The Potential of NO_3^- -N Utilization by a Woody Shrub Species *Lindera triloba*:

A Cultivation Test to Estimate the Saturation Point of Soil NO_3^- -N for Plants

²Graduate School of Informatics, Kyoto University, Kyoto 606-8501

Responses of seedlings of a shrub species, *Lindera triloba*, grown in perlite culture medium, to nitrate (NO_3^- -N) supply were investigated to estimate the saturating point of available NO_3^- -N for plant utilization. NO_3^- -N concentration and nitrate reductase activity (NRA) in leaves and roots were used as indicators of NO_3^- -N uptake and assimilation by *L. triloba*. Root NRA increased with NO_3^- -N supply when concentrations were low and reached a plateau at high NO_3^- -N concentrations. On the other hand, root NO_3^- -N concentration increased linearly with NO_3^- -N supply; therefore, it is suggested that NO_3^- -N uptake did not limit NO_3^- -N assimilation by *L. triloba*. In contrast, leaf NRA and leaf NO_3^- -N concentration were low and were not influenced by NO_3^- -N supply. This may be caused by the lack of transport of NO_3^- -N from roots to leaves. The NO_3^- -N retained in perlite was compared with NO_3^- -N pool sizes in soils from a forest where *L. triloba* occurs naturally to estimate the level of NO_3^- -N availability to plants in the forest soil. The maximum NO_3^- -N pool size in the forest soil was comparable to concentrations at which root NRA reached a plateau in perlite cultures. These results indicate that soil NO_3^- -N availability is below the saturation point for NO_3^- -N uptake by *L. triloba*, and it is the limiting factor of NO_3^- -N utilization by *L. triloba* under field conditions in which this species naturally occurs.

KEY WORDS: nitrate reductase activity (NRA), nitrate (NO_3^- -N) concentration, perlite, *Lindera triloba*

DOMAINS: plant sciences, enzymology, metabolism, nutrition, plant processes, physiology

INTRODUCTION

The increased nitrate (NO_3^- -N) deposition derived from human activities has altered ecosystem nitrogen (N) cycles and has increased N availability to plants. It could, therefore, reduce the diversity in ecosystems over the long term[1]. Under changing regional or global N cycles, NO_3^- -N uptake by plants is one of the most important processes in forest ecosystem N cycles. Because NO_3^- -N is a highly leachable anion in forest soils, plant NO_3^- -N uptake reduces not only N loss from ecosystem, but also other nutrient cations accompanied by NO_3^- -N leaching[2]; therefore, work is being conducted to elucidate the importance of plant NO_3^- -N use in N cycles in ecosystems[3,4,5], and information on the potential of plants for utilizing NO_3^- -N is needed to assess the roles of plants influencing N retention by ecosystems.

Regarding assimilation processes of NO_3^- -N by plants, the reduction of NO_3^- -N to NH_4^+ -N is required for the synthesis of organic N[6,7,8]. The first step after the uptake of NO_3^- -N is the reduction of NO_3^- -N to nitrite (NO_2^- -N), and the process catalyzed by nitrate reductase (NR) is known to be the rate-limiting step in the sequence of NO_3^- -N assimilation processes[7,9,10]; therefore, plant nitrate reductase activity (NRA) is a useful indicator of plant NO_3^- -N utilization potential. Also, the existence of NO_3^- -N in plant tissues can be evidence for plant NO_3^- -N uptake, as plants do not synthesize NO_3^- -N[11].

The objectives of this study were to estimate the potential of NO₃⁻-N use by plants and to determine whether the NO₃⁻-N pool size in a forest soil exceeds plant NO₃⁻-N uptake potential. For these objectives, we selected a shrub species of Lauraceae, *Lindera triloba* (Sieb. et Zucc.) Blume. *L. triloba* was one of the dominant understory species in a conifer plantation (Koyama, unpublished data), where nitrification potential had wide range (0 to 12.2 mg N 100 g dry soil⁻¹ 28 days⁻¹)[12]. Experiments were conducted (1) to describe the responses of NO₃⁻-N use by *L. triloba* to NO₃⁻-N supply and (2) to examine the relationship of NO₃⁻-N supply to the amount of NO₃⁻-N retained in the cultivation medium and to compare this with the NO₃⁻-N pool size in forest soil. In seedlings of *L. triloba* grown in perlite medium supplied with various amounts of NO₃⁻-N, leaf and root NRA were measured, in addition to leaf and root NO₃⁻-N assays. The amount of NO₃⁻-N retained in perlite was compared with the soil NO₃⁻-N pool size in a forest where *L. triloba* is distributed.

METHODS

Plant Cultivation and Treatment

All seeds of *L. triloba* (Sieb. et Zucc.) Blume were collected from a single seed tree in Mt. Ryuoh in Shiga Prefecture, central Japan (35°10'N, 136°20'E) in September 1997. The collected seeds were stored at about 8°C until sowed in horticultural soil in April 1998. On April 29, 1999, seedlings were washed in tap water followed by deionized water to remove soil from roots. They were then individually transplanted into plastic pots filled with approximately 600 ml perlite that was prerinsed with deionized water. Throughout the period of the experiment, all seedlings were placed under a roof of a plastic film to keep out rain.

For 42 days after transplanting, each seedling was supplied daily with 200 ml nutrient solution containing 0.35 mmol l⁻¹ NaH₂PO₄·2H₂O; 0.63 mmol l⁻¹ KCl; 0.5 mmol l⁻¹ CaCl₂·2H₂O; 0.25 mmol l⁻¹ MgSO₄·7H₂O; 59.37 μmol l⁻¹ Fe-EDTA; 0.43 μmol l⁻¹ Cu-EDTA; 0.42 μmol l⁻¹ Zn-EDTA; 0.45 μmol l⁻¹ Mn-EDTA; 32.35 μmol l⁻¹ H₃BO₃; 0.41 μmol l⁻¹ Na₂MoO₄·2H₂O, and NO₃⁻-N. Nitrate was added in solution as NaNO₃ at 0, 1, 10, 25, and 50 ppm (molar concentrations were 0, 0.071, 0.71, 1.79, and 3.57 mmol N l⁻¹). Each of the five treatments was replicated ten times.

Plant Analysis

The leaves and roots of cultivated *L. triloba* were collected from 10:00 to 14:00 on June 8, 1999 at the 42nd day after the start of NO₃⁻-N additions. NRA was measured by a modified version of the *in vivo* test[13,14,15,16]. Samples were kept at 4°C until laboratory analysis. Two hundred leaf disks each with a diameter of 2.5 mm were cut out, and fine roots (diameter < 2 mm) were cut into about 5-mm lengths after being rinsed with deionized water. After vacuum infiltration (6 mm Hg; twice for 30 s each) with 5 ml of incubation buffer, the samples were incubated for 1 h at 30°C in the dark. The composition of the incubation buffer was 0.1 M KNO₃, 0.1 M KH₂PO₄, and 3% 1-propanol, and the pH was adjusted to about 7.5 with NaOH. Enzyme activity was stopped by placing sample vials in hot water (80°C). Leaves and

roots were removed, oven-dried at 105°C, and then weighed to calculate the activity per unit dry weight. The concentration of NO₂⁻-N produced in the incubation buffer was measured colorimetrically by diazotization[17]. The effect of plant pigment was compensated for by measurement of complete controls lacking N-naphthylethylene diamine dihydrochloride.

The remaining leaves and fine roots were dried at 40°C and then ground. About 100 mg of ground sample was extracted with 10 ml of deionized water for 1 h at 45°C. The extract was filtered, and the concentration of NO₃⁻-N in the extract was analyzed by HPLC (SHIMADZU, HIC-6A, Kyoto, Japan) within 72 h to avoid the transformation of nitrate in the extract.

Perlite Analysis

A 5-g subsample of perlite from each cultivation pot was extracted with 50 ml of 2 M KCl and filtered. The NO₃⁻-N concentration in the extract was determined by diazotization after reduction of NO₃⁻-N to NO₂⁻-N with zinc powder[17]. The amount of NO₃⁻-N retained in perlite was calculated as N per 100 ml core (μmol N 100 ml⁻¹) and compared with the data of the NO₃⁻-N pool size in the forest soil where seeds of *L. triloba* were collected (Koyama, unpublished data). In the forest, 30 soil samples were collected from areas within a 30-cm radius from ten trunks of *L. triloba* in Mt. Ryuoh; this process was repeated five times during the 1998 growing season. A total of 150 soil samples were measured to determine NO₃⁻-N pool sizes in the forest.

Statistical Analysis

All statistical analyses were conducted using the statistical program SPSS 7.5.1[18]. Differences among NRAs or NO₃⁻-N concentrations in plants supplied with different concentrations of NO₃⁻-N were analyzed using a Kruskal–Wallis one-way analysis of variance. Multiple comparisons of mean values among treatments were performed by the sequential Bonferroni test[19] after the determination of pairwise P values by the Mann–Whitney test. In cases where multiple comparisons indicated that saturation had occurred in the relation between supplied NO₃⁻-N and NRA or NO₃⁻-N concentrations in the plants, Michaelis–Menten kinetics was applied for the relation of supplied NO₃⁻-N and plant NRA or NO₃⁻-N concentration as follows[20]:

$$v = S \times V_{\max} / (S + K_m)$$

where *v* is plant NRA or NO₃⁻-N concentration, *S* is the concentration of supplied NO₃⁻-N, *V*_{max} is maximum value, and *K*_m is the Michaelis constant. The two parameters, *V*_{max} and *K*_m, in the Michaelis–Menten kinetics were estimated by an Eadie–Hofstee plot (i.e., the relation of supplied NO₃⁻-N to supplied NO₃⁻-N/NRA)[21], and they were applied as initial values in the nonlinear regression analysis in SPSS. Spearman rank correlation coefficients were calculated to detect a relationship between NRA and NO₃⁻-N concentration in each of plant leaves and roots. Spearman rank correlation coefficients were also calculated to detect a relationship between leaves and roots for each of NRA and NO₃⁻-N concentration.

RESULTS

Plant NRA and NO₃⁻-N Concentration

Root NRA changed with NO₃⁻-N supply in the range from 0.071 to 1.79 mmol N l⁻¹ supplied NO₃⁻-N (Fig. 1a); however, there was no significant difference between root NRA of individuals supplied with 1.79 and 3.57 mmol N l⁻¹ NO₃⁻-N, indicating that root NRA had reached a plateau. The nonlinear regression analysis yielded values of Vmax = 0.46 (μmol N g dry wt⁻¹ h⁻¹) and Km = 1.33 (mmol N l⁻¹) for the relationship between root NRA and NO₃⁻-N supply. In contrast, leaf NRA remained low even at the highest concentration of NO₃⁻-N, and there was no significant difference among treatments. Root NO₃⁻-N concentrations increased with NO₃⁻-N supply (Fig 1c); however, leaf NO₃⁻-N concentrations remained low with increased NO₃⁻-N supply (Fig 1d), even though the NO₃⁻-N concentrations in leaves were higher than in roots when the concentration of supplied NO₃⁻-N was lower than 0.071 mmol N l⁻¹ (*p* < 0.01).

Comparisons of results between roots and leaves showed that there was no significant correlation between root NRA and leaf NRA or between root NO₃⁻-N concentration and leaf NO₃⁻-N concentration (Fig. 2). There was no significant correlation between leaf NO₃⁻-N concentration and leaf NRA, although root NRA was significantly correlated with root NO₃⁻-N concentration (*p* < 0.01) (Fig. 3).

Perlite NO₃⁻-N

The amount of NO₃⁻-N retained in perlite increased from 0 up to 154.26 μmol N 100 ml perlite⁻¹ and was significantly correlated with the NO₃⁻-N supply (*p* < 0.001) (Fig. 4a). Using the regres-

sion of supplied NO₃⁻-N to retained NO₃⁻-N in perlite, the perlite supplied with 2.06 mmol N l⁻¹ NO₃⁻-N was equal to the maximum NO₃⁻-N pool size in the forest soil (79.47 μmol N 100 ml soil⁻¹, Fig. 4b).

DISCUSSION

Effects of NO₃⁻-N Supply on NO₃⁻-N Use by *L. triloba*

When the concentration of supplied NO₃⁻-N was lower than 1.79 mmol N l⁻¹, NRA in *L. triloba* roots increased with NO₃⁻-N supply (Fig. 1a). Because there was no significant difference between root NRA supplied with 1.79 mmol N l⁻¹ and with 3.57 mmol N l⁻¹, it is likely that root NRA was saturated with 1.79 mmol N l⁻¹ of NO₃⁻-N. Two possible explanations can be considered for the control of root NRA by NO₃⁻-N: (1) limited uptake of NO₃⁻-N and (2) limited induction of NR by NO₃⁻-N after it is taken up. The concentration of NO₃⁻-N in plant organs is the difference between increase of NO₃⁻-N by uptake and decrease of NO₃⁻-N by reduction, as plants do not synthesize NO₃⁻-N[11]; therefore, NO₃⁻-N concentration in plant organs must be less than or equal to the NO₃⁻-N absorbed by the plant. Nonetheless, root NO₃⁻-N concentrations continuously increased with NO₃⁻-N supply, showing no plateau (Fig. 1c). This indicates that the saturation of root NRA was not caused by the limited absorption of NO₃⁻-N, although there was a significant correlation between root NO₃⁻-N concentration and root NRA (*p* < 0.01) (Fig. 3a). This suggested that the NO₃⁻-N uptake by *L. triloba* corresponds to the NO₃⁻-N supply, even though the NO₃⁻-N utilization of this species did not correspond to the absorbed NO₃⁻-N when excess amounts of NO₃⁻-N were supplied.

FIGURE 1. Effect of NO₃⁻-N supply on (a) root NRA (μmol N g dry wt⁻¹ h⁻¹), (b) leaf NRA (μmol N g dry wt⁻¹ h⁻¹), (c) root NO₃⁻-N concentration (μmol N g dry wt⁻¹), and (d) leaf NO₃⁻-N concentration (μmol N g dry wt⁻¹). The curved line shown in (a) shows the Michaelis–Menten kinetics. The bars show S.E.

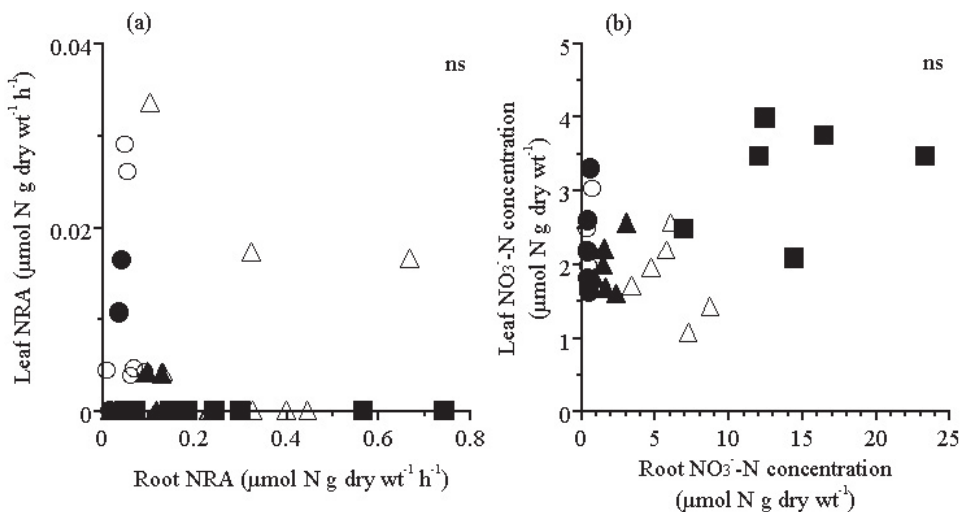

FIGURE 2. Relationship between (a) root NRA ($\mu\text{mol N g dry wt}^{-1} \text{h}^{-1}$) and leaf NRA ($\mu\text{mol N g dry wt}^{-1} \text{h}^{-1}$) and (b) root NO₃⁻-N concentration ($\mu\text{mol N g dry wt}^{-1}$) and leaf NO₃⁻-N concentration ($\mu\text{mol N g dry wt}^{-1}$). Concentrations of supplied NO₃⁻-N were 0 (●), 0.071 (○), 0.71 (▲), 1.79 (△), and 3.57 (■) mmol N l⁻¹.

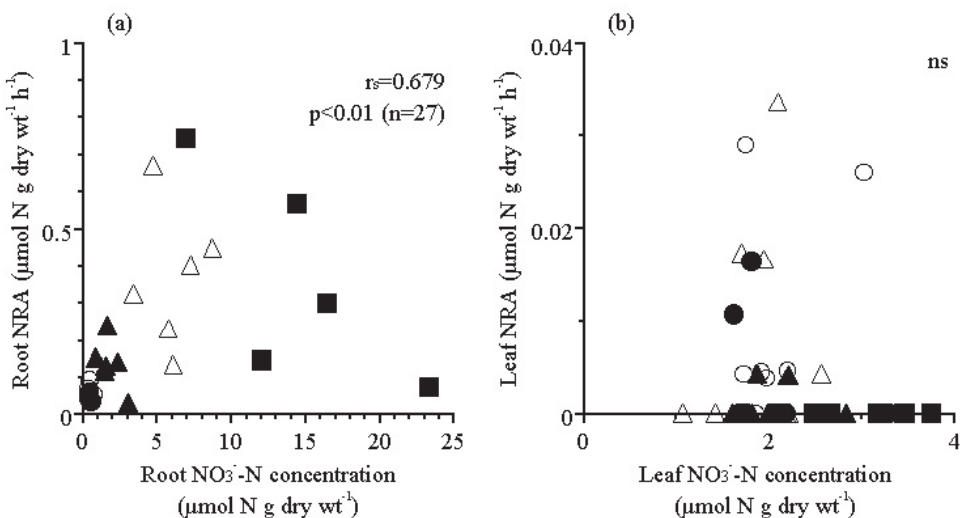

FIGURE 3. Relationship between (a) root NO₃⁻-N concentration ($\mu\text{mol N g dry wt}^{-1}$) and root NRA ($\mu\text{mol N g dry wt}^{-1} \text{h}^{-1}$) and (b) leaf NO₃⁻-N concentration ($\mu\text{mol N g dry wt}^{-1}$) and leaf NRA ($\mu\text{mol N g dry wt}^{-1} \text{h}^{-1}$). Concentrations of supplied NO₃⁻-N were 0 (●), 0.071 (○), 0.71 (▲), 1.79 (△) and 3.57 (■) mmol N l⁻¹.

FIGURE 4. Comparison of NO₃⁻-N content in perlite and forest soil. (a) Relationship between NO₃⁻-N supply (mmol N l⁻¹) and amount of retained NO₃⁻-N in perlite ($\mu\text{mol N } 100\text{ml}^{-1}$). (b) Frequency distribution for soil NO₃⁻-N pool size ($\mu\text{mol N } 100 \text{ ml}^{-1}$) in the forest where the seeds were collected (Koyama, unpublished data). The dotted lines connecting figures indicated (1) the maximum of NO₃⁻-N pool size in forest soil and (2) the corresponding NO₃⁻-N supply to achieve that maximum.

On the other hand, there was no significant difference in leaf NRA supplied with different concentrations of NO₃⁻-N (Fig. 1b). Moreover, mean leaf NRA values were constantly lower than root NRA, irrespective of supplied NO₃⁻-N concentration ($p < 0.001$). Two reasons can be offered for very low NRA in leaves compared with roots: (1) the lack of enzyme induction in leaves and (2) the lack of NO₃⁻-N transportation from roots to leaves. The former reason, however, is not plausible because an investigation on *L. triloba* naturally grown in a conifer plantation showed that this species has NRA in its leaves, and the activity was approximately comparable to root NRA detected in this study (Koyama, unpublished data); therefore, it is obvious that *L. triloba* is able to induce NR in its leaves when NO₃⁻-N is transported to the leaves. Besides leaf NRA, leaf NO₃⁻-N concentrations also remained low even when a high concentration of NO₃⁻-N was supplied, and root NO₃⁻-N concentration showed no relationship with leaf NO₃⁻-N concentration (Figs. 1d and 2b). The lack of a significant correlation between leaf NRA and leaf NO₃⁻-N concentration can be ascribed to the narrower range of NRA and NO₃⁻-N concentrations in leaves than in roots (Fig. 3b); therefore, leaves of *L. triloba* may play only minor part in NO₃⁻-N use in the case of seedlings, and it may be because NO₃⁻-N absorbed by roots was not transported to the leaves. The transportation of NO₃⁻-N in plants and the allocation of NRA are influenced by factors such as specific property, light condition, external NO₃⁻-N availability, plant age, and/or temperature [7,8,22,23,24,25,26]. Specific differences and light conditions cannot explain the absence of (or very low) leaf NRA in the present study. It is because the same species showed foliar NRA in field investigations as stated above; and the light availability must be higher in the cultivation experiment than under the field conditions in the conifer plantation, though it is commonly accepted that the better light conditions provide plants an advantage in leaf NO₃⁻-N reduction [7,25]; however, further information is required to clarify the effects of other possible factors.

Moreover, when the concentrations of supplied NO₃⁻-N were lower than 0.071 mmol N l⁻¹, NO₃⁻-N concentrations were significantly higher in leaves than in roots ($p < 0.01$), even though NRA was significantly lower in leaves than in roots across all levels of supplied NO₃⁻-N ($p < 0.01$). This result suggests that *L. triloba* has a storage pool of NO₃⁻-N in its leaves separate from the site of metabolism, and the NO₃⁻-N transported into the storage pool cannot be assimilated. It could, however, play a part in ionic and osmotic balance in the cells [27].

Estimation of NO₃⁻-N Availability in Forest Soil to NO₃⁻-N Use by *L. triloba*

Because the supplied solution (200 ml) overflowed the seedling receptacles, the NO₃⁻-N available to *L. triloba* was equivalent not to the total amount of added NO₃⁻-N but to the amount of NO₃⁻-N retained in perlite. Among the treatments, however, the amount of NO₃⁻-N retained in perlite was significantly correlated with the concentration of supplied NO₃⁻-N ($p < 0.001$) (Fig. 4a); therefore, the range of NO₃⁻-N pool size in forest soils (from 0 to 79.47 μmol N 100 ml soil⁻¹) was equivalent to the amount of NO₃⁻-N retained in perlite supplied with NO₃⁻-N of 0 to 2.06 mmol N l⁻¹ from the regression. The substitution of the maximum NO₃⁻-N pool size in forest soil (namely, supply of 2.06

mmol N l⁻¹ NO₃⁻-N) for the Michaelis–Menten kinetics gives 0.28 μmol N g dry wt⁻¹ h⁻¹ in NRA, which is equivalent to 60.8% of maximum value (0.46 μmol N g dry wt⁻¹ h⁻¹). Because there was no significant difference between the seedlings supplied with 1.79 mmol N l⁻¹ NO₃⁻-N and with 3.57 mmol N l⁻¹ NO₃⁻-N (Fig. 1a), root NRA might almost reach the plateau when 2.06 mmol N l⁻¹ NO₃⁻-N (that is equivalent to the maximum NO₃⁻-N pool size in forest soils) was supplied; however, as the frequency distribution for soil NO₃⁻-N pool size was positively skewed (Fig. 4b), 90% of forest soils had a smaller NO₃⁻-N pool size than perlite supplied with 0.71 mmol N l⁻¹ NO₃⁻-N. When NO₃⁻-N availability is in this range, roots of *L. triloba* are likely have a value of NRA lower than 0.16 μmol N g dry wt⁻¹ h⁻¹ (35.0% of maximum), assuming the preceding Michaelis–Menten kinetics apply. Moreover, root NRA increased with NO₃⁻-N supply across this range, suggesting that NO₃⁻-N availability is the limiting factor for NO₃⁻-N assimilation by *L. triloba* grown in forest soils. These comparisons between NO₃⁻-N retained in perlite and NO₃⁻-N in forest soils suggest that available NO₃⁻-N in forest soils is below the saturation concentration for *L. triloba*.
