## ABSTRACT

**Foid-bearing syenites and endoskarn xenoliths of the A.D. 472 Vesuvius eruption represent the magma chamber–carbonate wall-rock interface. Melt inclusions hosted in crystals from these rocks offer a rare opportunity to depict the formation and the composition of metasomatic skarn-forming fluids at the peripheral part of a growing K-alkaline magma chamber disrupted by an explosive eruption. Four principal types of melt inclusions represent highly differentiated phonolite (type 1), hydrosaline melt (type 3), unmixed silicate–salt melts (type 2), and a complex chloride-carbonate melt with minor sulfates (type 4). The high-temperature (700–800 °C) magmatic-derived hydrosaline melt is considered to be the main metasomatic agent for the skarn-forming reactions. The interaction between this melt (fluid) and carbonate wall rocks produces a Na-K-Ca carbonate-chloride melt that shows immiscibility between carbonate and chloride constituents at ~700 °C in 1 atm experiments. This unmixing can be viewed as a possible mechanism for the origin of carbonatites associated with intrusion-related skarn systems.**

**Keywords:** Vesuvius, skarn, melt inclusions, immiscibility.

## INTRODUCTION

Skarns are calc-silicate rocks that typically develop at the contact between magma bodies and carbonate wall rocks and in metamorphic environments (Einaudi et al., 1981; Meinert, 1998). Endoskarn is formed by contamination and/or metasomatism of the peripheral part of an igneous body (Kerrick, 1977; Einaudi et al., 1981). Exoskarn formation has three consecutive stages: isochemical thermal metamorphism, prograde metasomatism, and retrograde hydrothermal alteration (Brown et al., 1985). Metasomatic agents for skarn-forming reactions are believed to be introduced from crystallizing and degassing magmas. These reactions result in extensive decarbonation of the country rocks and may generate sufficient permeability for the infiltration of mineralizing fluids (Kwak, 1986; Dipple and Gerdes, 1998). The origin and composition of magmatic fluids involved in the early stages of skarn formation are debated (Kwak, 1986).

The exsolution of a magmatic fluid phase from a magma emplaced at crustal levels is well shown by recent melt and fluid inclusion studies (Roedder, 1992; Frezzotti, 1992; Low-

enstern, 1994; Yang and Bodnar, 1994; De Vivo et al., 1995; Kamenetsky et al., 1999; Thomas et al., 2000). The coexistence in phenocrysts of silicate melt and saline melt inclusions and the presence of multiphase inclusions (silicate glass + hydrosaline melt + volatiles) with highly variable volume ratios have been considered as strong evidence for immiscibility between silicate and nonsilicate melts during magma crystallization (Frezzotti, 1992, 2001; De Vivo et al., 1995). Magmatic inclusion evidence also exists for the exsolution of fluids from shallow magma chambers of alkaline volcanoes (De Vivo et al., 1995; Belkin et al., 1996; Fulignati et al., 1998). Exsolved hypersaline fluids that sequester ore-forming elements (e.g., Au, Ag, Cu, Pb, Zn, Sn) from magmas (Candela and Piccoli, 1995; Audetat et al., 1998; Ulrich et al., 1999) may play an important role in the genesis of hydrothermal ore deposits, e.g., Cu-Au-Mo porphyries and skarns (Kwak, 1986; Hedenquist and Lowenstern, 1994; Cline and Bodnar, 1994; Kamenetsky et al., 1999).

This paper reports on fluid exsolution from the peripheral part of the A.D. 472 (Pollena eruption) Vesuvius magma chamber, recorded in a series of melt and fluid inclusions in phenocrysts from the magma chamber and related skarn rocks. These inclusions clearly demonstrate a transition from the silicate melt to Si-

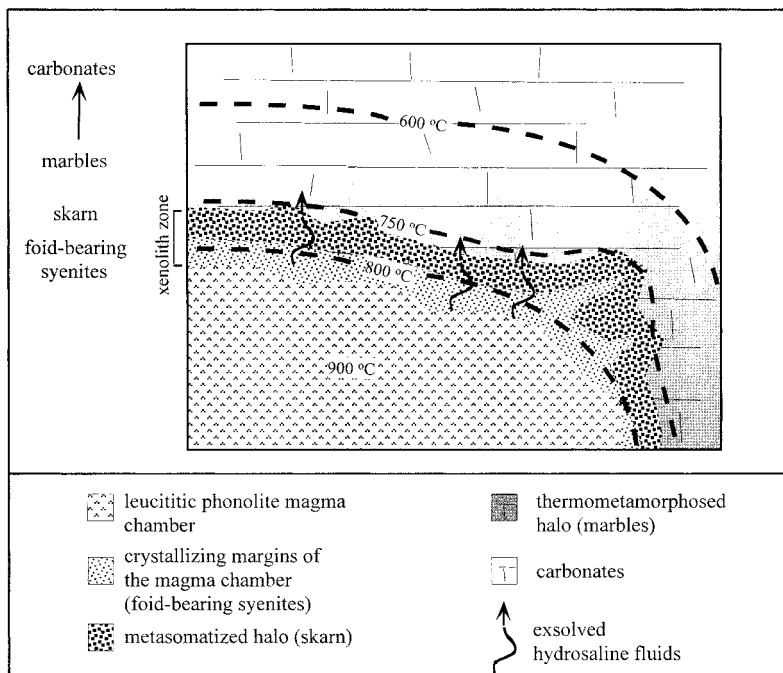

poor, volatile-rich phases (carbonate-chloride-sulfate melt) that form and further react with carbonate wall rocks at the margin of the magma chamber, as part of skarn formation.

## VESUVIUS: MAGMA CHAMBER AND A.D. 472 ERUPTION SAMPLES

The Vesuvius magmatic system is characterized by the presence of shallow reservoirs hosted within the Mesozoic carbonate basement (dolostone and limestone) that are periodically supplied with relatively hot (1150–1200 °C) mafic magma batches (Marianelli et al., 1995). Magma batches thermally equilibrate, crystallize, and mix with cooler resident magmas, forming zoned reservoirs. The chamber melts may reach highly alkalic phonolite composition with temperatures ~800–900 °C (Cioni et al., 1998). The resident magmas cause chemical reactions, metasomatic and thermometamorphic transformations inducing the formation of a complexly stratified interface between the magma chamber and country rocks. The outer margin of the magma chamber (Fig. 1), consisting of crystallized magmas (from glass-bearing fergusonites to foid-bearing K-syenites), continuously grades into carbonate country rocks through a skarn shell and thermometamorphic marble (Fulignati et al., 1998, 2000a, 2000b).

Our study focuses on the A.D. 472 sub-Plinian eruption products (young-stage magma chamber, after Cioni et al., 1998), which vary in composition from early leucititic phonolite (~900 °C) to later leucititic phonotephrite and contain cognate foid-bearing syenitic and calc-silicate (skarn) xenoliths. Syenites are nearly holocrystalline, nonequigranular rocks composed of K-feldspar, leucite, K-pargasitic amphibole, biotite, salitic clinopyroxene, melanitic garnet, interstitial nepheline, and accessory sphene and fluorapatite. Skarn xenoliths consist of fassaitic clinopyroxene, phlogopite, nepheline, calcite, and accessory apatite. On the basis of previous studies of the magma chamber–wall-rock interface in other Vesuvius eruptions (Belkin et al., 1985; Fulignati et al., 1998, 2000a, 2000b), and in accord with the results

**Figure 1.** Schematic section of upper part of A.D. 472 shallow magma chamber-wall-rock transition at Vesuvius. Dashed lines represent approximation of isotherms in surroundings of chamber inferred from this and previous (Marianelli, 1995; Fulignati et al., 2000a) studies.

of Belkin and De Vivo (1993), we envisage that these rocks derived from the margin and the immediate surroundings of the magma chamber (Fig. 1).

## MELT INCLUSION STUDIES

### Inclusion Types

Several types of coexisting primary melt inclusions were identified in foid-bearing syenites (types 1 to 3) and skarn samples (types 2 and 4)<sup>1</sup>.

Type 1 comprises two-phase melt inclusions (brown silicate glass and one to several small shrinkage bubbles) hosted in nepheline and K-feldspar (Fig. 2A).

Type 2 comprises multiphase melt inclusions in leucite and nepheline, consisting of brown or clear silicate glass and one (Fig. 2, C–E) or multiple (Fig. 2B) fluid-bearing globule(s). Globules contain a vapor bubble and heterogeneous crystalline material. When the bubble dominates a globule, the solids can be seen protruding from the bubble into the silicate glass, or forming a shell on the bubble-glass interface (Fig. 2, B–E). The glass/globule ratio is highly variable and in many inclusions globules are volumetrically significant (Fig. 2, D and E).

Type 3 are multiphase inclusions in neph-

eline from syenite (Fig. 2F). Type 4 are multiphase inclusions in nepheline and clinopyroxene from the endoskarn xenolith (Fig. 2G). Inclusions of both types are similar in appearance and often coexist in trapping planes with type 2 inclusions. They have different daughter solids, a deformed bubble, and a small amount of interstitial liquid. Crystals with cubic habits (chlorides?), birefringent euhedral phases (silicates, sulfates, and carbonates?), and opaque minerals (sulfides and oxides?) are always present among the solids.

### Heating Experiments with Melt Inclusions

The most significant results from heating experiments for type 3 and type 4 inclusions are described here.

Cubic crystals (chlorides?) in type 3 inclusions melt completely at 510–590 °C (number of measurements, N = 52). Melting of other daughter minerals including opaque phases and disappearance of the vapor bubble always occur at higher temperatures (690–810 °C, N = 70). It is interesting that in the coexisting type 2 inclusions the sequence and temperatures of phase transformations in the vapor- and crystal-bearing globules are similar to those observed in type 3 inclusions.

Heating of the nepheline-hosted type 4 inclusions produces complete melting of daughter crystals at 800–830 °C (N = 92) in all inclusions (Fig. 3), followed by vapor-bubble homogenization between 860 and 885 °C, but only in a few inclusions. Some solids (possi-

**Figure 2.** Representative melt inclusions in magmatic and skarn minerals. A: Type 1 silicate two-phase (glass + shrinkage bubble) inclusion. B, C, D: Type 2 inclusions from syenites. E: Type 2 inclusion from endoskarn with variable proportions of silicate glass and nonsilicate, vapor-bearing globules (see text for details). F and G: Type 3 and type 4, respectively, multiphase inclusions containing translucent (isotropic and birefringent) and opaque daughter minerals, deformed vapor bubble(s), and interstitial liquid. H: Scanning electron microscope images of exposed type 4 inclusions, containing chlorides (halite [Hal] and sylvite [Syl]), sulfates (glaserite [Gla] and arcanite [Arc]), and Na-Ca carbonate (Carb). All scale bars are 20  $\mu\text{m}$ . All microphotographs were taken before heating experiments.

bly heterogeneously trapped silicates) may persist to higher temperatures (840–980 °C; N = 59). Subsequently, rapid cooling (e.g., 50 °C/min) of type 4 inclusions always results in immiscibility between two clear liquids (Fig. 3) at ~670–700 °C (N = 38). The new melt usually forms a single globule around a vapor bubble (Fig. 3), but sometimes numerous globules form and then coalesce. A globule of this second melt is always a site of nucleation of the opaque phase (sulfide?) at <650 °C. Below 600 °C rapid crystallization within two unmixed liquids obscures phase boundaries and deforms the vapor bubble. Repeated heating and cooling on the same inclusion shows that the immiscibility is reversible at a constant temperature (~670–700 °C).

### Inclusion Compositions

The silicate glasses in type 1 melt inclusions have a K-phonolitic composition similar

**Figure 3. Microphotographs illustrating behavior of type 4 melt inclusion during heating (top row) and cooling (bottom row) experiments at different temperatures (Linkam TS1500 heating stage, University of Tasmania). Note unmixing between two liquids at temperatures <680 °C: globule of chloride melt (around vapor bubble) is enclosed in Na-K-Ca carbonate melt. In this experiment opaque phase (sulfide?) formed at 587 °C inside globule of chloride melt. Inclusion size is 33 × 27 μm. Cooling rate was ~50 °C/min.**

to that of the melt inclusions found in the A.D. 472 juvenile products (Table 1). In contrast, the compositions of glasses in type 2 melt inclusions from syenites (extremely high Al<sub>2</sub>O<sub>3</sub>, Na<sub>2</sub>O, and Cl; Table 1 [and see footnote 1]) have not been previously recorded in the Vesuvius rocks and glasses (e.g., Cioni et al., 1998). According to laser Raman spectroscopy, fluid-bearing globules in type 2 melt inclusions from syenites contain CO<sub>2</sub> and a complex mixture of nonsilicate minerals, including chlorides, sulfates, carbonates, bicarbonates, and fluorocarbonates (Table 2).

The daughter mineral assemblage of type 3 inclusions is represented by the same phases found in the globules inside type 2 melt inclusions from syenites, with the addition of fluoride and sulfides (Table 2). Dissolution temperatures of inferred halite in these inclusions correspond to 61–72 wt% NaCl<sub>equiv</sub> salinity.

Type 4 inclusions in the endoskarn minerals have a very complex paragenesis of daughter minerals (chlorides, carbonates, sulfates, and sulfides; Table 2). Accordingly, the two liquids unmixed during cooling in experiments

(Fig. 3) are cautiously identified as a globule of K-Na chloride melt in a larger volume of the Na-K-Ca carbonate melt with minor sulfates present (Fig. 2H).

## DISCUSSION AND CONCLUSIONS

Foid-bearing syenite and endoskarn xenoliths of the A.D. 472 eruption of Vesuvius represent the magma chamber–wall–rock interface, where complex skarn reaction processes occur. Thus, melt inclusions in these rocks offer a rare opportunity to illustrate the formation and composition of metasomatic, skarn-forming agents at the peripheral part of a growing K-alkaline magma chamber disrupted by an explosive eruption. The syneruptive quenching of magma and exotic xenoliths has preserved information about the earliest stages and consequences of skarn reaction processes.

We consider type 1 melt inclusions (Fig. 2A; Table 1) as representative of the late magmatic stage silicate melt (highly differentiated phonolite) that may have reacted with the carbonate country rocks by itself and/or via fluids derived from this melt. These interactions produce another silicate melt enriched in nonsil-

icate (e.g., carbonates and chlorides) components, and probably unstable in a cooling environment. Immiscibility or unmixing in this melt is well represented by type 2 melt inclusions that consist of silicate glass and nonsilicate (chloride-carbonate-sulfate) CO<sub>2</sub>-bearing globules (hereafter “salt melt”). The beginning of unmixing, i.e., the formation of numerous tiny salt melt globules, immiscible with a silicate melt, is possibly shown by the inclusion in Figure 2B. The high variability in the silicate melt/salt melt ratios in type 2 melt inclusions (Fig. 2, B–E) clearly indicates (according to the definitions in Roedder, 1984; Frezzotti, 2001) heterogeneous trapping of these two coexisting phases.

The next evolutionary stage, as represented by type 3 melt inclusions (Fig. 2F), is dominated by the salt melt phases. A close genetic relationship between silicate and salt melts is inferred here from the fact that glass-bearing type 2 and glass-free type 3 melt inclusions coexist within the growth planes and have a similar assemblage of daughter minerals (Table 2). We consider magmatic-derived high-temperature (700–800 °C) melts or fluids similar in composition to type 3 inclusions to be the most important in the skarn-forming reactions. In the Vesuvius skarn, the main compounds of metasomatic agents are represented by chlorides and carbonates with minor amounts of sulfates, sulfides, and fluorides. The presence of parisite and fluorite indicates that, in addition to chlorine, fluorine may play an important role in the transport of metal and rare earth elements (REEs), as has been implicated for the origin of REE mineralization associated with alkalic and carbonatite complexes (e.g., Birkett and Sinclair, 1998, and references therein).

The interaction between early high-temperature hypersaline fluids and carbonate country rocks is best recorded in inclusions in the endoskarn minerals (type 4 inclusions, Fig. 2G). In these we found a Na-K-Ca carbonate-chloride melt (Fig. 2H) that is a subject to immiscibility at ~690 °C, as demonstrated by our 1 atm heating and cooling experiments (Fig. 3). However, whether carbonate-chloride unmixing occurs in a given natural system depends on the cooling and pressure conditions. Therefore, we consider that the interaction between magmatic brines and carbonate wall rocks, in addition to inducing metasomatic reactions, can be viewed as a possible mechanism for carbonate melting, as suggested by Lentz (1998, 1999), for the formation of carbonatite melts associated with alkalic intrusions.

## ACKNOWLEDGMENTS

We thank T. Crawford and P. Davidson for critically reading this manuscript and for useful comments. The manuscript benefited immensely from the formal reviews by D.R. Lentz and J.B. Lowenstern. This research was sup-
