Abstract: Neutropenia and febrile neutropenia are two major complications of chemotherapy. Dose reductions, delays in treatment administration, and the use of granulocyte colony-stimulating factors are equally recommended options to preserve absolute neutrophil count in case of chemotherapy regimens bringing a risk of febrile neutropenia of 20% or higher. Recombinant granulocyte colony-stimulating factors, such as filgrastim and lenograstim, have a short elimination half-life ($t_{1/2}$) and need to be used daily, while others, like pegfilgrastim and lipegfilgrastim, are characterized by a long $t_{1/2}$ requiring only a single administration per cycle. Balugrastim is a novel long-acting recombinant granulocyte colony-stimulating factor obtained by means of a genetic fusion between recombinant human serum albumin and granulocyte colony-stimulating factor. Albumin binding increases the molecular weight and determines a high plasmatic stability leading to a $t_{1/2}$ of ~19 days. Balugrastim's efficacy, safety, and tolerability have been assessed in four different clinical trials involving breast cancer patients treated with doxorubicin and docetaxel. Pegfilgrastim was chosen as a comparator. Balugrastim was noninferior to pegfilgrastim with regard to the reduction of mean duration of severe neutropenia during cycle 1. Moreover, both treatments were comparable in terms of efficacy and safety profile. Balugrastim was well tolerated, with the only related adverse event being mild to moderate bone pain. The aim of this review is to summarize the currently available literature data on balugrastim.

Keywords: G-CSF, granulocyte colony-stimulating factors, albumin, febrile neutropenia, pegfilgrastim

Introduction to balugrastim and management issues in chemotherapy-induced neutropenia

Neutropenia and febrile neutropenia (FN) represent two frequent complications of chemotherapy treatments.¹ Neutropenia can be defined as a reduction in the normal count of neutrophils, while FN represents a medical emergency in which the absolute neutrophils count (ANC) falls below the value of $0.5 \times 10^9/L$ and the body temperature is equal or superior to $38^\circ C$ for >1 hour.² Neutrophils act as early responders against pathogens. Indeed, during mucositis, alterations in the microbial flora and the concomitant disruption of the barrier function of mucosa can lead to sepsis due to the lack of these early responding innate immune cells.³

Having recognized that these conditions can lead to dose reductions, delay in chemotherapy and hospitalization due to the high risk of infections and sepsis, the role of granulocyte colony-stimulating factors (G-CSFs) is fundamental.¹ The natural human G-CSF is a glycoprotein produced by monocytes, fibroblasts, and endothelial cells.⁴⁻⁸ G-CSF is not species-specific. It has been shown to primarily affect neutrophil

progenitor proliferation within the bone marrow and to stimulate the release of mature neutrophils into the peripheral blood,^{9–15} and promote differentiation,^{8,15} and selected end-cell functional activation, for example, enhanced phagocytic activity.^{16,17}

Recombinant granulocyte colony-stimulating factors (rG-CSFs) act as endogenous G-CSF and are clinically indicated in order to preserve ANC in the case of chemotherapy regimens associated with a risk of FN $\geq 20\%$.¹⁸ Some of these regimens are used in breast cancer (eg, cisplatin, doxorubicin, and cyclophosphamide [PAC], docetaxel, doxorubicin, cyclophosphamide [TAC], and dose dense 5-fluorouracil, epirubicin, and cyclophosphamide [FEC]).¹⁹ Rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone, used in non-Hodgkin's lymphomas, is associated with a 20% risk of FN.²⁰ Docetaxel-carboplatin doublet, used in non-small-cell lung cancer, doxorubicin and ifosfamide for sarcomas and docetaxel, cisplatin, and 5-fluorouracil increase the risk of FN by $>20\%$ as well.¹⁹ rG-CSFs can be administered both for primary and secondary prophylaxis. In the first case, G-CSF is used to prevent FN at the beginning of a "high-risk" treatment, while the use in secondary prophylaxis happens after a first neutropenic event.¹⁹ rG-CSFs, such as filgrastim and lenograstim, have a short elimination half-life ($t_{1/2}$), thus requiring administration on a daily basis.² On the other hand, long-acting rG-CSFs, such as pegfilgrastim and lippegfilgrastim, are pegylated molecules of filgrastim.² Because of this stabilizing modification, they have a reduced renal clearance and are mainly metabolized by neutrophils and require a single administration per cycle.²

A new generation of long-acting rG-CSFs has been recently developed by combining G-CSF with a protein or peptide (fusion proteins) in order to increase molecular weight and lengthen $t_{1/2}$.²¹ Balugrastim is a long-acting rG-CSF produced in the yeast *Saccharomyces cerevisiae* obtained by means of a genetic fusion between recombinant human serum albumin and G-CSF.^{21,22} By combining the N-terminus of G-CSF to the C-terminus of albumin, balugrastim has a high plasmatic stability and can be administered in a once-per-cycle fixed dosage.²¹ So far, few studies have investigated balugrastim's safety and activity. This review aims at summarizing the available literature data on this novel molecule, focusing on pharmacology, pharmacokinetics, toxicity, and efficacy.

Pharmacology, mechanism of action, and pharmacokinetics of balugrastim

Balugrastim is a 759 amino acid single polypeptide chain with a molecular mass of ~ 85 kDa.²³ The biological active

compound of balugrastim is G-CSF, a naturally occurring cytokine that has several effects on hematopoietic progenitor cells.²⁴ The natural human G-CSF is a glycoprotein composed of a single polypeptide chain of 175 amino acids and is glycosylated at threonine 133.²⁵ By fusion of G-CSF to human serum albumin, the turnover rate of G-CSF is reduced and it has a longer duration of action.²⁶ The $t_{1/2}$ of balugrastim is ~ 19 days in humans, and the G-CSF fusion protein is highly soluble.²⁶ Balugrastim can be used as a long-lasting adjunct therapy to patients receiving myelosuppressive chemotherapy for reducing incidence and duration of chemotherapy-induced neutropenia and FN.²⁶

Balugrastim exhibits nonlinear pharmacokinetics.²⁷ Clearance of balugrastim is dependent on its concentration and neutrophil count. Normally, G-CSF is cleared by the kidney,²⁸ but the human serum albumin component of balugrastim not only acts as a carrier of G-CSF, it also extends its plasma half-life by minimizing renal clearance.²⁹ Therefore, the main elimination of balugrastim is via receptor-mediated neutrophil endocytosis.²⁹

Subcutaneous administration of 3.45 and 11.5 $\mu\text{g}/\text{kg}$ of balugrastim resulted in maximum serum concentrations of 4 and 49 ng/mL , respectively, within 2–8 hours.^{11,30} After intravenous administration, the volume of distribution averaged 150 mL/kg and the elimination half-life was ~ 3.5 hours.³¹

Intravenous (1–70 $\mu\text{g}/\text{kg}$ twice daily) as well as subcutaneous administration (1–3 $\mu\text{g}/\text{kg}$ once daily, or by continuous subcutaneous infusion 3–11 $\mu\text{g}/\text{kg}/\text{day}$) of G-CSF resulted in a dose-dependent increase in neutrophil counts over the dose range of 1–70 $\mu\text{g}/\text{kg}/\text{day}$.^{32–34} One study described the subcutaneous use of 450 $\mu\text{g}/\text{kg}$ balugrastim without severe side effects in breast cancer patients.³⁵

Clearance rates of balugrastim were ~ 0.5 – 0.7 $\text{mL}/\text{min}/\text{kg}$.²⁷ Single parenteral doses or daily intravenous doses over a 14-day period resulted in comparable half-lives.²⁷ The half-lives were similar for intravenous administration (231 minutes, following doses of 34.5 $\mu\text{g}/\text{kg}$) and for subcutaneous administration (210 minutes, following G-CSF dosages of 3.45 $\mu\text{g}/\text{kg}$).²⁷ Continuous 24-hour intravenous infusions of 20 $\mu\text{g}/\text{kg}$ over an 11–20-day period produced steady-state serum concentrations of balugrastim with no evidence of drug accumulation over the time period investigated.²⁷

Firstly, balugrastim safety was evaluated in a Phase I/IIa study.³⁵ The results of this study must be considered very carefully because of the very limited statistical power.³⁵ Pharmacokinetic analysis demonstrated that balugrastim serum concentrations were detectable across different dose

groups (50, 150, 300, and 450 $\mu\text{g}/\text{kg}$) in most patients (45 out of 50 patients) for at least 144 hours post dose.³⁵ Drug exposure was higher in cycle 1 compared to cycle 0, most likely because chemotherapy reduces the number of neutrophils, which play an important role in the clearance of balugrastim.³⁵ In cycle 1, balugrastim was detected longer than 144 hours in most patients (45/50 sampled) only in the 150, 300, and 450 $\mu\text{g}/\text{kg}$ dose groups, supporting once-per-cycle dosing.³⁵ The median $t_{1/2}$ of balugrastim in cycle 1 was ~36 hours for the 300 $\mu\text{g}/\text{kg}$ dose group and 30 hours for the 450 $\mu\text{g}/\text{kg}$ dose group.³⁵

In one multicenter Phase II study, safety and efficacy of balugrastim versus pegfilgrastim were further evaluated in breast cancer patients scheduled to receive myelosuppressive chemotherapy.¹ In this study, three doses (30, 40, and 50 mg) were considered.¹ Results from the compartmental modeling analysis indicated that balugrastim was slowly absorbed from the subcutaneous injection site, with the majority of the medication absorbed within 24–36 hours.¹ The mean absorption $t_{1/2}$ for balugrastim ranged in this study between 8.1 and 15.4 hours and tended to increase with escalations in dose.¹ For most patients, 80% of dose absorption occurred within the first 24–36 hours.¹ Mean coefficient of variation (C_{max}) values for patients treated with balugrastim 30, 40, or 50 mg were 408, 1,580, and 1,200 ng/L, respectively.¹ Median time to C_{max} (T_{max}) value was 12.0 hours for the balugrastim 30 mg group and 24.0 hours for both the higher dose group.¹

Recently, the results of two Phase III studies comparing the effects of balugrastim treatment versus pegfilgrastim in breast cancer patients receiving chemotherapy have been published.^{18,26} Pegfilgrastim is another recombinant G-CSF produced in *Escherichia coli*.³⁶ The $t_{1/2}$ of pegfilgrastim is extended by attachment of polyethylene glycol moiety. Such modification facilitates once-per-chemotherapy-cycle dosing.³⁶ In a double-blind randomized Phase III study, 40 mg of balugrastim and 6 mg of pegfilgrastim per chemotherapy cycle were used and compared in patients with breast cancer receiving chemotherapy.²³ These two

drugs showed comparable plasma $t_{1/2}$ in cycle 1 of 38.7 and 41.7 hours, respectively.²⁶ The other trial was a multicenter, randomized, open-label, Phase III noninferiority study.¹⁸ In this study, the efficacy and safety of once-per-cycle 40 mg or 50 mg of balugrastim and 6 mg of pegfilgrastim were compared again only in patients with breast cancer receiving chemotherapy with doxorubicin and docetaxel.¹⁸ In this patient cohort, the median terminal elimination $t_{1/2}$ was found to be 37.4 hours for 40 mg and 35.5 hours for 50 mg of balugrastim.¹⁸ The mean C_{max} (coefficient of variation [CV]%) for 40 and 50 mg of balugrastim was 875 (76.3%) and 975 (74.1%) ng/mL, respectively.^{1,18} The median T_{max} was ~24 hours for both treatment groups.¹⁸ Mean estimates for apparent total clearance were 1.34 and 1.18 L/hour for the 40 mg and 50 mg balugrastim groups, respectively.¹⁸ Mean estimates for the apparent volume of distribution were 80.1 (for 40 mg balugrastim group) and 69.2 (for 50 mg balugrastim group).¹⁸

Differences in pharmacology and pharmacokinetics between balugrastim and pegfilgrastim are listed in Table 1.

Efficacy studies

Balugrastim's efficacy has been mainly evaluated in Phase II and in two Phase III trials (Table 2).^{1,18,26} In all cases, only patients affected by breast cancer and receiving chemotherapy with doxorubicin 60 mg/m² and docetaxel 75 mg/m² every 21 days were enrolled. The choice of this systemic therapy was determined by the high risk of FN given by the combination therapy (33%).^{1,18,26} Gladkov et al^{1,18} enrolled 78 patients for the Phase II and 256 patients for Phase III trials. In the Phase II study, patients were treated with escalating doses of balugrastim (30, 40, or 50 mg) or the standard dose of pegfilgrastim (6 mg).¹ Similarly, in the open-label randomized Phase III study, patients were randomly assigned to 40 or 50 mg of balugrastim or 6 mg of pegfilgrastim (1:1:1 ratio).¹⁸ Conversely, Volovat et al²⁶ designed a two-phase study: first, a double-blind session (n=304) with a randomization to balugrastim 40 mg or pegfilgrastim 6 mg (1:1 ratio) and second, an open-blind single-arm phase in

which patients (n=77) further received balugrastim. In both studies, patients received a subcutaneous injection of either balugrastim or pegfilgrastim 24 hours after chemotherapy for up to four cycles.^{1,18,26}

The Phase II study was aimed at investigating different doses of balugrastim with a dose-escalation system in order to select two dosages for the Phase III trial.¹ Time to ANC recovery (days between ANC nadir and ANC >0.5×10⁹/L) for cycle 1 was similar for balugrastim 40 mg (2.6 days) and 50 mg (2.0 days), pegfilgrastim (2.4 days), and longer for balugrastim 30 mg (3.1 days).¹ Moreover, in the same cycle, patients treated with balugrastim 30 mg suffered from a 20% incidence of FN, which was a higher result than the rates for balugrastim 40 mg (9.5%) and 50 mg (10%), and pegfilgrastim (8%).¹ Based on these results, dosages of 40 and 50 mg were chosen for comparison with pegfilgrastim in the subsequent randomized Phase III.¹⁸

The two Phase III studies shared the same primary endpoint, which was the duration of severe neutropenia (DSN) in cycle 1, defined as the amount of days with ANC inferior to 0.5×10⁹/L.^{18,26} Gladkov et al¹⁸ reported a nonsignificant difference in DSN between the different treatment groups during cycle 1. Indeed, mean DSNs for balugrastim 40 and 50 mg, and pegfilgrastim were 1.0, 1.3, and 1.2 days (*P*=0.704), respectively.¹⁸ Similarly, in Volovat's study, mean DSN in the balugrastim 40 mg group was 1.1 days compared to 1.0 day obtained by using pegfilgrastim (95% two-sided confidence interval: -0.13 to 0.37 days).²⁶ In the end, balugrastim was assumed to be noninferior to pegfilgrastim.^{18,26} Moreover, while the mean DSN was shorter in cycles 2–4 than in cycle 1, no statistically significant difference in the mean DSN between balugrastim and pegfilgrastim was reported in these cycles as well.^{18,26}

As far as secondary efficacy endpoints are concerned, incidence of severe neutropenia (ANC <0.5×10⁹/L), incidence

of grade 3/4 neutropenia and its duration did not differ between balugrastim and pegfilgrastim, but decreased in rate and length from cycle 1 to cycles 2–4.^{18,26} Similarly, incidence of FN in cycle 1 was similar between pegfilgrastim and balugrastim in both studies: rates were 3.5% for balugrastim 40 mg, 6.0% for balugrastim 50 mg, and 2.3% in the pegfilgrastim group (*P*=0.398),¹⁸ versus 2% for balugrastim 40 mg and 4% for pegfilgrastim, *P*=0.446.²⁶

Values of mean ANC nadir and time to ANC nadir did not differ between pegfilgrastim and balugrastim treatments in both studies.^{18,26} Mean ANC nadir in cycle 1 was considerably lower than in subsequent cycles, with values of 0.7, 0.6, and 0.7×10⁹/L, respectively, for balugrastim 40 mg and 50 mg, and pegfilgrastim 6 mg, (*P*=0.423).¹⁸ Between cycles 2 and 4, mean ANC nadir reached the lowest point of 1.2 in cycle 3 with balugrastim 50 mg and a highest value of 1.6×10⁹/L in cycle 4 with balugrastim 40 mg.¹⁸ Similar values were reported by Volovat et al²⁶ regarding mean ANC nadir for cycle 1 (0.8 for both pegfilgrastim and balugrastim, *P*=0.763). Mean times to ANC nadir in cycle 1 were 6.4, 6.7, and 6.5 days, respectively, for balugrastim 40 mg and 50 mg, and pegfilgrastim (*P*=0.610), and slightly increased in further cycles, with a minimum of 6.8 days in cycle 1 with balugrastim 40 mg and a maximum of 7.8 days with pegfilgrastim, both in cycles 3 and 4.¹⁸ The randomized double-arm study registered a mean time to ANC nadir of 6.7 days for pegfilgrastim and of 6.8 days for balugrastim 40 mg (*P*=0.963).²⁶ Mean time to ANC recovery was significantly longer in the cohort treated with pegfilgrastim (2.6 days) compared to balugrastim 40 mg (2.0 days) and 50 mg (2.1 days), (*P*=0.005).¹⁸ The effect of balugrastim was lost in the following cycles, with no significant difference in mean time to ANC recovery between different treatments and cycles.¹⁸ Similarly, no significant difference in mean time to ANC recovery for cycle 1 was found in the other study

considered, with 2.1 days for pegfilgrastim and 2.0 days for balugrastim 40 mg ($P=0.259$).²⁶ Overall survival was not affected by the different treatments administered: 91.8% patients treated with balugrastim 40 mg were alive after a 1-year follow-up period compared to 84.5% for balugrastim 50 mg and 90.7% for pegfilgrastim.¹⁸

Taken together, the results of the efficacy analysis accounted for the noninferiority of balugrastim treatment over pegfilgrastim. Additionally, no differences in primary and secondary endpoints were found between the two different dosages of balugrastim that were investigated. Balugrastim showed a unique advantage over pegfilgrastim in shortening the mean time to ANC recovery.^{1,18,26}

Safety and tolerability

Balugrastim's safety and tolerability were mainly tested in a Phase I/IIa and Phase II study.^{1,35} In the first one, Avisar et al³⁵ administered escalating doses of balugrastim (50, 150, 300, and 450 g/kg) in cycle 0 (2 weeks before the beginning of chemotherapy) and in cycles 1 and 2. Thirteen patients were treated with doxorubicin 50 mg/m² and docetaxel 75 mg/m² every 21 days.³⁵ Since the balugrastim dose was escalated safely to the dosage of 450 g/kg without any limiting toxicity, the following Phase IIa trial included further 51 patients who were randomized to receive balugrastim 300 or 450 g/kg, or pegfilgrastim 6 mg (2:2:1 ratio).¹ The assessment of safety performed before the beginning of chemotherapy in the Phase I trial reported only six total adverse events (AEs) experienced by four patients.³⁵ For the balugrastim 300 g/kg cohort, two patients experienced grade 1 urinary tract infection and pyrexia, while two patients treated with balugrastim 450 g/kg suffered from grade 2 bone pain, grade 2 headache (twice), and grade 3 hypertension.³⁵ Most of the other AEs reported during cycles 1 and 2 of the Phase I study and Phase II were reasonably ascribable to chemotherapy and not to balugrastim.³⁵ Considering AEs were most likely related to balugrastim, bone pain occurred five times in four patients treated with balugrastim during Phase II therapy: one event was related to balugrastim 300 g/kg (grade 1), while the remaining four cases occurred during balugrastim 450 g/kg (grade 2).³⁵ Two cases of headache, one episode of hypertension, one case of pyrexia, and one injection site reaction, all grade 1, were registered with balugrastim 450 g/kg.³⁵ Moreover, a grade 2 rash occurred with the same dosage.³⁵

In the Phase II dose-finding study, bone pain occurred in two patients (grade 1 and grade 2) treated with balugrastim 50 mg (10%), while it was not observed for the other

dosages.¹ The same AE was found in two patients (grade 1) in the balugrastim cohort (7.7%).¹ Phase III studies confirmed these findings.^{18,26} Gladkov et al¹⁸ reported a higher amount of grade 4 AEs in the 50 mg balugrastim cohort (46.4%) than in the 40 mg group (34.1%) and pegfilgrastim (36%). Similarly, Volovat et al²⁶ showed a slightly higher amount of AEs after balugrastim treatment (19.6% for balugrastim, 18.7% in pegfilgrastim treatment in the double-blind phase). Bone pain and related symptoms amounted to 11.8% for balugrastim versus 10.7% for balugrastim in the double-blind phase and 18.2% in the balugrastim open-label phase.²⁶

Antibodies to balugrastim were reported in two out of 169 patients, while antibodies against the albumin domain of balugrastim were detected in six cases. However, the antibody response to balugrastim was low titer, transient, and had no neutralizing effect.¹⁸

Neither increases in spleen dimensions nor splenic ruptures have been reported during balugrastim administration,^{1,18,26,35} while a transient increase in spleen volume during G-CSF administration and rare cases of splenic rupture have been noticed both in healthy peripheral blood stem cell donors and cancer patients treated with G-CSF, granulocyte macrophage colony-stimulating factor, or pegylated G-CSF.^{3,37}

Similarly, we did not find any reported case of acute myeloid leukemia (AML) or myelodysplasia secondary to balugrastim use.^{1,18,26,35} Although rare events, the incidence of both AML and myelodysplasia was found to have increased significantly with G-CSF use in patients treated with chemotherapy.^{3,37} On the other hand, a nonsignificant correlation between G-CSF use and onset of secondary AML or myelodysplasia was reported in healthy peripheral blood stem cell donors.^{3,37}

In conclusion, balugrastim's administration was shown to be extremely safe. Bone pain was described as the most frequent AE directly connected to the subcutaneous injection. Its onset was more frequent with higher doses of balugrastim (eg, 50 mg and 450 g/kg).^{1,18,35}

Quality of life, patient satisfaction, and acceptability

From the first-in-human Phase I study to the recent Phase III randomized trials, balugrastim-related AEs did not require an interruption or discontinuation of treatment. No toxic death occurred in any of the considered studies.^{1,18,26,35} Bone pain was easily managed with common analgesics only.²⁶ Consent withdrawals were registered for five patients in the Phase II dose-finding study (two in the balugrastim 40 mg, three in the

balugrastim 50 mg cohort),¹ seven patients in the Phase III two-arms trial (five patients treated with balugrastim and two with pegfilgrastim)²⁶ and seven patients in the Phase III three-arms study (four patients treated with balugrastim 40 mg, two patients with balugrastim 50 mg, and one patient with pegfilgrastim).¹⁸ As a whole, treatment with balugrastim did not cause any severe AEs, and the quality of life was not compromised at all by its use.

Conclusion and place in therapy

Balugrastim is a new long-lasting rG-CSF created by linking G-CSF to recombinant human albumin in *S. cerevisiae*. Its $t_{1/2}$ of ~19 days makes it possible to be conveniently administered in a once-per-cycle subcutaneous injection. Phase I and II trials reported a good safety and tolerability profile in breast cancer patients treated with doxorubicin and docetaxel for breast cancer. Two Phase III studies compared balugrastim with pegfilgrastim demonstrating a comparable efficacy between the two treatments and the noninferiority of balugrastim with regard to the reduction in mean DSN during the first cycle of chemotherapy. The dose of 40 mg was associated with better efficacy parameters compared to the 50 mg dose, such as reduced mean DSN and minor incidence of FN during cycle 1. Moreover, balugrastim 40 mg registered fewer grade 4 AEs than 50 mg.

Secondary AMLs and myelodysplasias were not described after balugrastim use. This is probably due to the recent development of the drug and the short period of follow-up available. Indeed, leukemogenic events caused by G-CSF were reported after a median follow-up of at least 4 years. Therefore, long-term studies are necessary to adequately evaluate balugrastim safety.

Balugrastim represents a valid alternative to pegfilgrastim when a long-acting rG-CSF is required in clinical practice. Since all studies were performed in homogeneous populations of breast cancer patients treated with docetaxel and doxorubicin, further research involving different tumor types and chemotherapy combinations is definitely needed.

Therapeutics and Clinical Risk Management

Publish your work in this journal

Therapeutics and Clinical Risk Management is an international, peer-reviewed journal of clinical therapeutics and risk management, focusing on concise rapid reporting of clinical studies in all therapeutic areas, outcomes, safety, and programs for the effective, safe, and sustained use of medicines. This journal is indexed on PubMed Central, CAS,

Submit your manuscript here: <http://www.dovepress.com/therapeutics-and-clinical-risk-management-journal>

EMBASE, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
