consider a second order Taylor expansion of equation (2) around  $w[s, c(s)]$  and a first order expansion of the expectation of  $s$  conditional on  $c$  and vice versa:

$$\begin{aligned} w(s, c) &\cong w_0 + w_s s + w_c c + \frac{1}{2}w_{ss}s^2 + w_{sc}sc + \frac{1}{2}w_{cc}c^2 & (5) \\ w_{cc} &= \beta y_{cc} < 0 \\ \mathbb{E}[c|s] &\cong \rho_0 + \rho c \\ \mathbb{E}[s|c] &\cong \tau_0 + \tau s \end{aligned}$$

The inequality in the second line follows from the concavity of  $y[s, c(s)]$ . Note that the second order expansion implies the implicit assumption that the complexity dispersion parameter is constant along the domain of  $s$ . Variation in  $y_{cc}$  along the domain of  $s$  is a higher order phenomenon that will be ignored in the subsequent analysis. The same applies to variation in the cost of search  $x$ . The subsequent proposition relates the other partial derivatives of  $w(s, c)$  to the parameters of the joint distribution of  $s$  and  $c$ .

**Proposition 1** *Normalize  $w$ ,  $s$  and  $c$  such that  $E[w] = 0$ ,  $E[w(s, c) | s] = s$  and  $E[w(s, c) | c] = c$ . Then, the Taylor expansions in equation (5) imply:*

$$w(s, c) \cong w_0 + s - \omega [\rho s^2 - (1 + \rho) sc + c^2] \quad (6)$$

---

$$\begin{aligned} \mathbb{E}[\Delta c] &= \frac{\int_{-\Delta c^*}^{\Delta c^*} f(v) v dv}{\int_{-\Delta c^*}^{\Delta c^*} f(v) dv} = \frac{\frac{2}{3}f_1\Delta c^{*3} + O(\Delta c^{*4})}{2f_0\Delta c^* + O(\Delta c^{*2})} = O(\Delta c^{*2}) \\ \mathbb{E}[\Delta c^2] &= \frac{\int_{-\Delta c^*}^{\Delta c^*} f(v) v^2 dv}{\int_{-\Delta c^*}^{\Delta c^*} f(v) dv} = \frac{\frac{2}{3}f_0\Delta c^{*3} + O(\Delta c^{*4})}{2f_0\Delta c^* + O(\Delta c^{*2})} = \frac{1}{3}\Delta c^{*2} + O(\Delta c^{*3}) \end{aligned}$$

where  $\omega \equiv -\frac{1}{2}w_{cc} = -\frac{1}{2}\beta y_{cc} > 0$  and  $\sqrt{\rho} = \text{Cor}[s, c]$  and where  $w_0$  is an appropriate constant.

The proof is delegated to Appendix A. Proposition 1 provides a simple economic theory for a wage function that is concave in  $s$  and  $c$ . In the Walrasian equilibrium,  $s$  and  $c$  are perfectly correlated with  $c = s$ , and hence  $\text{Var}[c] = \text{Var}[s]$ . This equality does not hold in a search equilibrium. We show in Appendix A that  $\text{Var}[c] = \rho \text{Var}[s]$ , which is smaller than  $\text{Var}[s]$  since  $\sqrt{\rho}$  is a correlation. This is due to absolute advantage: in the optimal assignment  $c(s)$ , a variation in  $s$  has a first order effect in  $y(s, c)$  (and hence on  $w(s, c)$ ), while a variation in  $c$  has only a second order effect on  $y(s, c)$ , since by construction  $y_c[s, c(s)] = 0$ . Hence, comparing the two single variable regressions, the regression on  $s$  "explains" a larger share of the variance of  $w(s, c)$  than the one on  $c$ . Since we have normalized  $E[w(s, c) | s] = s$  and  $E[w(s, c) | c] = c$ , the variance of  $s$  must be larger than that of  $c$ .

The proof of Proposition 1 implies:

$$E[\Delta c^2 | s] \cong \rho(1 - \rho)\sigma^2$$

where  $\sigma^2 \equiv \text{Var}[s]$ , see Appendix A. Substitution of these results in equation (3) yields a simple expression for  $x$ :

$$x = -\frac{3}{2}y_{cc}\rho(1 - \rho)\sigma^2 = 3\frac{\omega}{\beta}\rho(1 - \rho)\sigma^2 \quad (7)$$

The variance of  $w$  satisfies, see Appendix A:

$$\begin{aligned} \text{Var}[w] &\simeq \sigma^2 + (1 - \rho)^2(1 + \rho)\rho\omega^2\sigma^4 \\ &\simeq \sigma^2 + \frac{1 + \rho}{9\rho}\beta^2x^2 \leq \sigma^2 + \frac{1}{12}x^2 \cong \sigma^2 \end{aligned} \quad (8)$$

where the second step uses (7). The inequality applies if  $\rho \geq 1/2$  and  $\beta \leq 1/2$  which is reasonable from an empirical point of view, see e.g. Abowd and Lemieux (1993). The latter approximation shows that the variance of the second order term is small relative to the first order term for values of  $x$  up to 0.50.

Summing up, we have extended the assignment model of the previous section with a simple model of search frictions with Nash bargaining over wages. In this world, wages are a concave function of worker and job characteristics. A second order Taylor expansion

of this wage function allows us to characterize the relation between this wage function, the joint distribution of  $s$  and  $c$ , and the cost of search  $x$ . We need only two additional assumptions on functional forms to derive these relations: both the cost of search  $x$  and the complexity dispersion parameter  $y_{cc}$  must be constant along the support of  $s$ .

### 3 Empirical analysis

#### 3.1 The measurement of the key variables

A fundamental problem in the empirical analysis of non-Walrasian features of wages and worker-to-job assignments is the difficulty to distinguish between deviations from the frictionless assignment and measurement error in the data. Hence, if we want to apply the framework developed above for an empirical analysis, we have to allow for the fact that the three main ingredients of our analysis are all observed with a fair amount of unobserved heterogeneity or measurement error. These imperfections are modelled as follows:

$$\begin{aligned}
 s &\equiv \bar{s} + \underline{s} & (9) \\
 \bar{s} &\equiv (q - \mathbf{E}[q])' \beta \\
 c &\equiv \bar{c} + \underline{c} \\
 \bar{c} &\equiv (m - \mathbf{E}[m])' \gamma \\
 \bar{w} &= w + \underline{u}
 \end{aligned}$$

where  $\bar{w}$  is the observed log wage,  $\mathbf{E}[\underline{s}] = \mathbf{E}[\underline{c}] = \mathbf{E}[\underline{u}] = 0$  and  $\mathbf{E}[\bar{s}\underline{s}] = \mathbf{E}[\bar{c}\underline{c}] = \mathbf{E}[w\underline{u}] = \mathbf{E}[\underline{s}\underline{u}] = \mathbf{E}[\underline{c}\underline{u}] = 0$ ,  $q$  is a vector of observed worker characteristics, and  $m$  is a vector of observed job characteristics. Without loss of generality, we normalize all observed and unobserved variables such that they have a zero mean. Both the skill index  $s$  and the complexity index  $c$  are assumed to be made up of two orthogonal parts. The first part is observed by the econometrician ( $\bar{s}$  and  $\bar{c}$  respectively) while the second is not ( $\underline{s}$  and  $\underline{c}$  respectively). The random variable  $\underline{u}$  captures the measurement error in wages. Hence, it is uncorrelated to any other random variable in the model. Bound and Krueger (1991) report that the ratio of variance of the signal to the total variance in log hourly wages is 0.84 for the CPS.

Equation (9) places hardly any restrictions on the structure of observed and unobserved components of  $s$  and  $c$ . At first sight, the linearity of the relation between  $s$  and  $q$  and between  $c$  and  $m$  seems to be a strong assumption. However, we can include everything and its square in  $q$  and  $m$ , so that this specification can capture any differentiable non-linear relation up to an arbitrary small degree of misspecification. Similarly, the additive separability between the observed and the unobserved component is not a restriction: it implies that we define  $\bar{c} \equiv E[c|q]$  and  $\underline{c}$  as the variation in  $c$  orthogonal on  $E[c|q]$ .

### 3.2 The estimation of $\bar{s}$ and $\bar{c}$

How can we estimate the parameter vectors  $\beta$  and  $\gamma$  and hence the observed part of the skill and complexity indexes,  $\bar{s}$  and  $\bar{c}$ ? If the real world is described by the Walrasian model of Section 2.1, then the answer is simple. We can simply apply OLS to the relations  $w^*(s)$  and  $w^*[s(c)]$  which directly relate wages to observed worker and job characteristics. Hence, in that case  $\beta$  and  $\gamma$  can be consistently estimated from the following regression models:

$$\begin{aligned}\bar{w} &= (q - E[q])' \beta + \underline{\varepsilon}_s \\ \bar{w} &= (m - E[m])' \gamma + \underline{\varepsilon}_c\end{aligned}\tag{10}$$

where  $\underline{\varepsilon}_s$  and  $\underline{\varepsilon}_c$  are error terms. The error terms in both regressions reflect the unobserved part of worker and job characteristics and the measurement error in log wages, that is:  $\underline{\varepsilon}_s = \underline{s} + \underline{u}$  and  $\underline{\varepsilon}_c = \underline{c} + \underline{u}$ . Note that we run separate regressions for the supply and the demand side of the market. If we had included  $q$  and  $m$  simultaneously, it would be unclear whether our estimates reflect a supply or a demand side relationship;  $q$  would have served partly as a proxy for the unobserved part in the complexity index,  $\underline{c}$ , and  $m$  would have served partly as a proxy for the unobserved part in the skill index,  $\underline{s}$ . Since  $s$  and  $c$  are perfectly correlated, it is quite likely that  $\bar{s}$  is correlated with  $\underline{c}$  and that  $\bar{c}$  is correlated with  $\underline{s}$ . Only by estimating both relations separately, we can give a structural interpretation to the regression coefficients. In fact, this procedure is similar to the approach proposed by Rosen (1974). We return to this issue below.

The simple procedure laid out in equation (10) works fine in a Walrasian world. However, if the real world is characterized by search frictions and if log wages therefore satisfy the concave function (6), then, as suggested by a number of commentators on a previous

version of this paper, this procedure does not seem to work anymore. Equation (6) includes quadratic terms in  $s$  and  $c$ , so that estimates of  $\beta$  and  $\gamma$  that do not allow for this non-linearity seem to be biased. The subsequent proposition shows this intuition to be false:

**Proposition 2** *If (6) holds and measurement error in  $s$ ,  $c$  and  $w$  is as in (9), then  $\beta$  and  $\gamma$  are consistently estimated by equation (10).*

**Proof.** Equation (6) is constructed such that

$$\begin{aligned} \mathbb{E}[w(s, c) | s] &= s \\ \mathbb{E}[w(s, c) | c] &= c \end{aligned}$$

Since  $\mathbb{E}[s|\bar{s}] = \bar{s}$  and  $\mathbb{E}[c|\bar{c}] = \bar{c}$  and since  $\underline{u}$  is uncorrelated to anything else, these equations imply  $\mathbb{E}[\bar{w}|\bar{s}] = \bar{s}$  and  $\mathbb{E}[\bar{w}|\bar{c}] = \bar{c}$ . Hence, equation (10) gives consistent estimates of  $\beta$  and  $\gamma$ . ■

The intuition for Proposition 2 is that the correlation between  $w$  and  $s^2$  introduced in equation (6) by the term  $-\omega\rho s^2$  is exactly offset by the correlations introduced by both other second order terms,  $\omega(1+\rho)sc$  and  $-\omega c^2$ , since  $s$  and  $c$  are positively correlated. Taking these three terms together,  $w$  and  $s^2$  are uncorrelated. Mutatis mutandis the same analysis applies to the correlation between  $w$  and  $c^2$ . Apart from the unobserved heterogeneity in  $s$  and  $c$  respectively and the measurement error in log wages, the error terms  $\underline{\varepsilon}_s$  and  $\underline{\varepsilon}_c$  capture also the effect of suboptimal assignment due to search frictions. Proposition 2 is just a reflection of the way in which we have constructed our search model. We derived partial derivatives of  $w(s, c)$  by imposing the restrictions  $\mathbb{E}[w(s, c) | s] = s$  and  $\mathbb{E}[w(s, c) | c] = c$ . There is no loss of generality involved in imposing these restrictions, they just apply a proper scaling on the indexes  $s$  and  $c$ , see the discussion in Section 2.1. Proposition 2 implies that  $w$  and  $\bar{s}^2$  should be uncorrelated. This implication is imposed in our estimation procedure. We apply an iterative procedure such that if we enter both  $\bar{s}$  and  $\bar{s}^2$  in regression (10), then the coefficient on the second order term  $\bar{s}^2$  is indeed exactly zero.<sup>10</sup> Mutatis mutandis the same applies to our regression for  $\bar{c}$ .

<sup>10</sup>First, we run the regression:  $w = \beta_1 \bar{s}_1 + \beta_2 \bar{s}_1^2 + \underline{\varepsilon}_s$ , where  $\bar{s}_1$  is constructed from equation (9). Second, we construct a new variable  $\bar{s}_2 = \beta_1 \bar{s}_1 + \beta_2 \bar{s}_1^2 - \mathbb{E}[\beta_1 \bar{s}_1 + \beta_2 \bar{s}_1^2]$  and rerun the first regression where we replace  $\bar{s}_1$  by  $\bar{s}_2$ . We repeat these steps till  $\beta_2 = 0$ .

Our empirical analysis for the United States applies the CPS March supplements for 1989-92. We consider full time, non-farmer, private sector workers aged between 16 and 65, which yields 222179 observations. We constructed hourly wages. The vector  $q$  includes the usual variables: total years of schooling, a third order polynomial in experience, highest completed education, being married, having a full or part time contract and various cross terms of experience, education and being married;  $m$  contains 520 occupation and 242 industry dummies. Besides  $q$  and  $m$ , we add calendar time dummies to capture the effect of inflation and the business cycle. Obviously, these time dummies are not included in the construction of  $\bar{s}$  and  $\bar{c}$ . Let  $R_{ws}^2$  and  $R_{wc}^2$  denote the  $R^2$  statistics for both regressions (10);  $R_{ws}^2 = 0.3358$  and  $R_{wc}^2 = 0.3632$ . Hence, the observed part of the skill and complexity indexes capture a reasonable part of the total variance in log wages.

### 3.3 Interpreting regressions with both $\bar{s}$ and $\bar{c}$

When we enter  $\bar{s}$  and  $\bar{c}$  in an OLS regression on log wages simultaneously, we obtain the following results (t-values between brackets):

$$\begin{array}{rcl} \bar{w} & = & \alpha_s \bar{s} + \alpha_c \bar{c} + \underline{e} \\ R^2 & & 0.601 \quad 0.668 \\ 0.4445 & & (180) \quad (209) \end{array} \quad (11)$$

Can we give a structural interpretation to these coefficients? In Appendix B, we proof the following result:

**Proposition 3** *Consider the Walrasian assignment model  $w = s = c$ , the measurement model in equation (9), and the regression equation (11). The coefficients  $\alpha_s$  and  $\alpha_c$  satisfy:*

$$\begin{bmatrix} \alpha_s \\ \alpha_c \end{bmatrix} = \frac{1}{R_{\bar{s}}^2 R_{\bar{c}}^2 - C^2} \begin{bmatrix} R_{\bar{c}}^2 (R_{\bar{s}}^2 - C) \\ R_{\bar{s}}^2 (R_{\bar{c}}^2 - C) \end{bmatrix}$$

where  $R_{\bar{s}}^2$  and  $R_{\bar{c}}^2$  are the share of the variances of  $\bar{s}$  and  $\bar{c}$  in the total variances of  $s$  and  $c$  respectively, and where  $C \equiv \text{Corr}[\bar{s}, \bar{c}]$ .

The proof follows directly from the formulas for OLS regression coefficients. We cannot identify  $R_{\bar{s}}^2$ ,  $R_{\bar{c}}^2$  and  $C$  from the data directly, even in this Walrasian world, since we have no way to decompose the error terms  $\underline{\varepsilon}_s$  and  $\underline{\varepsilon}_c$  in equation (11) into  $\underline{u}$  on the one hand and  $\underline{s}$  and  $\underline{c}$  on the other hand.  $R_{ws}^2$  and  $R_{wc}^2$  are therefore a lower bound for  $R_{\bar{s}}^2$  and

$R_c^2$  respectively. The estimated coefficients  $\alpha_s$  and  $\alpha_c$  provide further information. The better the information on the skill variable ( $R_s^2$  is high), the higher the coefficient  $\alpha_s$ , and mutatis mutandis the same for the complexity variable. For the special case  $R_s^2 = R_c^2$ , we have  $\alpha_s = \alpha_c = (1 + C)^{-1}$ : the higher the correlation between the skill and complexity variable, the lower will be the coefficients  $\alpha_s$  and  $\alpha_c$ . The intuition is that with imperfect information,  $\underline{s}$  becomes a proxy for  $\bar{c}$  and the other way around. If  $R_s^2 = R_c^2 = 1$ , then  $C = 1$  (since  $\text{Cor}[s, c] = 1$ ) and the model would be unidentified by perfect collinearity of its regressors. It is tempting to give the coefficients  $\alpha_s$  and  $\alpha_c$  a structural interpretation. For example, referring to the old debate started by Doeringer and Piore's (1971) analysis of segmented labor markets where wages are an attribute of jobs rather than of workers: a high value of  $\alpha_c$  is then interpreted as support for the segmented labor market view of the world, while a high value of  $\alpha_s$  is interpreted as support for the traditional human capital interpretation. Similarly, Krueger and Summers (1988) use this type of regression to estimate inter-industry wage differentials. Those are then interpreted as evidence for non Walrasian wage setting. The above analysis makes the simple and well known point that the regression coefficients can be just a reflection of the relative amount of unobserved heterogeneity in  $s$  and  $c$ , and that any structural interpretation is therefore hazardous.

Can we use this framework to distinguish between the Walrasian model and the model extended with search frictions? The critical difference between both models is that in the latter log wages are positively related to the cross term  $sc$ , see equation (6), while in the former  $s$  and  $c$  are perfectly correlated and hence we are unable to establish the interaction effect of  $s$  and  $c$  on log wages  $w$ .  $E[wsc]$  being positive is the essence of comparative advantage: the larger  $c$ , the larger the effect of  $s$  on  $w$ . The obvious way to address this question is to extend equation (11) with second order terms in the observed part of the skill and complexity indices,  $\bar{s}$  and  $\bar{c}$  respectively:

$$\begin{array}{rcl}
 \bar{w} & = & \alpha_s \bar{s} + \alpha_c \bar{c} + \alpha_{ss} (\bar{s}^2 - E[\bar{s}^2]) + \alpha_{cc} (\bar{c}^2 - E[\bar{c}^2]) + \alpha_{sc} (\bar{s}\bar{c} - E[\bar{s}\bar{c}]) + \varepsilon \\
 R^2 & & 0.607 \quad 0.664 \quad -0.172 \quad -0.170 \quad 0.429 \\
 0.4479 & & (182) \quad (207) \quad (21) \quad (22) \quad (37)
 \end{array} \tag{12}$$

The second order terms show up highly significantly.<sup>11</sup> The issue is whether this result is sufficient to reject the simple Walrasian model,  $\bar{w} = s + \underline{u} = c + \underline{u}$ , or that it can be interpreted in the same way as equation (11), such that  $\bar{s}^2$  captures part of the effect of  $\underline{c}$  and  $\bar{c}^2$  that of  $\underline{s}$ . We proof a negative and a positive result. For this purpose, it is useful to define:  $\vec{z} \equiv [\bar{s}, \underline{s}, \bar{c}, \underline{c}]'$ .

**Proposition 4** *Posit the Walrasian model  $w = s = c$  and the measurement model (9). Then, any value of  $\alpha_{sc}$  can be rationalized from the correlation of  $\bar{s}\bar{c}$  to  $\underline{s}$  and/or  $\underline{c}$ .*

**Proof.**  $\vec{z}$  can be linearly decomposed into four orthogonal components,  $\vec{v}$ , such that  $w = v_1 + v_2 + v_3 + v_4$ ,  $\bar{s} \equiv v_1 + v_3$ , and  $\bar{c} \equiv v_2 + v_3$ . Hence, the remaining component  $v_4$  is orthogonal to  $\bar{s}$  and  $\bar{c}$ :  $E[v_i v_4] = 0$ ,  $i = 1, 3$ . However, the orthogonality of the components of  $\vec{v}$  does not impose any restrictions on the value of third moments,  $E[v_i v_j v_4]$ ,  $i = 1, 2, 3$ ,  $j = 1, 2, 3$ . Therefore, any value of  $\alpha_{sc}$  can be rationalized this way. ■

Proposition 5 requires an assumption on the joint distribution of  $\bar{s}$ ,  $\underline{s}$ ,  $\bar{c}$ , and  $\underline{c}$ .

**Assumption 2:**  $\vec{z}$  follows a multivariate normal distribution.

**Proposition 5** *Equation (9) and Assumption 2 imply that if the Walrasian model is the true model, then  $\alpha_{ss} = \alpha_{sc} = \alpha_{cc} = 0$  in (12).*

**Proof.** Due to Assumption 2,  $\vec{z}$  can be linearly decomposed into four orthogonal normally distributed components. Consider the expression for the coefficients of an OLS regression,  $\vec{\alpha} = [X'X]^{-1} X'\vec{y}$ , where  $X$  is the matrix of explanatory variables and where  $\vec{y} \equiv \{\bar{w}\}$  is the vector of observed log wages. The coefficients of second order terms are different from zero only if either the first and the second order terms are correlated (the cross product of the first and second order terms in  $X'X \neq 0$ ) or the second order terms are correlated with  $\bar{w}$  ( $X'\vec{y} \neq 0$ ). Regarding  $X'X$ : both  $s$  and  $c$  are linear combinations of  $\vec{z}$ . Since  $\vec{z}$  can be linearly decomposed in four orthogonal components,  $\vec{v}$ , the first and the second order terms are only correlated if the third moments of these components

---

<sup>11</sup>A commentator wondered why  $\bar{s}^2$  and  $\bar{c}^2$  enter significantly, while  $\bar{s}$  and  $\bar{c}$  are constructed such that their square term yields coefficient zero, see Section 3.1. The reason is that  $\bar{s}^2$  and  $\bar{c}^2$  are correlated with  $\bar{s}\bar{c}$ . Another commentator suggested that  $\bar{c}$  entering significantly implies the rejection of equation (6), since there  $w_c = 0$ . However,  $\bar{c}$  is correlated to  $\underline{s}$ , so that observed job characteristics serve as a proxy for unobserved worker characteristics, similar to Proposition 2.

are different from zero, or if the cross terms  $E[v_i v_j^2] \neq 0$ . However, these moments are zero, due to Assumption 2. Regarding  $X'y$ : since  $\underline{u}$  is uncorrelated with anything else, a potential correlation must be due to the vector of true log wages,  $w$ . Under the Walrasian model, it satisfies:  $w = s = c$ . Hence,  $w$  is a linear combination of  $\vec{z}$ . Then, a similar argument as for  $X'X$  establishes that  $w$  is uncorrelated with the second order terms, since otherwise either a third moment or a cross term of  $\vec{v}$  should be non-zero. Both are ruled out by Assumption 2. ■

**Corollary 2:**

*Under Assumption 2, the inclusion of second order terms does not affect the estimated value of  $\alpha_s$  and  $\alpha_c$  in the Walrasian model, since the second and first order terms are uncorrelated, so that the  $X'X$  matrix is block diagonal.*

Proposition 4 states the negative claim that we cannot learn about the relevance of the search model from the regression equation (12) without further assumptions on the joint distribution of  $\vec{z}$ . Moreover,  $\bar{s}\bar{c}$  can capture variation in  $s$  and  $c$  that is correlated to neither  $\bar{s}$  nor  $\bar{c}$ , so that even the fact that  $\alpha_s$  and  $\alpha_c$  are unaffected by the introduction of the second order terms (as predicted by Corollary 2) does not imply the rejection of the Walrasian model. Proposition 5 achieves the opposite of Proposition 4. It makes the positive claim that for a quite standard distributive assumption, the second order coefficients are highly informative on the size of search frictions. Under this assumption, any deviation of  $\alpha_{sc}$  from zero implies a rejection of the Walrasian model.<sup>12</sup> However, Assumption 2 can never be fully tested. We can test the normality of the distribution of  $\bar{s}$  and  $\bar{c}$ , and thereby of  $v_1, v_2$  and  $v_3$  but, we can never test the normality of  $v_4$ . Even the residuals from equation (11),  $\underline{e}$ , do not provide information, for two reasons. First, we cannot distinguish between  $v_4$  and the measurement error in wages  $\underline{u}$ , so that non-normality can be attributed to either source. Second, even if  $\text{Var}[\underline{u}] = 0$ , both the Walrasian model with a non-normal  $v_4$  and the search model with a normal  $v_4$  imply the non-normality of  $\underline{e}$ .

Empirically, we do find that the coefficients  $\alpha_s$  and  $\alpha_c$  do not change much by the inclusion of the second order terms, see equation (11) and (12). The covariance matrix of  $X$  and  $\vec{y}$ , including  $E[w^3]$ , is shown in Table 1. For the third moments, the t-statistics for

---

<sup>12</sup>Note that Assumption 2 is more strict than is needed for Proposition 4. Any symmetric distribution is consistent with this argument.

the significance of the deviation from zero are listed underneath the covariances.<sup>13</sup> We do not present the fourth moment because they have no effect on our estimates of the higher order terms ( $\alpha_{ss}$ ,  $\alpha_{cc}$  and  $\alpha_{sc}$ ). Although the covariances of the first and the second order terms are small, they are all significant. This is not surprising since given the large number of observations (0.2 million), any small deviation of normality will be detected with high significance. We conclude that the distribution of  $\bar{s}$  and  $\bar{c}$  is not exactly normal but that it comes close.

Table 1 Covariance matrix of  $w$ ,  $\bar{s}$  and  $\bar{c}$  for the U.S.

|t-values| between brackets (under the null hypothesis of joint normality of  $\bar{s}$ ,  $\bar{c}$ ,  $w$ )

However, we have two further pieces of evidence that makes the interpretation of the second order terms as capturing correlations with unobserved worker and job characteristics highly unlikely. First, although we have not yet derived the precise relation between the search model in equation (6) and the regression model (12) (we do this in the next section), it seems natural to assume that the signs of  $w_{ss}$ ,  $w_{sc}$ , and  $w_{cc}$  carry over to  $\alpha_{ss}$ ,  $\alpha_{sc}$ , and  $\alpha_{cc}$ . These sign restrictions hold in equation (12). Similarly, equation (6) implies  $w_{sc} = |w_{ss} + w_{cc}|$ . One would expect that this restriction carries over to equation (12):  $\alpha_{sc} = |\alpha_{ss} + \alpha_{cc}|$ . By and large, this restriction holds.<sup>14</sup> In Section 5, we account for the

<sup>13</sup>The assumption that  $\bar{s}$  is distributed normally yields no prediction regarding the value of  $E[\bar{s}^2]$ . However, the assumption implies:  $E[\bar{s}(\bar{s}^2 - E[\bar{s}^2])] = 0$  and  $E[(\bar{s}^2 - E[\bar{s}^2])^2] = 2E[\bar{s}^2]$ .

<sup>14</sup>A commentator on a previous version claimed that this restriction is imposed by the way we have constructed  $\bar{s}$  and  $\bar{c}$ , such that in a regression with only  $\bar{s}$  and  $\bar{s}^2$ , the coefficient on  $\bar{s}^2$  is zero (and the same for  $\bar{c}$ ). This claim is incorrect. This can be seen immediately by considering the case where  $E[\bar{s}] = E[\bar{c}] = E[\bar{s}\bar{c}]$  and where the true model is  $w = \alpha_s \bar{s} + \alpha_c \bar{c} + \alpha_{sc} \bar{s}\bar{c} + \varepsilon$ . This case satisfies the constraints imposed by the construction of  $\bar{s}$  and  $\bar{c}$ , but does not satisfy  $\alpha_{sc} = |\alpha_{ss} + \alpha_{cc}|$ .

effect of the unobserved components in  $s$  and  $c$  on this restriction. That derivation brings our test even closer to the actual results.

Second, we repeat our regressions for five other OECD countries.<sup>15</sup> Table 2 presents the results. All countries satisfy the three sign restrictions on the coefficients for the second order terms that are implied by the hypothesis that wages are concave in worker and job characteristics. Except for Germany, they all satisfy the constraint that  $\alpha_{sc} \cong |\alpha_{ss} + \alpha_{cc}|$ . This strongly suggests that we have come across an empirical regularity. If this regularity was due to some systematic non-normality in the joint distribution of  $\vec{z}$ , then we would expect that this regularity would also show up in the covariance of first and second order effects as reported in Table 1 for the US. In Appendix C, we present the covariance matrices for the other countries. They show no regularity. We therefore conclude that the significance of the higher order terms is unlikely to be due to unobserved heterogeneity. However, we can not rule out that our results are driven by an exotic non-symmetric distribution of unobservables which is very different across OECD economies. But we believe that the search model provides a much more parsimonious explanation for our findings. In the next section we give a more structural interpretation of our results.

<sup>15</sup>The data come from the Luxembourg Income Study (<http://www.lisproject.org>) which is based on the Family Budget Survey (INSEE) for France, the SOEP (DIW) for Germany, the SEP (CBS) for the Netherlands and the Family Expenditure Survey (UKDA) for the UK. For Portugal we use the Quadros de Pessoal for Portugal (Ministry of Labour and Solidarity). The samples include full time, non-farmer, private sector workers aged between 16 and 65. We calculated  $\bar{s}$  and  $\bar{c}$  for each country the same way as we discussed before where  $\bar{s}$  captures all the observable worker characteristics (including higher order terms) that were available and  $\bar{c}$  captures all the job characteristics. In particular, the information we had on  $\bar{c}$  varied considerably, i.e. industry and occupation coding varied between 2 and 4 digits.

### 3.4 A structural interpretation in the context of the search model

If  $s$  and  $c$  would be fully observed, the empirical implementation of equation (7) would be simple. We would calculate the correlation between  $s$  and  $c$ ,  $\sqrt{\rho}$ , from the data, estimate equation (6) to obtain an estimate for  $\omega$  and calculate  $x$  from equation (7), using a value for  $\beta$  derived from the empirical literature, for example Abowd and Lemieux (1993). Given that we do not have such perfect measures, the imperfect correlation between the observed indices  $\bar{s}$  and  $\bar{c}$  can be due to either unobserved characteristics *or* search frictions which cause  $s$  and  $c$  themselves to be imperfectly correlated. It is useful in the context of the search model to define  $C$  as the ratio of the correlation between the observed skill and complexity indexes on the one hand, and the correlation between their true values on the other hand. Hence:

$$\text{Cor} [\bar{s}, \bar{c}] = \sqrt{\rho}C \quad (13)$$

with  $0 < C < 1$ : unobserved heterogeneity in  $s$  and  $c$  reduces their correlation. Proposition 6 provides a structural interpretation for the coefficients of equation (12):

**Proposition 6** *Consider the search model (6), the measurement model (9), and the normality Assumption 2. Then, the regression coefficients in (12) converge to:*

$$\begin{bmatrix} \alpha_s \\ \alpha_c \end{bmatrix} = \frac{1}{R_{\bar{s}}^2 R_{\bar{c}}^2 - \rho C^2} \begin{bmatrix} R_{\bar{c}}^2 (R_{\bar{s}}^2 - \rho C) \\ R_{\bar{s}}^2 (R_{\bar{c}}^2 - C) \end{bmatrix} \quad (14)$$

while the coefficients for the second order terms converge to:

$$\begin{aligned} \begin{bmatrix} \alpha_{ss} \\ \alpha_{sc} \\ \alpha_{cc} \end{bmatrix} &= \omega (1 - \rho)^2 \frac{R_{\bar{s}}^2 R_{\bar{c}}^2}{(R_{\bar{s}}^2 R_{\bar{c}}^2 - \rho C^2)^2} \begin{bmatrix} -\rho R_{\bar{c}}^2 C \\ (R_{\bar{s}}^2 R_{\bar{c}}^2 + \rho C^2) \\ -R_{\bar{s}}^2 C \end{bmatrix} \\ &= \omega (1 - \rho)^2 \frac{\alpha_s \alpha_c}{(\alpha_s + \alpha_c - 1)^2} \begin{bmatrix} -\alpha_s (1 - \alpha_s) \\ 1 + 2\alpha_s \alpha_c - \alpha_s - \alpha_c \\ -\alpha_c (1 - \alpha_c) \end{bmatrix} \end{aligned} \quad (15)$$

where we apply equation (14) in the second line.

The proof is delegated to Appendix D. Contrary to the Walrasian case,  $\alpha_s$  and  $\alpha_c$  are identified if both  $s$  and  $c$  are perfectly observed ( $R_{\bar{s}}^2 = R_{\bar{c}}^2 = C = 1$ ). The reason is that  $s$  and  $c$  are no longer perfectly correlated in the presence of search frictions, so that there is

no multicollinearity problem and the estimated coefficients converge to their true values  $\alpha_s = w_s = 1$  and  $\alpha_c = w_c = 0$  in that case.

Equation (15) reveals that the search model imposes two non-linear restrictions on the extended Mincer equation (12), relating the coefficients  $\alpha_{sc}/\alpha_{ss}$  and  $\alpha_{sc}/\alpha_{cc}$  to  $\alpha_s$  and  $\alpha_c$ . As can be easily verified from the first line of equation (15), if  $s$  and  $c$  are perfectly observable ( $R_{\bar{s}}^2 = R_{\bar{c}}^2 = C = 1$ ), then  $\alpha_{cc} = -\omega$ . The second line of equation (15) yields a number of testable implications of the search model. First, from Proposition 5, if there were no search frictions ( $\rho = 1$ ), then the coefficients of the second order terms would be zero. This possibility is clearly rejected by the data. Second, the sign of  $\alpha_{sc}$  must be positive and the signs of  $\alpha_{ss}$  and  $\alpha_{cc}$  must be negative. These restrictions are clearly satisfied, see the estimation results for equation (12) in Section 2. A stricter tests applies the two non-linear restrictions. We estimate (10), (12) and (15) simultaneously by non-linear least squares. The  $R^2$  of this model and (12) is equal up to four decimals.<sup>16</sup> This is strong evidence in favor of the interpretation of the second order terms as being due to search frictions.

Regrettably, we are unable to identify  $\omega$  and  $\rho$  separately, since they enter in the same way in all three equations (15). We can therefore estimate  $\omega(1 - \rho)^2$ , but not its two components. The intuition is that a high value of  $\alpha_{sc}$  can be due to two factors. Either, the correlation between  $\bar{s}$  and  $\bar{c}$  is low due to large search frictions and no measurement error, leading to a high  $\text{Var}[c|s]$  and hence a low correlation  $\rho$  between  $s$  and  $c$ . But then  $\alpha_{cc}$  is a fairly accurate estimate of  $\omega$ . Or, the low correlation between  $\bar{s}$  and  $\bar{c}$  is mainly low due to large measurement error in  $s$  and  $c$ , so that  $\text{Var}[c|s]$  is low and  $\rho$  is high. But then  $\alpha_{cc}$  underestimates  $\omega$  due to attenuation bias, so that the cost of a suboptimal assignment is high due to a strong curvature of  $y(s, c)$ . Since we cannot establish  $\rho$  directly from the data, we have no way to distinguish between both stories. Alternatively, we can phrase this problem in terms of equation (3). Either, there is a lot of unobserved heterogeneity in  $s$  and  $c$ , so that we underestimate  $|y_{cc}|$  by attenuation bias, but then we overstate  $\Delta^{*2}$  because most of the imperfect correlation between  $\bar{s}$  and  $\bar{c}$  is due to unobserved heterogeneity, not to search frictions. Or, we observe  $s$  and  $c$  well. In that case, our estimate of  $|y_{cc}|$  is reasonably close, but then all the imperfect correlation is due to search frictions.

---

<sup>16</sup>However, because we have more than 200,000 observation it is just rejected by an F-test.

The non-linear least squares estimation of (15) for the US yields (t-value between brackets):

$$\omega (1 - \rho)^2 = 0.1476 \quad (32)$$

The observed correlation between  $\bar{s}$  and  $\bar{c}$  provides a lower bound for  $\rho$ , where all imperfect correlation between  $\bar{s}$  and  $\bar{c}$  is attributed to search frictions and none to unobserved heterogeneity:  $\rho > \text{Cor}[\bar{s}, \bar{c}]^2$ . Hence, equations (7), (8), (13), (14), (15) and the fact that  $\text{Var}[w] = 0.402$  imply:

$$\begin{aligned} \rho &> \text{Cor}[\bar{s}, \bar{c}]^2 = 0.3296 \\ \omega &= 0.1476 \times (1 - \rho)^{-2} > 0.3285 \\ \beta x &= 3\omega\rho(1 - \rho) \text{Var}[w] > 0.0736 \end{aligned}$$

Table 3 structural estimates (lower bounds) for other countries

Country	year	$\omega (1 - \rho)^2$	$\rho >$	$\omega >$	$\beta x >$
France	94	0.1640	0.3633	0.4046	0.0685
Germany	94	0.1431	0.1597	0.2027	0.0151
The Netherlands	94	0.1743	0.2142	0.2823	0.0248
Portugal	97	0.0869	0.3873	0.2315	0.0470
UK	86	0.3969	0.1875	0.6013	0.0600

The values for other OECD countries are given by Table 3 for  $\text{Var}[w] = 0.4 \cong \sigma^2$ , see equation (8). Many studies have tried to establish  $\beta$  empirically. Alternatively, we can line up with the common practice in the search literature, and set  $\beta$  equal to its "neutral" value of  $1/2$ , as we do here. Then, the complexity dispersion parameter should be  $|y_{cc}| \equiv 2\beta^{-1}\omega = 4\omega > 0.30$  (see Proposition 1) and the cost of search  $x > 15\%$ . However, direct estimates of  $\omega$  suggest much higher values than 0.33. Teulings (2005) derives a relation between the complexity dispersion parameter and Katz and Murphy's (1992) estimate of the elasticity of substitution between low and high skilled workers. This relation implies that the complexity dispersion parameter is in the order of 2,<sup>17</sup> so  $\omega = 0.5$

<sup>17</sup>This might even be a conservative estimate of the complexity dispersion parameter, since it assumes that demand for the output of various job types  $c$  is governed by a Leontieff technology. Hence, changes in the assignment of workers to jobs are the only source of substitutability between worker types. A more flexible technology than Leontieff would shift part of the substitutability to the demand for job types  $c$ , thereby reducing the amount of substitution due to the assignment process, hence raising  $\omega$ .

which suggests a higher value for  $\rho$ .<sup>18</sup> Using this value for  $\omega$  and applying equation (13) and (17) (from Appendix C) yields:

$$\begin{aligned}\rho &= 1 - \sqrt{\frac{0.148}{0.500}} = 0.456 \\ C &= \frac{\text{Cor} [\bar{s}, \bar{c}]}{\sqrt{\rho}} = \sqrt{\frac{0.330}{0.456}} = 0.851 \\ R_{\bar{s}}^2 &= \frac{0.664}{1 - 0.607} \times 0.456 \times 0.851 = 0.656 \\ \beta x &= 3 \times 0.5 \times (1 - 0.656) \times 0.656 \times 0.402 = 0.136\end{aligned}$$

The value of the share of observed characteristics in the total variance of  $c$ ,  $R_{\bar{s}}^2$ , seems to be in line with what is known about the signal to noise ratio for in particular education data. If we take those numbers as a benchmark, the cost of search is in the order of  $x \cong 27\%$ .

However, there is an alternative way to estimate  $x$ , not from wage data, but from unemployment. One can show that the cost of search are distributed evenly among its three components: the rate of unemployment, the rate of vacancies, and the cost of suboptimal assignment, provided that  $\beta = 1/2$  and that there is no on the job search, see Teulings and Gautier (2004). Hence, the cost of search is three times the natural unemployment rate, that is,  $x \cong 3 \times 5\% = 15\%$ , about half as high as the estimate based on wage data.

Can we reconcile these two independent and conflicting pieces of evidence? In Gautier, Teulings and van Vuuren (2004), we extend the model in Section 2.2 with on the job search. In the model without on the job search, the reservation wage is equal to the value of search while unemployed. In the model with on the job search, this equality no longer holds. There, the reservation wage is smaller than the value of search while unemployment because workers no longer give up the full option value of search, since they can continue search on the job. We therefore define  $x$  as the difference between  $y^*(s)$  and the flow value of unemployment. This extension narrows the gap for two reasons. First,  $y^*(s)$  remains the same but the value of unemployment increases when introducing on the job search because the wage that maximizes the Nash product now contains a "no quit" premium.

---

<sup>18</sup> $|y_{cc}| = (\eta_{\text{low-high}} \text{Var}[w])^{-1} = (1.4 \times 0.40)^{-1} \simeq 2$ . This relation provides a lower bound for  $\omega$  since it assumes a Leontieff technology in the demand for the output of various  $c$ -types. Allowing for substitution between  $c$ -types yields higher values of  $\omega$ .

Secondly,  $E[\Delta c^2]$  becomes smaller because workers keep moving to the diagonal  $c(s)$  in Figure 1.<sup>19</sup>

## 4 Final remarks

We conclude this paper by relating our results to the three strands in the literature that have been discussed in Section 1. First, our results have implications for the discussion on inter-industry wage differentials initiated by Krueger and Summers' (1988) classic paper. The framework laid out in Section 2 basically points at a fundamental problem of interpreting the results of wage regressions including both worker and job characteristics in the set of regressors: the one will be a proxy for the unobserved component of the other and vice versa. This insight is all but new. Since Krueger and Summers (1988), many papers have addressed this issue by using panel data, initially to control for unobserved worker characteristics, and more recently to control for unobserved worker and job characteristics simultaneously, by using matched firm-worker data, see Abowd, Kramarz, and Margolis (1998). The debate has not yet been settled.

The contribution of this paper is to show that the set up in Krueger and Summers might be mistaken. Their regressions suggest that some industries are universally "better" than others, as they pay higher wages. This feature is due to the additivity of their log wage function in worker and job characteristics. Hence, their wage function is not log supermodular, as is required for comparative advantage. In a world with comparative advantage / log supermodularity there is no such thing as a universally "better" job. The wage for a worker of a particular type is concave in the characteristics of the job she holds, and there is an interior maximum. A "higher" job type than this "optimal" job type yields a lower wage. Furthermore, the "optimal" job type depends on a worker's characteristics. In our regressions, we allow for this concavity by entering second order terms in worker and job characteristics. These turn out to be highly significant, which puts into question the interpretation of Krueger and Summers' industry dummies as capturing efficiency wage effects or rents. Similarly, our results have implications for the methodology of Abowd, Kramarz, and Margolis (1998). Interestingly, while unobserved characteristics deem hopeless any attempt to provide a structural interpretation of the relative magnitude

---

<sup>19</sup> $x \simeq 4\omega(1-\rho)^2 \frac{\rho}{1-\rho} \text{Var}[w] = 0.44$ . While the relation between  $x$  and unemployment becomes  $-2u \ln u$  which equals 0.30 for  $u$  is 0.05.

of the coefficients for worker and job characteristics in a cross section analysis, we have shown that the second order terms are much less sensitive to this problem. One must make quite extreme assumptions on the distribution of the error terms to rationalize these coefficients by unobserved heterogeneity. We provide some simple formulas to correct the coefficients of the second order terms for the effect of unobserved heterogeneity assuming their distribution to be normal.

Second, a comparison of our approach to the literature on the estimation of assignment models offers an alternative interpretation for what is at stake. Rosen's (1974) seminal paper on hedonic pricing and assignment sparked a debate on what variation is required for identification of the underlying production and utility functions in this type of model. In terms of this paper, how can we identify the curvature of  $y(s, c)$ ? As pointed out by Heckman and Sedlacek (1985), following early contributions by Roy (1951), identification is problematic because people self-select into the job type  $c$  that yields the highest output in a Walrasian equilibrium. In their models with only two job types, there is sufficient within job variation in  $s$  left to identify a large part of  $y(s, c)$ , after correcting for the selectivity of worker types by using standard techniques. In our model, which is essentially a continuous version of the Roy model, this strategy no longer works. The equilibrium assignment is characterized by a one-to-one correspondence of  $s$  to  $c$ , denoted  $s(c)$ . This one-to-one correspondence yields a perfect correlation between  $s$  and  $c$ , which renders any attempt to estimate the full functional form of  $y(s, c)$  hopeless by a standard multicollinearity problem. One can establish  $y[s, c(s)] = y^*(s)$  (from the zero profit condition  $w^*(s) = y^*(s)$ ) and one can establish its first derivative  $y_s[s, c(s)]$  (from the first order condition for optimal assignment,  $w^{*'}(s) = y_s[s, c(s)]$ ), but not its curvature  $y_{ss}[s, c(s)]$ . In a Walrasian equilibrium, we observe  $y(s, c)$  only for its optimal assignment  $c = c(s)$ , and not for other values of  $c$ . Kahn and Lang (1988) suggested to use variation between markets in the distribution of the supply of  $s$  or the demand for  $c$ . This leads to different equilibrium assignments  $c(s)$  in various markets, which allows for the identification of  $y_{ss}(s, c)$ . Ekeland, Heckman, and Nesheim (2004) exploit the generic non-linearity of the equilibrium assignment  $c(s)$ .

Here, we travel another route. Workers cannot afford to search for ever for an optimal job when search is costly. They are forced to accept jobs at which they produce less than the maximum output, that is,  $c \neq c(s)$ . This process breaks down the perfect

correlation between  $s$  and  $c$  that characterizes the Walrasian equilibrium. Obviously, we have information on log wages  $w(s, c)$  and not on log output  $y(s, c)$ . However, when we assume that gains from a better match quality are shared in some fixed way between the worker and the firm, the curvature in wages is informative on the curvature in output, see Figure 2. Adding second order terms in  $s$  and  $c$  allows us to estimate this curvature in wages. Regrettably, the formulas to correct the coefficients for the effect of measurement error do not allow for a complete identification of the underlying structure. They only provide sensible lower bounds for the importance of search frictions. The formulas imply that the output losses due to search frictions are in the order of 25 %, which is substantial.

## Appendix

### A Proof of Proposition 1

The normalizations of  $w$ ,  $s$  and  $c$  imply:

$$\begin{aligned} \mathbb{E}[\mathbb{E}[w(s, c) | s]] &= \mathbb{E}[s] = \mathbb{E}[w] = 0 \\ \mathbb{E}[\mathbb{E}[w(s, c) | c]] &= \mathbb{E}[c] = \mathbb{E}[w] = 0 \end{aligned}$$

Hence, since  $\mathbb{E}[\mathbb{E}[c|s]] = \mathbb{E}[c] = 0$ :

$$\mathbb{E}[\mathbb{E}[c|s]] = \mathbb{E}[\rho_0 + \rho s] = \rho_0 = 0$$

and by the same argument  $\tau_0 = 0$ . Hence, we can write:

$$\begin{aligned} s &= \tau c + \Delta s \\ c &= \rho s + \Delta c \end{aligned}$$

where  $\mathbb{E}[\Delta c] = \mathbb{E}[\Delta s] = \text{Cov}[c, \Delta s] = \text{Cov}[s, \Delta c] = 0$ . By the definition of  $c(s)$  we have:

$$\begin{aligned} w_c[s, c(s)] &= w_c + w_{sc}s + w_{cc}c(s) = 0 \Rightarrow \\ c(s) &= -\frac{w_c + w_{sc}s}{w_{cc}} \end{aligned}$$

Hence,  $c(s)$  is a linear function of  $s$ . Therefore  $\mathbb{E}[c(s)] = c[\mathbb{E}(s)] = c(0)$ . Since  $c(s) = \mathbb{E}[c|s]$ ,  $\mathbb{E}[c(s)] = \mathbb{E}[\mathbb{E}[c|s]] = \mathbb{E}[c] = 0$ , we have  $c(0) = 0$ . This implies  $w_c = 0$ . Combining these results yields:

$$\begin{aligned}
w(s, c) &= w_0 + w_s s + \frac{1}{2} w_{ss} s^2 + w_{sc} s c + \frac{1}{2} w_{cc} c^2 \\
&= w_0 + w_s s + \frac{1}{2} w_{ss} s^2 + w_{sc} s (\rho s + \Delta c) + \frac{1}{2} w_{cc} (\rho s + \Delta c)^2 \\
&= w_0 + w_s (\tau c + \Delta s) + \frac{1}{2} w_{ss} (\tau c + \Delta s)^2 + w_{sc} (\tau c + \Delta s) c + \frac{1}{2} w_{cc} c^2 \\
&\Rightarrow \left. \begin{aligned} d^2 \mathbf{E}[w(s, c) | s] / ds^2 &= w_{ss} + 2\rho w_{sc} + \rho^2 w_{cc} \equiv 0 \\ d^2 \mathbf{E}[w(s, c) | c] / dc^2 &= \tau^2 w_{ss} + 2\tau w_{sc} + w_{cc} \equiv 0 \end{aligned} \right\} \\
&\Rightarrow \left. \begin{aligned} d\mathbf{E}[w(s, c) | s] / ds &= w_s \equiv 1 \\ d\mathbf{E}[w(s, c) | c] / dc &= \tau w_s \equiv 1 \end{aligned} \right\} \Rightarrow \tau = 1 \Rightarrow \begin{aligned} w_{sc} &= (1 + \rho) \omega \\ w_{ss} &= -2\rho\omega \end{aligned}
\end{aligned}$$

where  $\omega \equiv -\frac{1}{2} w_{cc}$  and  $\sigma^2 \equiv \text{Var}[s]$ . Hence,  $\text{Cov}[s, c] = \mathbf{E}[s(\rho s + \Delta c)] = \rho\sigma^2 = \mathbf{E}[c(c + \Delta s)] = \mathbf{E}[c^2]$ ,  $\text{Var}[c] = \rho\sigma^2$  and  $\mathbf{E}[\Delta c^2] \cong \rho(1 - \rho)\sigma^2$ . *Q.E.D.*

## A.1 Second moment of $w$

The variance of  $w$  is derived from Proposition 1:

$$\begin{aligned}
w &= w_0 + s - \omega [-\rho s^2 + (1 + \rho) s (\rho s + \Delta c) - (\rho s + \Delta c)^2] \\
&= w_0 + s - \omega [(1 + \rho) s \Delta c - \Delta c^2]
\end{aligned}$$

using an expression for  $w_0$  (which can be derived from the relation  $\mathbf{E}[w] = 0$ ) and  $\text{Var}[s] = \sigma^2$ ,  $\text{Var}[\Delta c] = \rho(1 - \rho)\sigma^2$ ,  $\mathbf{E}[\Delta c^3] \cong 0$  (by its symmetry around  $\mathbf{E}[\Delta c]$ ) and  $\mathbf{E}[\Delta c^4] \cong 3\text{Var}[\Delta c]^2$  (taking the ratio between 4<sup>th</sup> and 2<sup>th</sup> moment for the normal distribution):

$$\text{Var}[w] \simeq \sigma^2 + \rho(1 - \rho)^2 (1 + \rho) \sigma^4 \omega^2$$

## B Proof of Proposition 3

Define:  $X_1 \equiv [s, c]$  be the matrix of 'true' first order effects. Accordingly, let  $\bar{X}_1$  denote the 'observed' first order effects. Since all variables are measured in deviation from their mean, we can ignore the intercept. By the definitions in Section 2, the moments of the sub-matrices  $\bar{X}_1' \bar{X}_1$  and  $\bar{X}_1' y$  read:

$$\begin{aligned}
\frac{1}{N} \mathbf{E}[\bar{X}_1' w] &= \sigma^2 \begin{bmatrix} R_s^2 \\ R_c^2 \end{bmatrix} \\
\frac{1}{N} \mathbf{E}[\bar{X}_1' \bar{X}_1] &= \sigma^2 \begin{bmatrix} R_s^2 & C \\ C & R_c^2 \end{bmatrix}
\end{aligned}$$

where  $N$  is the number of observations in the regression. Consider equation (11). Applying the expression for OLS coefficients proves the Proposition. *Q.E.D.*

## D Proof of Proposition 6

Previous definitions imply the following covariance matrix of  $\bar{s}, s, \bar{c},$  and  $c$ :

$$\text{Var}[\bar{s}, \bar{c}, s, c] = \sigma^2 \begin{bmatrix} R_{\bar{s}}^2 & \rho C & R_{\bar{s}}^2 & \rho R_{\bar{s}}^2 \\ \rho C & \rho R_{\bar{c}}^2 & \rho R_{\bar{c}}^2 & \rho R_{\bar{c}}^2 \\ R_{\bar{s}}^2 & \rho R_{\bar{c}}^2 & 1 & \rho \\ \rho R_{\bar{s}}^2 & \rho R_{\bar{c}}^2 & \rho & \rho \end{bmatrix} \quad (16)$$

Analogous to  $X_1$  and  $\bar{X}_1$ , let  $X_2 \equiv [s^2 - E[s^2], sc - E[sc], c^2 - E[c^2]]$ , the covariance matrix of 'true' second order effects and let  $\bar{X}_2$  denote the covariance matrix of 'observed' second order effects, both net of their mean. Since all variables are considered in deviation from their mean, we can ignore the intercept. By Assumption 2,  $\bar{X}_1' \bar{X}_2 = 0$ , so that the  $X'X$  matrix for equation (12) is block diagonal. Hence, we can invert the sub-matrices  $\bar{X}_1' \bar{X}_1$  and  $\bar{X}_2' \bar{X}_2$  separately. Hence, the first and second order terms can be derived independently.

First, consider the first order terms.  $\bar{X}_1' \bar{X}_1$  can be taken from equation (16). Since second order terms are uncorrelated to first order terms, only the term  $s$  in equation (6) is correlated to  $\bar{X}_1$ . Hence:  $\text{E}[\bar{X}_1' w] = \text{E}[\bar{X}_1' s]$ , which can again be taken from equation (16). Applying the expression for OLS coefficients yields:

$$\begin{bmatrix} \alpha_s \\ \alpha_c \end{bmatrix} = \begin{bmatrix} R_{\bar{s}}^2 & \rho C \\ \rho C & \rho R_{\bar{c}}^2 \end{bmatrix}^{-1} \begin{bmatrix} R_{\bar{s}}^2 \\ \rho R_{\bar{c}}^2 \end{bmatrix} = \frac{1}{R_{\bar{s}}^2 R_{\bar{c}}^2 - \rho C^2} \begin{bmatrix} R_{\bar{c}}^2 (R_{\bar{s}}^2 - \rho C) \\ R_{\bar{s}}^2 (R_{\bar{c}}^2 - C) \end{bmatrix}$$

Rearranging terms gives:

$$\begin{aligned}\frac{C}{R_c^2} &= \frac{1 - \alpha_c}{\alpha_s} \\ \frac{\rho C}{R_s^2} &= \frac{1 - \alpha_s}{\alpha_c}\end{aligned}\tag{17}$$

Next, consider the second order terms. Define:  $w_2 \equiv \omega[-\rho, 1 + \rho, -1]'$  be the vector of coefficients of the 'true' second order effects. Only the second order terms in equation 6) are correlated to  $\bar{X}_2$ . These second order terms read:  $X_2 w_2$ . Hence:  $E[\bar{X}_2' w] = E[\bar{X}_2' X_2] w_2$ . The moments of the sub-matrices  $\bar{X}_2' \bar{X}_2$  and  $\bar{X}_2' X_2$  read:<sup>20</sup>

$$\begin{aligned}\frac{1}{N} E[\bar{X}_2' X_2] &= \sigma^4 \begin{bmatrix} 2R_s^4 & 2\rho R_s^4 & 2\rho^2 R_s^4 \\ 2\rho R_s^2 R_c^2 & (\rho + \rho^2) R_s^2 R_c^2 & 2\rho^2 R_s^2 R_c^2 \\ 2\rho^2 R_c^4 & 2\rho^2 R_c^4 & 2\rho^2 R_c^4 \end{bmatrix} \\ \frac{1}{N} E[\bar{X}_2' \bar{X}_2] &= \sigma^4 \begin{bmatrix} 2R_s^4 & 2\rho R_s^2 C & 2\rho^2 C^2 \\ 2\rho R_s^2 C & \rho R_s^2 R_c^2 + \rho^2 C^2 & 2\rho^2 R_c^2 C \\ 2\rho^2 C^2 & 2\rho^2 R_c^2 C & 2\rho^2 R_c^4 \end{bmatrix}\end{aligned}$$

Define:  $\alpha_2 \equiv [\alpha_{ss}, \alpha_{sc}, \alpha_{cc}]$ . Then:

$$\begin{aligned}\alpha_2 &= \text{plim} \left[ (\bar{X}_2' \bar{X}_2)^{-1} \bar{X}_2' w \right] = \text{plim} \left[ (\bar{X}_2' \bar{X}_2)^{-1} \bar{X}_2' X_2 \right] w_2 \\ &= \omega (1 - \rho)^2 \frac{R_s^2 R_c^2}{(R_s^2 R_c^2 - \rho C^2)^2} \begin{bmatrix} -\rho R_c^2 C \\ (R_s^2 R_c^2 + \rho C^2) \\ -R_s^2 C \end{bmatrix}\end{aligned}\tag{18}$$
