## ABSTRACT

**Background.** Although the relationship between a history of kidney stones and chronic kidney disease (CKD) has been explored in many studies, it is still far from being well understood. Thus, we conducted a meta-analysis of studies comparing rates of CKD in patients with a history of kidney stones.

**Methods.** PubMed, EMBASE, and the reference lists of relevant articles were searched to identify observational studies related to the topic. A random-effects model was used to combine the study-specific risk estimates. We explored the potential heterogeneity by subgroup analyses and meta-regression analyses.

**Results.** Seven studies were included in this meta-analysis. Pooled results suggested that a history of kidney stones was associated with an increased adjusted risk estimate for CKD [risk ratio (RR), 1.47 95% confidence interval (CI) [1.23–1.76]], with significant heterogeneity among these studies ( $I^2 = 93.6\%$ ,  $P < 0.001$ ). The observed positive association was observed in most of the subgroup analyses, whereas the association was not significant among studies from Asian countries, the mean age  $\geq 50$  years and male patients.

**Conclusion.** A history of kidney stones is associated with increased risk of CKD. Future investigations are encouraged to reveal the underlying mechanisms in the connection between kidney stones and CKD, which may point the way to more effective preventive and therapeutic measures.

**Subjects** Epidemiology, Nephrology, Urology

## INTRODUCTION

Kidney stones, solid concretions or crystal aggregations formed in the kidneys from dietary minerals in the urine, are common and responsible for significant morbidity. Racial differences are seen in kidney stone disease, primarily occurring in whites, followed by Hispanics, blacks, and Asians (*Romero, Akpinar & Assimos, 2010*). Kidney stone prevalence also varies by age and sex. In the United States, the lifetime prevalence of kidney stones is 12% among men and 7% among women (*Pearle, 2001; Pearle, Calhoun & Curhan, 2005*). Over the past decade, kidney stones have become increasingly recognized as heralds of

**OPEN ACCESS**

certain systemic disorders, including subclinical atherosclerosis, hypertension, diabetes, metabolic syndrome, and cardiovascular disease (Ferraro et al., 2013). All of the above conditions are known risk factors for chronic kidney disease (CKD). In this context, a number of epidemiologic studies assessed the relationship between a history of kidney stones and CKD. Although a previous review performed by Keddis & Rule (2013) has summarized the association between kidney stone history and an increased risk of CKD, the review has not provided an overall estimation of the effect of kidney stones on CKD. Data from two cross-sectional studies have shown that kidney stones were associated with CKD (Ingsathit et al., 2010; Shoag et al., 2014). However, it is difficult to establish the detrimental effects of kidney stones on CKD. Across two case-control studies, patients with kidney stone history had about a two-fold higher risk for CKD (Keller, Chen & Lin, 2012; Vupputuri et al., 2004). In addition, several cohort studies have also showed increased risk of CKD in patients with kidney stones (Alexander et al., 2012; Ando et al., 2015; Hippisley-Cox & Coupland, 2010; Rule et al., 2009), nevertheless, not all studies have shown a similar association (Kummer et al., 2015). Therefore, a meta-analysis of case-control and cohort studies was performed to qualify and quantify the risk, which may highlight the importance of providing additional intervention methods in this area.

## Methods

This study was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement checklist (Supplemental Information 1) (Stroup et al., 2000).

## Search strategy

PubMed and EMBASE were searched for observational studies to November 4, 2015, using the terms “renal stones” or “renal stone” or “kidney stones” or “kidney stone” or “nephrolithiasis” and “chronic kidney disease” or “kidney failure” or “renal disease” or “kidney disease” or “renal insufficiency” or “renal failure” or “kidney failure” and “risk” or “incidence” or “epidemiology.” With these parameters, two investigators (WS and LL) independently filtered out all the eligible articles and hand-searched references of retrieved papers for additional available studies. Conflicting results achieved consensus by discussion.

## Inclusion criteria

The inclusion criteria were: (1) case-control or cohort studies involving participants 18 years or older; (2) provided the multivariate-adjusted odds ratio (OR), risk ratio (RR), hazard ratio (HR), or standardized incidence ratio (SIR) with 95% confidence interval (CI), or sufficient information to calculate these; and (3) a comparison group made up of participants without kidney stones history was used.

## Exclusion criteria

The exclusion criteria were: non-human studies, reviews, comments, editorials, case reports, and cross-sectional studies. If a cohort study was reported in more than one publication, we chose the latest article.

## Data extraction and quality evaluation

The following data were extracted from the included studies: first author's name, year of publication, study design, country, sample size, mean age, mean follow-up period, method of kidney stones and CKD diagnosis, participants with baseline CKD excluded (yes or no), and adjustment factors. When needed, we contacted the original author for clarification. The quality of each study was independently evaluated by two investigators (WS and YR) using the Newcastle-Ottawa Scale (NOS) ([Wells et al., 2000](#)). Articles scoring 0–3, 4–6, and 7–9 were defined as poor, fair and good quality, respectively. Discrepancies between investigators were solved by consensus.

## Statistical analysis

The studies included in the meta-analysis reported different effect measures (odds ratio or hazard ratio). The HR in each primary study was directly considered as RR ([Spruance et al., 2004](#)). The OR was transformed into RR by the formula  $RR = OR / [(1 - P_0) + (P_0 \times OR)]$  (where  $P_0$  is the incidence of the outcome of interest of the nonexposed group) ([Zhang & Yu, 1998](#)). The combined RR and the corresponding 95% CI were obtained using the random-effects method of [DerSimonian & Laird \(1986\)](#). The heterogeneity of RR across the studies was assessed with Chi-squared based Q-statistic test ( $P < 0.10$ ) and quantified using  $I^2$  index ([Higgins et al., 2003](#)), where 25%, 50% and 75% indicate low, moderate and high heterogeneity, respectively. Sources of heterogeneity were explored by subgroup analyses and univariable random-effects meta-regression. Stratified analyses were conducted based on study design (case-control or cohort), region (Asian or non-Asian), sample size ( $< 50,000$  or  $\geq 50,000$ ), participant's average age ( $< 50$  or  $\geq 50$  years), mean follow-up ( $< 7.5$  or  $\geq 7.5$  years), and gender (men or women). Sensitivity analyses were conducted to assess the robustness of results by sequential omission of individual studies ([Copas & Shi, 2000](#)). All analyses were performed in Stata 10.0 (College Station, TX, USA). A 2-tailed  $P$  value  $< 0.05$  was considered significant.

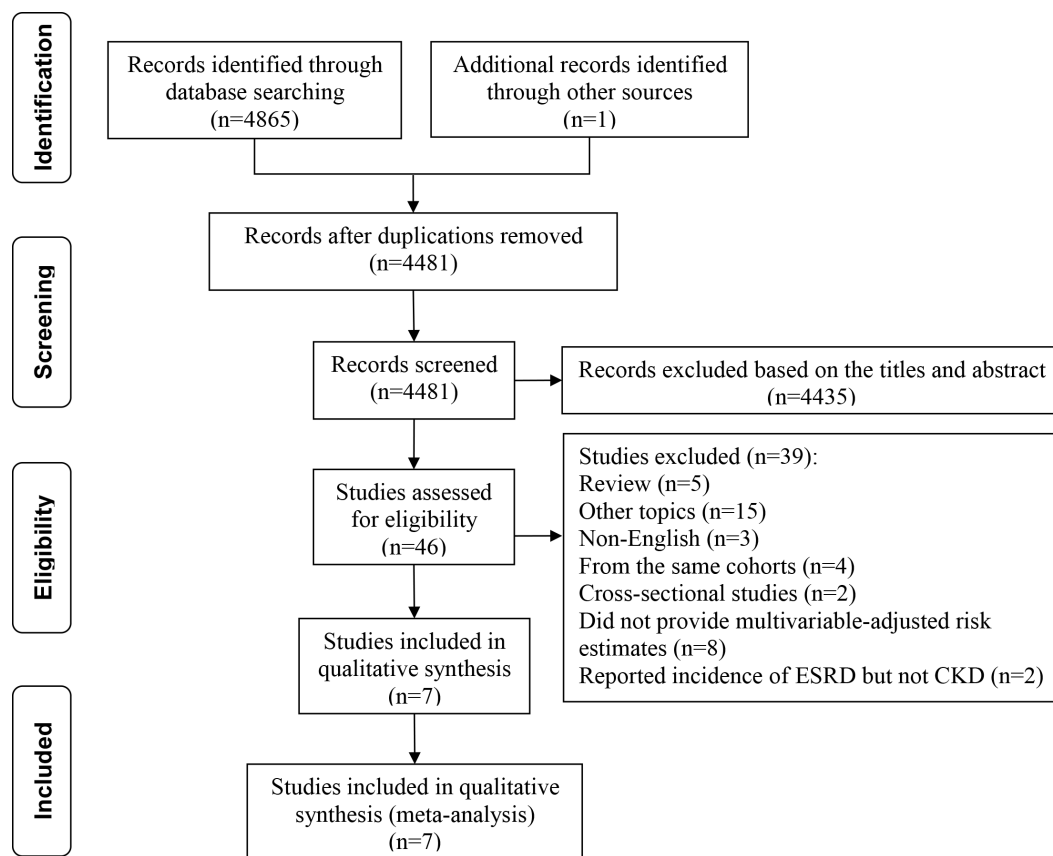

## RESULTS

### Study selection, characteristics, and quality

As shown in [Fig. 1](#), our literature search returned 4,866 results for relevant articles, and the full text was retrieved for 46 articles, from which we identified seven observational studies for inclusion in the meta-analysis ([Keller, Chen & Lin, 2012](#); [Vupputuri et al., 2004](#); [Alexander et al., 2012](#); [Ando et al., 2015](#); [Hippisley-Cox & Coupland, 2010](#); [Rule et al., 2009](#); [Kummer et al., 2015](#)). One study was published in abstract form, and all other studies were in full text form. The main characteristics of the included studies are presented in [Table 1](#). The primary analysis included data for 2,810,233 participants derived from seven observational studies. According to the NOS, six studies were of good quality and one of fair quality ([Table S1](#)).

### Risk of kidney stones on CKD events

As shown in [Fig. 2](#), the multivariate-adjusted RR of CKD within the seven individual study populations ranged between 1.09 and 1.98, with an overall multivariate-adjusted RR of 1.47 (95% CI [1.23–1.76]). Significant heterogeneity was observed ( $I^2 = 93.6\%$ ,  $P < 0.001$ ).

**Figure 1** Flow chart of study selection.

## Subgroup analyses

In subgroup analyses, case-control studies showed a significantly higher CKD risk (RR 1.98; 95% CI [1.85–2.11]) in individuals with kidney stones compared with cohort studies (RR 1.35; 95% CI [1.12–1.63]). Stratification based on sample size resulted in a pooled RR of 1.46 (95% CI [1.12–1.91]) in small sample studies and 1.49 (95% CI [1.10–2.03]) in large sample studies. Stratification based on region resulted in a pooled RR of 1.52 (95% CI [0.90–2.57]) in Asian populations and 1.44 (95% CI [1.20–1.73]) in Western populations. The observed positive association was also similar among studies with a mean age <50 years (RR 1.52; 95% CI [1.27–1.82]) and those with a mean age  $\geq$  50 years (RR 1.56; 95% CI [0.98–2.48]), although the latter did not reach statistical significance. Stratification based on follow-up time resulted in a pooled RR of 1.21 (95% CI [1.10–1.32]) for studies with a follow-up time <7.5 years and a pooled RR of 1.46 (95% CI [1.17–1.83]) for studies with a follow-up time  $\geq$  7.5 years. Stratification based on gender indicated that the pooled risks for CKD remained significant in female patients with kidney stones (RR 1.57; 95% CI [1.04–2.38]). However, the risk was slightly lower and did not remain significant in male patients with kidney stones (RR 1.40; 95% CI [0.98–1.99]). High heterogeneity was present in subgroup analyses with the exception of case-control studies and mean follow-up time <7.5 years ( $I^2 = 0\%$ ). In addition, when meta-regression performed, none

of these variables had a significant interaction with the risk estimate (all  $P$  values  $> 0.05$ ) (Table 2).

### Sensitivity analyses and reporting bias

Sensitivity analysis indicated that the estimate remained significant despite omission of any of the studies [RR varied between 1.38 (95% CI [1.16–1.65]) and 1.54 (95% CI [1.29–1.85])] (Table S2). We did not construct a funnel plot as they are known to be unreliable when used with fewer than 10 studies (Higgins & Green, 2011).

## DISCUSSION

This study is the first meta-analysis to present the risk of CKD in patients with kidney stone history. We confirmed kidney stones were associated with an increased risk of CKD with a RR of 1.47 (95% CI [1.23–1.76]).

As with other published meta-analyses of this type (Cheungpasitporn et al., 2015; Yan et al., 2014), our study has a high level of heterogeneity. We conducted subgroup analyses and meta-regression analyses to explore sources of heterogeneity. The risk of CKD remained approximately 1.5 in all subgroups. The lack of a significant effect in Asians, those aged  $\geq 50$  years and males is notable. For example, a low incidence of kidney stones in Asians and a high prevalence of CKD in the white respondents (Jha et al., 2013; Romero, Akpınar & Assimios, 2010) may contribute to these results. However, it is also possible that the

**Notes.**

RR, risk ratio; CI, confidence interval.

<sup>a</sup>P value for heterogeneity among studies assessed with Cochran's Q test.<sup>b</sup>P value for interaction evaluated by meta-regression models.

differences in information size (the non-Asian population of 2,755,883 in our analysis was far larger than the Asian population of 54,340) may explain these findings. This conclusion is supported by the results of the meta-regression, which showed that study design, region, sample size, mean age, mean follow-up time, and gender explained little of the variation between studies.

Similarly, our study indicated that female patients with kidney stones showed a slightly higher risk for CKD than male patients. The increased risk was not significant in male patients with kidney stones. It is unclear if this represents a difference in underlying pathophysiology. Differences by sex are not infrequent. In *Hippisley-Cox & Coupland's (2010)* or *Shoag et al.'s (2014)* study, only female patients with kidney stones history showed a significant increased risk of developing moderate to severe chronic kidney disease. A similar finding has also been observed in a meta-analysis on the association of kidney stones and risk of incident coronary heart disease (*Ferraro et al., 2013*). The incidence of other risk factors for CKD, such as hypertension (*Gillen, Coe & Worcester, 2005*) and diabetes (*Ando et al., 2011*), also was found to be significantly higher in women but not in men with kidney stones. Further studies are needed to explore sex and racial differences in the association between kidney stones and CKD.

Note that the CKD risk in patients with kidney stones becomes more substantial when we restrict analyses to cohort studies and studies with follow-up time ≥7.5 years. The risk

of CKD was lower in cohort studies versus case-control studies (RR 1.35 vs 1.98), which is important as well-conducted cohort studies provide a higher level of evidence than case-control studies. It may be that the risk of CKD associated with kidney stones is not as high as our primary analysis would suggest. Regarding follow-up time, although not a significant difference, the risk was higher in studies with  $\geq 7.5$  years follow up versus those with  $< 7.5$  years, which may reflect the slowly progressive natural history of CKD.

The pathophysiologic relation between kidney stones and new-onset CKD is rather unclear, but several potential reasons may explain the observed associations. First, for sterile stones, repeated episodes of obstruction associated with kidney stones may cause a sequence of tubular cell events followed by macrophage interstitial infiltration including an inflammatory cascade and interstitial fibroblast production, which can lead to glomerulosclerosis, reduced glomerular filtration rate, and renal insufficiency (*De Water et al., 1999; Gambaro, Favaro & D'Angelo, 2001*). Second, for infection-related stones, stones form in the presence of highly alkaline urine and these stones may begin to obstruct calyces and renal pelvis (*Bichler et al., 2002; Viers et al., 2015*), besides, ammonium ions in alkaline urine are also highly toxic and can injure or kill healthy cells (*Gambaro, Favaro & D'Angelo, 2001*). These factors contribute to CKD. Third, CKD is a recognized complication of kidney stones as a result of rare hereditary disorders such as primary hyperoxaluria and cystinuria (*Leumann, 1985; Worcester et al., 2006*). Fourth, stone treatment itself may account for the excess risk of kidney damage. Animal experiments have confirmed that extracorporeal shock wave lithotripsy disrupts the tubular basement membrane (*Evan et al., 1991*). Fifth, kidney stones and CKD may share responsible causal risk factors.

Several limitations of this meta-analysis should be addressed. First, significant heterogeneity existed across the studies, thus, we conducted a subgroup analysis and meta-regression analysis. Unfortunately, we could not thoroughly explain the source of heterogeneity, suggesting other unknown confounding variables may be the source of heterogeneity. Second, the meta-analysis included studies with different study designs, follow-up time, diagnostic criteria, and adjusted confounders, which could introduce inherent limitations. For example, the cut-off points used to define CKD such as  $\text{eGFR} < 45 \text{ mL/min/1.73 m}^2$  vs  $\text{eGFR} < 60 \text{ mL/min/1.73 m}^2$  differ substantially in terms of both prevalence and associated morbidity. Third, we did not have information on stone composition for most of participants with kidney stone history, and thus cannot evaluate the specific risk associated with different stone types. Similar limitations were seen on stone burden, medications, lithotripsy, other surgeries and genetic risk factors. Finally, although all the included studies controlled for several known risk factors for CKD, residual confounders may be present due to the observational nature of our study.

In conclusion, our study suggests a history of kidney stones is significantly associated with increased risk of CKD. Further efforts should be made to explore the potential biological mechanism to confirm these findings and they will stimulate the development of more effective preventive and therapeutic measures.

## ADDITIONAL INFORMATION AND DECLARATIONS

### Funding

This work was supported by the National Nature Science Foundation of China (NSFC) (No. 81200531 and 81570667 for Shuwang Ge; No. 81470948 and 81270770 for Gang Xu). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.
