Natural gradient descent is a principled method for adapting the parameters of a statistical model on-line using an underlying Riemannian parameter space to redefine the direction of steepest descent. The algorithm is examined via methods of statistical physics that accurately characterize both transient and asymptotic behavior. A solution of the learning dynamics is obtained for the case of multilayer neural network training in the limit of large input dimension. We find that natural gradient learning leads to optimal asymptotic performance and outperforms gradient descent in the transient, significantly shortening or even removing plateaus in the transient generalization performance that typically hamper gradient descent training. I. INTRODUCTION

One of the most popular forms of neural network training is on-line learning, in which training examples (input-output pairs) are presented sequentially and independently at each learning iteration (for an overview of on-line learning in neural networks, see [1]). Natural gradient descent (NGD) was recently proposed by Amari as a principled alternative to standard on-line gradient descent (GD) [2]. When learning the parameters of a statistical model, in our case a feedforward neural network, this algorithm has the desirable properties of asymptotic optimality, given a realizable learning problem and differentiable model, and invariance to reparametrizations of our model distribution. NGD is already established as a popular on-line algorithm for independent component analysis [2] and shows much promise for other statistical learning problems. Yang and Amari recently introduced an NGD algorithm for training a multilayer perceptron [3,4]. In this paper we provide an analysis of NGD for this problem using a statistical mechanics formalism. Our results indicate that NGD provides significantly improved performance over GD and we quantify these gains for both the transient and asymptotic stages of learning (preliminary results from this work have been reported in [5]).

The intuition behind NGD comes from viewing the parameter space of a statistical model as a Riemannian space. A natural measure of infinitesimal distance between probability distributions is given by the Kullback-Leibler divergence [6]. In this case the Fisher information matrix can be shown to be the appropriate Riemannian metric. The natural gradient direction is defined as the direction of steepest descent under this metric and is obtained by premultiplying the standard Euclidean error gradient with the inverse of the Fisher information matrix. Since this metric is derived from a divergence between neighboring model distributions, the algorithm is clearly independent of model parametrization. An additional beneficial feature of using this matrix premultiplier is that it remains positive-definite and therefore ensures convergence to a minimum of the generalization error (assuming the learning rate is annealed appropriately). This

is to be contrasted with other variable-metric algorithms that utilize the inverse averaged Hessian matrix. Premultiplying the error gradient with the inverse Hessian may make other fixed points stable, so that the algorithm could converge to maxima or saddle points on the mean error surface. Although such methods can be adapted to ensure a positive-definite matrix premultiplier, such adaptations are rather *ad hoc* in nature and are not theoretically well motivated outside of the asymptotic regime.

Variable-metric methods are often difficult to implement as on-line algorithms since they require the averaging and inversion of a large matrix. In the case of NGD we require knowledge of the input distribution in order to calculate the Fisher information matrix. Yang and Amari discuss methods for preprocessing training examples in order to obtain a whitened Gaussian process for the inputs [4]. If this is possible then, when the input dimension N is large compared to the number of hidden units K , inversion of the Fisher information for two-layer feedforward networks requires only $O(N^2)$ operations, providing an efficient and practical algorithm in many cases. Such a simplification is not possible for Hessian based methods, because the Hessian involves an average over input-output pairs. In general it will not be possible to apply this preprocessing because the input distribution may be far from Gaussian and difficult to estimate. In this case other on-line methods will be required in order to approximate the NGD algorithm. We have recently proposed a method based on a matrix momentum algorithm [7] that allows efficient on-line inversion and averaging of the Fisher information matrix. This algorithm can be shown to approximate NGD closely and also provides optimal asymptotic performance, although at the cost of introducing an extra variable parameter [8].

Here, we will consider the idealized situation in which we have the Fisher information matrix at our disposal. We solve the averaged dynamics of NGD using a statistical mechanics framework which becomes exact as $N \rightarrow \infty$ for finite K (see, for example, [9–16]). This allows us to compare performance with standard GD in both the transient and asymptotic phases of learning, so that we can quantify the advantage that

NGD can be expected to provide. Numerical results for a small network provide evidence of improved performance. In order to obtain more generic results we introduce a site-symmetric ansatz for the special case of a realizable learning scenario, so that we can efficiently explore a broad range of task complexity and nonlinearity. We show that trapping time in an unstable fixed point that dominates the training time, the symmetric phase, is significantly reduced by using NGD and exhibits a slower power law increase as task complexity grows. We also find that asymptotic performance is greatly improved, with the generalization performance of NGD equalling the known universal asymptotics for batch learning [17].

II. NATURAL GRADIENT DESCENT

We consider a probabilistic model $p_{\mathbf{J}}(\zeta|\xi)$ for the distribution of a scalar output ζ given a vector of inputs $\xi \in \mathbb{R}^N$ which is parametrized by $\mathbf{J} \in \mathbb{R}^{KN}$. The Kullback-Leibler divergence provides an appropriate measure for the distance between distributions [6] and for two nearby points in parameter space we find

$$\begin{aligned} \text{KL}(p_{\mathbf{J}}(\zeta, \xi) || p_{\mathbf{J}+\text{d}\mathbf{J}}(\zeta, \xi)) \\ = \int d\xi p(\xi) \int d\zeta p_{\mathbf{J}}(\zeta|\xi) \ln \left(\frac{p_{\mathbf{J}}(\zeta|\xi)}{p_{\mathbf{J}+\text{d}\mathbf{J}}(\zeta|\xi)} \right) \\ \simeq \text{d}\mathbf{J}^T \mathbf{G} \text{d}\mathbf{J}, \end{aligned} \quad (1)$$

where \mathbf{G} is the Fisher information matrix,

$$\begin{aligned} \mathbf{G}(\mathbf{J}) = \int d\xi p(\xi) \int d\zeta p_{\mathbf{J}}(\zeta|\xi) \\ \times [\nabla_{\mathbf{J}} \ln p_{\mathbf{J}}(\zeta|\xi)] [\nabla_{\mathbf{J}} \ln p_{\mathbf{J}}(\zeta|\xi)]^T. \end{aligned} \quad (2)$$

This matrix provides a Riemannian metric within the space of model parameters. We choose the training error $\epsilon_{\mathbf{J}}(\zeta, \xi) \propto -\ln p_{\mathbf{J}}(\zeta|\xi)$. The direction of steepest descent within this Riemannian space in terms of expected error is obtained by premultiplying the mean Euclidean error gradient with \mathbf{G}^{-1} [2].

In an on-line learning scheme we draw inputs sequentially $\xi^\mu: \mu=1, 2, \dots$ from some distribution $p(\xi)$ each labeled according to some stochastic rule $p_{\mathbf{B}}(\zeta^\mu|\xi^\mu)$. The NGD algorithm is defined by a corresponding sequence of weight updates,

$$\mathbf{J}^{\mu+1} = \mathbf{J}^\mu + \frac{\eta}{N} \mathbf{G}^{-1} \nabla_{\mathbf{J}} \ln p_{\mathbf{J}}(\zeta^\mu|\xi^\mu), \quad (3)$$

where the learning rate is scaled by the input dimension for convenience. This algorithm therefore utilizes an unbiased estimate of the steepest descent direction in our Riemannian parameter space. If the rule can be realized by the model and exemplars are corrupted by output noise then annealing the learning rate as $\eta=1/\alpha$ at late times (where $\alpha \propto \mu/N$) results in optimal asymptotic performance in terms of the quadratic estimation error, saturating the Cramer-Rao lower bound and equalling in performance even the best batch algorithms [2].

Consider the deterministic mapping $\phi_{\mathbf{J}}(\xi) = \sum_{i=1}^K g(\mathbf{J}_i^T \xi)$, which defines a soft committee machine (we call this the student network), where $g(x)$ is some sigmoid activation function for the hidden units, $\mathbf{J} \equiv \{\mathbf{J}_i\}_{1 \leq i \leq K}$ is the set of input to hidden weights and the hidden to output weights are set to one. We choose the following Gaussian noise model:

$$p_{\mathbf{J}}(\zeta|\xi) = \frac{1}{\sqrt{2\pi\sigma_m^2}} \exp \left(\frac{-[\zeta - \phi_{\mathbf{J}}(\xi)]^2}{2\sigma_m^2} \right). \quad (4)$$

The Fisher information matrix for this model distribution is given by $\mathbf{G} \equiv \mathbf{A}/\sigma_m^2$ with \mathbf{A} in block form,

$$\mathbf{A}_{ij} = \int d\xi p(\xi) g'(\mathbf{J}_i^T \xi) g'(\mathbf{J}_j^T \xi) \xi \xi^T. \quad (5)$$

A particularly convenient choice for activation function is $g(x) \equiv \text{erf}(x/\sqrt{2})$ as this allows the average over inputs to be carried out analytically for an isotropic Gaussian input distribution $p(\xi) = \mathcal{N}(\mathbf{0}, \mathbf{I})$,

$$\begin{aligned} \mathbf{A}_{ij} = \frac{2}{\pi \sqrt{\Delta_{ij}}} \left(\mathbf{I} - \frac{1}{\Delta_{ij}} [(1 + Q_{jj}) \mathbf{J}_i \mathbf{J}_i^T \right. \\ \left. + (1 + Q_{ii}) \mathbf{J}_j \mathbf{J}_j^T - Q_{ij} (\mathbf{J}_i \mathbf{J}_j^T + \mathbf{J}_j \mathbf{J}_i^T)] \right), \end{aligned} \quad (6)$$

where $\Delta_{ij} = (1 + Q_{ii})(1 + Q_{jj}) - Q_{ij}^2$ and $Q_{ij} \equiv \mathbf{J}_i^T \mathbf{J}_j$.

III. STATISTICAL MECHANICS FRAMEWORK

In order to analyze NGD beyond the asymptotic regime we use a statistical mechanics description of the learning process which is exact in the limit of large input dimension N and provides an accurate model of mean behavior for realistic values of N [9,10]. We consider the case where outputs are generated by a teacher network corrupted by Gaussian noise,

$$p_{\mathbf{B}}(\zeta^\mu|\xi^\mu) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp \left(\frac{-[\zeta^\mu - \phi_{\mathbf{B}}(\xi^\mu)]^2}{2\sigma^2} \right), \quad (7)$$

where $\phi_{\mathbf{B}}(\xi^\mu) = \sum_{n=1}^M g(\mathbf{B}_n^T \xi^\mu)$. Due to the flexibility of this mapping [18] we can represent a variety of learning scenarios within this framework. The weight update at each iteration of NGD is then given by

$$\mathbf{J}_i^{\mu+1} = \mathbf{J}_i^\mu + \frac{\eta}{N} \sum_{j=1}^K \delta_j^\mu \mathbf{A}_{ij}^{-1} \xi^\mu, \quad (8)$$

where $\delta_i^\mu \equiv g'(\mathbf{J}_i^T \xi^\mu) [\phi_{\mathbf{B}}(\xi^\mu) - \phi_{\mathbf{J}}(\xi^\mu) + \rho^\mu]$ and ρ^μ is zero-mean Gaussian noise of variance σ^2 . Notice that knowledge of the noise variance is not required to execute this algorithm since the contributions from the Fisher information matrix and log-likelihood cancel [recall Eq. (3)]. The model noise variance is therefore not included as a variable parameter and the algorithm is well defined even in the deterministic case where $\sigma_m^2 \rightarrow 0$.

The Fisher information matrix can be inverted using the partitioning method described in [4] (see Appendix A); each

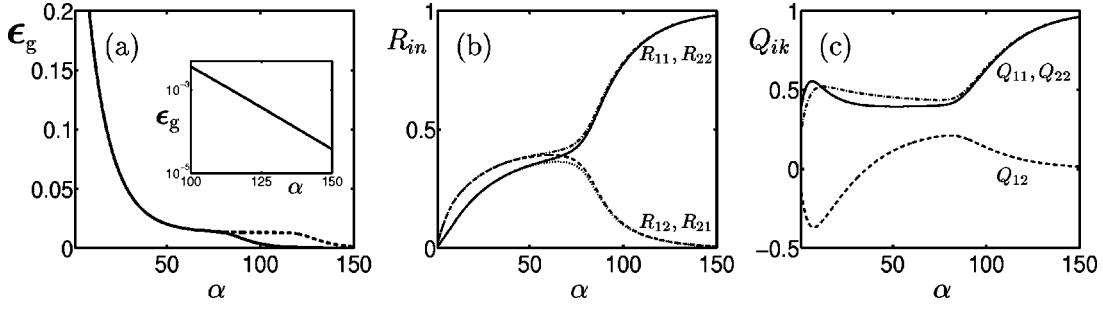

FIG. 1. Numerical integration of the NGD equations of motion. A two-node soft committee machine learns from examples generated by a two-node isotropic teacher ($K=M=2$, $T_{nm}=\delta_{nm}$) in the absence of noise. The learning rate is fixed at $\eta=0.05$ and initial conditions are $R_{in}, Q_{i \neq k} \in U[0, 10^{-3}]$ and $Q_{ii} \in U[0, 0.5]$. The generalization error is shown by the solid line in (a) with the exponential asymptotic decay shown on a log scale in the inset (the dashed line shows the effect of reducing the initial conditions by a factor of 10^{-3}). The student-teacher and student-student overlaps are shown in (b) and (c), respectively.

block is some additive combination of the identity matrix and outer products of the student weight vectors,

$$\mathbf{A}_{ij}^{-1} = \theta_{ij} \mathbf{I} + \sum_{kl} \Theta_{kl}^{ij} \mathbf{J}_k \mathbf{J}_l^T. \quad (9)$$

where θ_{ij} are scalars while Θ^{ij} are K dimensional square matrices. Using the methods described in [9] it is then straightforward to derive equations of motion for a set of order parameters $\mathbf{J}_i^T \mathbf{J}_j = Q_{ij}$, $\mathbf{J}_i^T \mathbf{B}_n = R_{in}$ and $\mathbf{B}_n^T \mathbf{B}_m = T_{nm}$, measuring the various overlaps between student and teacher vectors. These order parameters are necessary and sufficient to determine the generalization error $\epsilon_g = \langle \frac{1}{2} (\phi_{\mathbf{J}}(\xi) - \phi_{\mathbf{B}}(\xi))^2 \rangle_{\xi}$, which we defined to be the expected error in the absence of noise [9]. The equations of motion are in the form of coupled first order differential equations for the order parameters with respect to the normalized number of examples,

$$\begin{aligned} \frac{dR_{in}}{d\alpha} &= \eta f_{in}(R, Q, T), \\ \frac{dQ_{ik}}{d\alpha} &= \eta g_{ik}(R, Q, T) + \eta^2 h_{ik}(R, Q, T, \sigma^2), \end{aligned} \quad (10)$$

where $R=[R_{in}]$, $Q=[Q_{ik}]$ and $T=[T_{nm}]$. The explicit expressions are given in Appendix B. These equations can be integrated numerically in order to determine the evolution of the generalization error.

IV. NUMERICAL RESULTS

In Fig. 1 we show an example of the NGD dynamics for a realizable and noiseless learning scenario ($K=M=2$, $T_{nm}=\delta_{nm}$). Figure 1(a) shows the evolution of the generalization error while Figs. 1(b) and 1(c) show the student-teacher and student-student overlaps respectively (the indices have been re-ordered *a posteriori*). We have used initial conditions corresponding to an input dimension of about $N \approx 10^6$, although we expect the dynamical equations to describe mean behavior accurately for much smaller systems as was found to be the case for GD [10]. The dashed line in Fig. 1(a) shows the effect of reducing the initial conditions for each R_{in} and $Q_{i \neq k}$ by a factor of 10^{-3} , which corresponds to an input dimension of about $N \approx 10^{12}$. The symmetric phase

seems to grow logarithmically as N increases, as was also found to be the case for GD [12].

As is the case for GD [9] the dynamics for this example can be characterized by two major phases of learning, the symmetric phase and asymptotic convergence. Following a short initial transient the order parameters are trapped in a subspace characterized by a lack of differentiation between the activities of different teacher nodes. After an initial reduction, the generalization error remains at a constant non-zero value and the student-teacher overlaps are virtually indistinguishable. This symmetric phase is an unstable fixed point of the dynamics and eventually small perturbations due to the random initial conditions lead to escape and convergence towards zero generalization error. If the teacher is deterministic, as in this example, then the generalization error converges to zero exponentially unless the learning rate is chosen too large [see the inset to Fig. 1(a)]. If the teacher's output is corrupted by noise then the learning rate must be annealed in order for the generalization error to decay asymptotically (we will consider this regime in more detail in Sec. V B).

The dynamics differs from the GD result in that the symmetric phase is typically less pronounced, although the dashed line in Fig. 1(a) shows how the symmetric phase increases in duration as N increases (because of a reduced asymmetry in the initial conditions). The dynamics for GD and NGD are qualitatively different for small learning rates, where fluctuations in the gradient are completely suppressed and the η^2 terms in Eq. (10) can be neglected. In this limit the symmetric phase disappears completely for NGD, while it still dominates the learning time for GD. The symmetric phase is a fluctuation driven phenomena for NGD, rather than a perturbation around the deterministic result. As described in the next section, this makes analysis of the symmetric phase more difficult than for GD since a small learning rate expansion is no longer meaningful.

A quantitative comparison of GD and NGD is difficult because both algorithms have a free parameter, the learning rate η , which can be chosen arbitrarily and which will be critical to performance. In order to make a principled comparison we choose to compare the algorithms when their learning rates are chosen to be optimal. This can be achieved by using a variational method that allows us to determine the globally optimal time-dependent learning rate for each algorithm [14]. The resulting learning rate optimizes the total

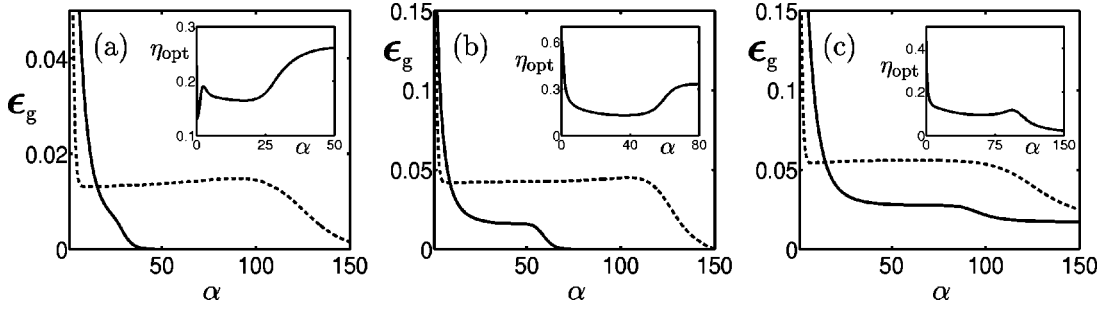

FIG. 2. The optimal performance of a two-node student ($K=2$) for NGD (solid line) and GD (dashed line) for (a) overrealizable: $M=1$, (b) realizable: $M=2$ and (c) unrealizable: $M=3$ learning scenarios. The optimal learning rate schedule for NGD is shown by the inset to each figure. The teacher is isotropic ($T_{nm} = \delta_{nm}$), noise free and initial conditions are as in Fig. 1.

change in generalization error over a fixed time-window and is found by extremization of the following functional (see [14] for details and results for optimized GD):

$$\Delta \epsilon_g[\eta(\alpha)] = \int_{\alpha_0}^{\alpha_1} \frac{d\epsilon_g}{d\alpha} d\alpha = \int_{\alpha_0}^{\alpha_1} \mathcal{L}[\eta(\alpha), \alpha] d\alpha. \quad (11)$$

Numerical results suggest that the optimal learning rates determined here are close to the critical learning rate within the symmetric phase for both methods, above which the student weight vector norms increase without bound.

In Fig. 2 we compare the performance of optimized GD and optimized NGD for a two-node student learning from a noiseless, isotropic teacher starting from the same initial conditions ($K=2$, $T_{nm} = \delta_{nm}$). Figures 2(a), 2(b), and 2(c) show results for teachers with $M=1$, $M=2$, and $M=3$ hidden nodes respectively. In each case the optimal learning rate schedule for NGD is shown by the inset. It should be noted that although there is a significant temporal variation in the optimized η , very similar performance would be achieved by choosing η to be fixed at its average value. We see that NGD significantly outperforms GD in each example. For the overrealizable example shown in Fig. 2(a) the difference is most significant, with NGD displaying no obvious symmetric plateau. Performance of the NGD algorithm seems to reflect the difficulty inherent in the task, while GD displays very similar performance in each case. It is interesting to compare our results with those found using a locally optimal rule derived by variational arguments [15]. The variational approach requires rather detailed information about the teacher's structure and would be difficult to approximate with a practical algorithm. However, we find rather similar performance with NGD, especially for the $K=M=2$ example shown both here and in [15]. The performance bottleneck for GD is due to an inherent symmetry in the student parametrization, while for NGD the task complexity seems to be more important. Also notice that the generalization error is significantly lower during the symmetric plateau for NGD in each case, which is due to reduced weight vector norms (this is also true for the locally optimal algorithm). It is the growth of these norms which limits increases in the learning rate for GD and it appears that NGD is much more effective in controlling this effect. Another interesting difference between the NGD and GD dynamics is in the short transient prior to the symmetric phase. The NGD dynamics seems to converge much slower to the symmetric fixed point, as shown in Fig. 2, reflecting the fact that the strong eigenvalues, related to eigenvectors

that lead the dynamics to the symmetric fixed point, are effectively reweighed and suppressed by the NGD rule.

V. GENERIC RESULTS FOR A SYMMETRIC SYSTEM

Although our equations of motion are sufficient to describe learning for arbitrary system size, the number of order parameters is $\frac{1}{2}K(K+1) + KM$ so that the numerical integration soon becomes rather cumbersome as K and M grow and analysis becomes difficult. To obtain generic results in terms of system size we therefore exploit symmetries which appear in the dynamics for isotropic tasks and structurally matched student and teacher ($K=M$ and $T=T_{nm}$). This site-symmetric ansatz is only rigorously justified for the special case of symmetric initial conditions and further investigations are required to determine the validity of this approximation in general for large values of K (fixed points other than those considered here have been reported for GD [12] and it is unclear whether or not their basins of attraction are negligible). Simulations of the GD dynamics for K up to 10, with random initial conditions, show good correspondence with the symmetric system. In this case we define a four dimensional system via $Q_{ij} = Q\delta_{ij} + C(1 - \delta_{ij})$ and $R_{in} = R\delta_{in} + S(1 - \delta_{in})$ which can be used to study the dynamics for arbitrary K and T (here, δ_{ij} denotes the Kronecker δ). In Appendix A we show how the Fisher information matrix can be inverted for the reduced dimensionality system and the resulting equations of motion are given in Appendix B 1.

Analytical study of the symmetric phase for GD is only feasible for small learning rates, since in this case the symmetric fixed point is easily determined and a linear expansion around this fixed point is possible [9,13]. Such an analysis is not feasible for NGD because the dynamics never approaches this fixed point (the Fisher information matrix becomes singular when $Q=C$). In any case, a small η analysis will be of limited value since it is the fluctuation driven terms in the dynamics [terms proportional to η^2 in Eq. (10)] that set the learning time scale and determine the optimal and maximal learning rate during the symmetric phase. In order to study the performance of both methods for larger learning rates we will therefore apply the optimal learning rate framework described in the preceding section [14].

The impact of output noise on the symmetric phase dynamics is not considered explicitly here. For low noise levels there is no noticeable effect on the length of the symmetric phase, or on the order parameters and generalization error within this phase. For larger noise levels the symmetric

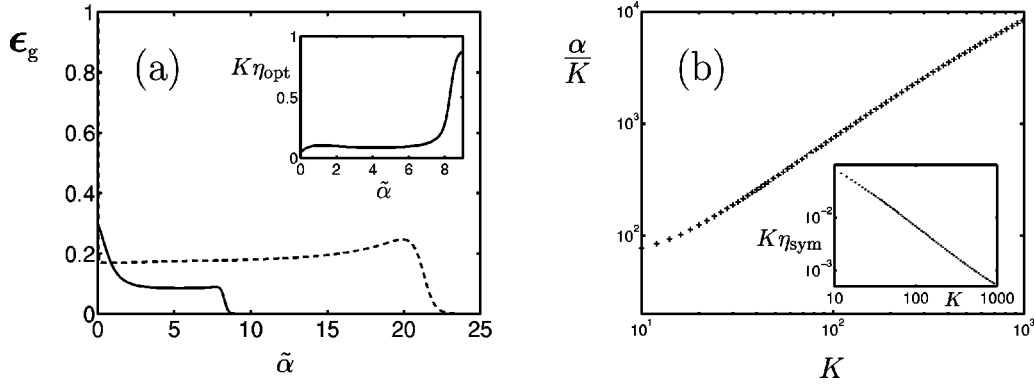

FIG. 3. In (a) the generalization error is shown for optimal NGD (solid line) and optimal gradient descent (dashed line) for $K = 10$ in the site-symmetric system (we define $\tilde{\alpha} = 10^{-2}\alpha$). The inset shows the optimal learning rate for NGD. In (b) the time required for optimal NGD to reach a generalization error of $10^{-4}K$ is shown as a function of K on a log-log scale. The inset shows the optimal learning rate within the symmetric phase. In both (a) and (b) we used $T = 1$, zero noise and initial conditions $R = 10^{-3}$, $Q = U[0, 0.5]$ and $S = C = 0$. A brief stage of GD is used before NGD is started.

phase increases in length and the student norms increase, resulting in a larger generalization error. We expect that these are secondary effects and that most essential features of this phase are captured by the noiseless dynamics. This is not true for later stages of learning, where the inclusion of noise completely alters qualitative features of the dynamics. These asymptotic effects are considered in Sec. V B below.

A. Globally optimal performance

The optimal learning rate is determined as describe before Eq. (11) in Sec. IV. In the following examples we use a brief initial learning phase with GD (until $\alpha = 1$) as this results in faster entry into the symmetric phase and also leads to quicker convergence of the learning rate optimization. The effect on learning time will be negligible as K becomes very large, but this procedure might be used to improve performance in practice for realistically sized networks.

Figure 3 summarizes our results for transient learning in the absence of noise. In Fig. 3(a) we compare optimal performance for $K = 10$ and $T = 1$, which indicates a significant shortening of the symmetric phase for NGD (the inset shows the optimal learning rate for NGD). Figure 3(b) shows the time required for NGD to reach a generalization error of $10^{-4}K$ as a function of K (for $T = 1$). The learning time is dominated by the symmetric phase, so that these results provide a scaling law for the length of the symmetric phase in terms of task complexity. We find that the escape time for NGD scales as K^2 , while the inset shows that the learning rate within the symmetric phase approaches a K^{-2} decay. Scaling laws for GD were determined in [13] (also using a site-symmetric ansatz), showing a $K^{8/3}$ law for escape time and a learning rate scaling of $K^{-5/3}$ within the symmetric phase. The escape time for the adaptive learning rule studied in [13] scales as $K^{5/2}$, which is also worse than NGD.

B. Asymptotic convergence with noise

After the symmetric phase, the order parameters begin convergence towards their asymptotic values ($R_\infty = Q_\infty = T$, $S_\infty = C_\infty = 0$) and for the realizable scenario considered here the generalization error converges towards zero (recall that we have defined the generalization error to be the expected

error in the absence of noise). In the absence of output noise this convergence is exponential for a fixed learning rate so long as we do not choose the learning rate too high. However, in the presence of output noise the learning rate must be annealed in order to achieve zero generalization error asymptotically. It is known that NGD is asymptotically optimal, in terms of the covariances of the student-teacher weight deviations (the quadratic estimation error), with $\eta = 1/\alpha$, saturating the Cramer-Rao bound and equalling in performance even the best batch methods [2]. However, the quadratic estimation error has no direct interpretation in terms of generalization ability. In Fig. 4 we show results for optimized NGD dynamics with $K = 5$ and $T = 1$. Figure 4(a) shows the generalization error and Fig. 4(b) shows the corresponding optimal learning rate schedules for three noise levels ($\sigma^2 = 0.1$, $\sigma^2 = 0.01$ and $\sigma^2 = 0.001$). The graphs are on log-log scales and show that the optimized learning rates indeed converge to a $1/\alpha$ decay after leaving the symmetric phase. The generalization error decays at the same rate, but with a prefactor that depends on the noise level.

In order to determine the asymptotic generalization error decay analytically we apply recent results for the annealing dynamics of GD [16]. This allows a comparison between the asymptotic generalization error for NGD and the result for GD. In Appendix B 2 we solve the asymptotic dynamics for annealed learning. As expected, the optimal annealing schedule for NGD is found by setting $\eta = 1/\alpha$ at late times. By contrast, although the optimal learning rate for GD is also inversely proportional to α , the optimal prefactor depends on K and T in a nontrivial manner [16]. For both optimized GD and NGD the generalization error decays according to an inverse power law:

$$\epsilon_g \sim \frac{\epsilon_0 \sigma^2}{\alpha} \quad \text{as} \quad \alpha \rightarrow \infty. \quad (12)$$

The exact result for NGD takes a very simple form $\epsilon_0 = \frac{1}{2}K$ independent of the value of T . This equals the universal asymptotics for optimal maximum likelihood and Bayes estimators, which depend only on the learning machine's number of degrees of freedom [17]. NGD is therefore

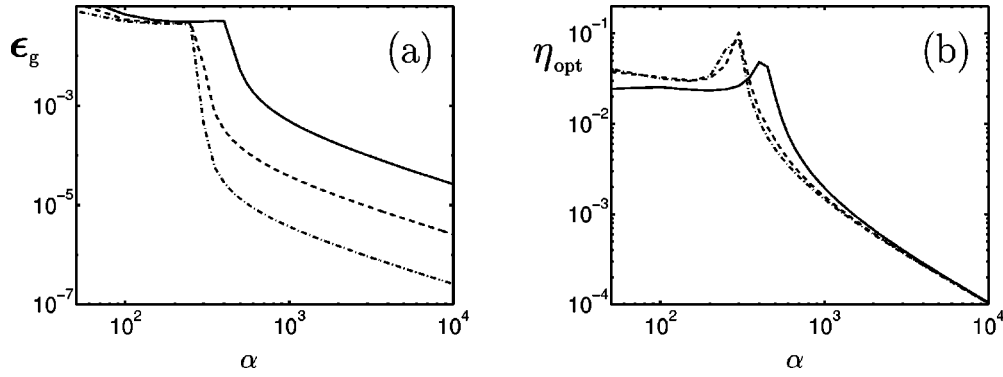

FIG. 4. Optimal NGD with teacher corrupted by Gaussian noise for $K=5$ and $T=1$ in the site-symmetric system, shown on a log-log scale. The generalization error and optimal time-dependent learning rates are shown in (a) and (b) respectively, with $\sigma^2=0.1$ (solid line), $\sigma^2=0.01$ (dashed line), and $\sigma^2=0.001$ (dot-dashed line).

asymptotically optimal in terms of both generalization error and quadratic estimation error.

In Fig. 5 we compare the prefactor of the generalization error decay for NGD and optimal GD. Figure 5(a) shows the result for $T=1$ as a function of K , indicating an approximately linear scaling law for GD (The result above shows that the NGD scaling is linear in K .) In Fig. 5(b) we compare the decay prefactors for each method as a function of T , showing how the difference diverges as T is reduced (the GD results are for large K). This can be explained by examining the asymptotic expression for the Fisher information matrix, shown in Eq. (A6). For large T the diagonals of this matrix are $O(1/\sqrt{T})$ and equal (for large N) while all other terms are at most $O(1/T)$, so that the Fisher information is effectively proportional to the identity matrix in this limit and NGD is asymptotically equivalent to GD. However, for small T the diagonals are $O(T^2)$ while the off-diagonals remain finite, so that the Fisher information is dominated by off-diagonals in this limit.

VI. CONCLUSION

We have used a statistical mechanics formalism to solve and analyze the dynamics of NGD for learning in a two-layer feedforward neural network. In order to quantify the comparative performance of NGD and GD we compared the optimized performance of each algorithm by determining the

optimal learning rate in each case. We found that NGD provided significant gains in performance over GD in every case examined, both in the transient and asymptotic stages of learning. A site-symmetric ansatz was applied in order to simplify the dynamical equations for a realizable and isotropic task. This allowed the dynamics of large networks to be integrated efficiently so that we could determine generic behavior for large networks. We found that the learning time scaled as K^2 where K is the number of hidden nodes, compared to a scaling of $K^{8/3}$ for GD [13]. Asymptotically NGD is known to provide optimal performance with $\eta=1/\alpha$ in terms of the quadratic estimation error. An asymptotic solution to the annealed learning rate dynamics showed this schedule to also be optimal in terms of generalization error, with the error decay saturating the universal asymptotics for optimal maximum likelihood and Bayes estimators [17]. We compared this result with the optimized schedule for GD and plotted the relative performance for various values of task nonlinearity T . The difference in performance was found to be largest for small values of T . However, in the case of NGD the optimal annealing schedule at late times is known while for GD it is a complex function of K and T that will be difficult to estimate in general.

One possible drawback for NGD is the rather complex transient behavior of the optimal learning rate. For example, in the realizable isotropic case the optimal learning rate scales as K^{-2} in the symmetric phase and K^{-1} asymptoti-

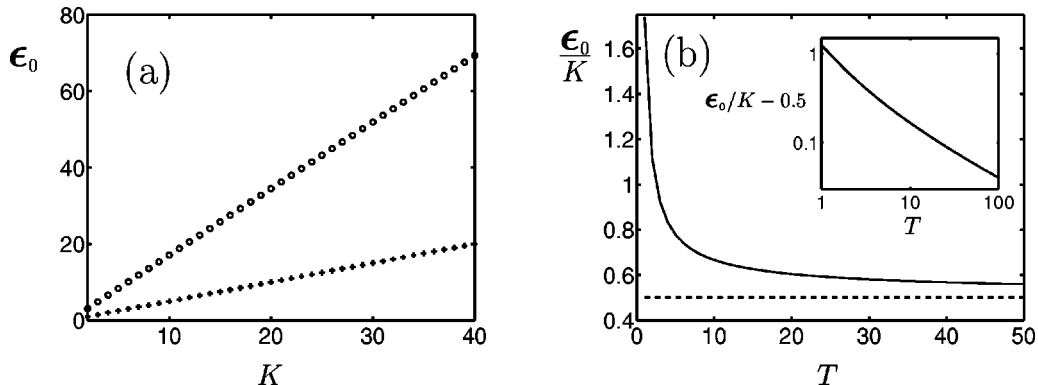

FIG. 5. Prefactor for the asymptotic decay of the generalization error: (a) shows the prefactor for $T=1$ as a function of K for optimal GD (circles) and NGD (crosses) while (b) shows how the prefactor for optimal GD (large K) decays towards $K/2$ as T increases, which is the prefactor for NGD. The inset to (b) shows the GD result on a log-log scale.

cally in the absence of noise. It is also unclear where learning rate annealing should begin in the presence of output noise. Asymptotically the optimal annealing schedule is known, so the situation is better than for GD, but the problem of setting a good learning rate in the transient remains. In practical applications there will also be an increased cost required in estimating and inverting the Fisher information matrix [4]. Here, we have only considered the idealized situation in which the Fisher information matrix is exactly known. In [8] we adapt a matrix momentum algorithm due to Orr and Leen [7] in order to obtain efficient averaging and inversion of the Fisher information matrix on line. This algorithm is shown to provide a good approximation to NGD, although this is at the cost of including an extra parameter.

We would like to thank Shun-ichi Amari for useful discussions. This work was supported by EPSRC Grant No. GR/L19232.

APPENDIX A: INVERTING THE FISHER INFORMATION MATRIX

In general the Fisher information matrix should be inverted using the block inversion method described in [4]. The parameters in Eq. (9) are then complicated functions of Q which must be determined iteratively (see [19] for a similar method applied to the Hessian matrix for $M=K=2$). Below we consider the simpler situation of a site-symmetric system, in which case the inversion can be carried out in closed form for arbitrary K . Asymptotically the result is shown to be further simplified.

1. Site-symmetric system

Exploiting symmetries in the dynamics of realizable isotropic learning ($K=M$ and $T_{nm}=T\delta_{nm}$) we consider a reduced dimensionality system with $Q_{ij}=Q\delta_{ij}+C(1-\delta_{ij})$. We can then write block (i,j) of the Fisher information matrix as [see Eq. (6)],

$$\mathbf{A}_{ij}=(a\delta_{ij}+b)\mathbf{I}+(c\delta_{ij}+d)\mathbf{J}_i\mathbf{J}_i^T+d\mathbf{J}_j\mathbf{J}_j^T+e(\mathbf{J}_i\mathbf{J}_j^T+\mathbf{J}_j\mathbf{J}_i^T), \quad (\text{A1})$$

where we have defined

$$b=\frac{2}{\pi\sqrt{[(1+Q)^2-C^2]}}, \quad a=\frac{2}{\pi\sqrt{1+2Q}}-b, \\ c=\frac{4(1+Q-C)}{\pi((1+Q)^2-C^2)^{3/2}}-\frac{4}{\pi(1+2Q)^{3/2}}, \\ d=\frac{-2(1+Q)}{\pi((1+Q)^2-C^2)^{3/2}}, \quad e=\frac{2C}{\pi((1+Q)^2-C^2)^{3/2}}.$$

Block (i,j) in the inverse of \mathbf{A} is then given by

$$\mathbf{A}_{ij}^{-1}=\left(\frac{1}{a}\delta_{ij}-\frac{b}{a(a+bK)}\right)\mathbf{I}+\sum_{k=1}^K\sum_{l=1}^K\Gamma_{ij}^{kl}\mathbf{J}_k\mathbf{J}_l^T, \quad (\text{A2})$$

and symmetries suggest the following general form for Γ :

$$\Gamma_{ij}^{kl}=\gamma_1\delta_{ij}\delta_{ik}\delta_{il}+\gamma_2(\delta_{ik}\delta_{il}+\delta_{jk}\delta_{jl})+\gamma_3(\delta_{ik}\delta_{jk}+\delta_{il}\delta_{ij}) \\ +\gamma_4\delta_{kl}\delta_{ij}+\gamma_5\delta_{ik}\delta_{jl}+\gamma_6\delta_{jk}\delta_{il}+\gamma_7(\delta_{jl}+\delta_{ik}) \\ +\gamma_8(\delta_{jk}+\delta_{il})+\gamma_9\delta_{kl}+\gamma_{10}\delta_{ij}+\gamma_{11}. \quad (\text{A3})$$

We therefore have to set 11 free parameters in order to fully specify Γ . This is achieved by substituting Eqs. (A1) and (A2) into the definition of the inverse,

$$\sum_{k=1}^K\mathbf{A}_{ik}\mathbf{A}_{kj}^{-1}=\delta_{ij}\mathbf{I} \quad \forall i,j. \quad (\text{A4})$$

Equating like terms leads to a set of 15 equations and we can choose any linearly independent subset of 11 equations in order to determine γ . For one particular choice we find

$$\gamma=\mathbf{M}^{-1}\beta, \quad (\text{A5})$$

where the nonzero terms in $\mathbf{M}_{11\times 11}=[m_{i,j}]$ and $\beta_{1\times 11}=[\beta_i]$ are defined below:

$$m_{1,1}=m_{2,2}=m_{4,3}=(Q-C)(d+e)+cQ+a, \\ m_{1,2}=m_{2,9}=m_{4,8}=c[Q+C(K-1)], \\ m_{1,3}=m_{2,8}=m_{4,10}=(Q-C)(dK+c), \\ m_{1,4}=m_{1,6}=c(Q-C), \quad m_{2,4}=m_{4,6}=cC, \\ m_{2,6}=m_{4,4}=m_{5,4}=m_{5,6}=d(Q-C), \\ m_{3,2}=m_{6,4}=m_{8,6}=m_{11,8}=a, \\ m_{3,3}=m_{6,6}=m_{7,4}=m_{7,6}=m_{8,4}=m_{11,10}=e(Q-C), \\ m_{5,1}=m_{9,5}=b+dQ+eC, \\ m_{5,2}=m_{7,2}=m_{10,9}=(d+e)(Q+C(K-1)),$$

$$\begin{aligned}
m_{5,3} &= d(Q - C) + Kb + a, & m_{7,1} &= m_{10,2} = m_{10,3} = eQ + dC, \\
m_{7,3} &= m_{10,10} = e(Q - C) + cC + (d + e)KC, \\
m_{7,5} &= m_{10,7} = (Q - C)(d + c + e) + a + cC + K(Qe + Cd), \\
m_{7,7} &= m_{10,11} = (Q - C)(K(d + e) + c) + cCK + (d + e)CK^2, \\
m_{9,2} &= b, & m_{9,3} &= m_{10,4} = m_{10,6} = (d + e)C, \\
m_{9,7} &= Kb + a + (d + e)(Q + C(K - 1)), \\
m_{10,8} &= (Q - C)(d + 2e) + cC + 2KC(d + e),
\end{aligned}$$

$$\beta_1 = -\frac{c}{a}, \quad \beta_4 = \frac{b(c + dK)}{a(a + bK)} - \frac{d}{a}, \quad \beta_5 = -\frac{d}{a},$$

$$\beta_7 = \beta_8 = -\frac{e}{a}, \quad \beta_{10} = \beta_{11} = \frac{eb}{a(a + bK)}.$$

2. Asymptotic inversion

For realizable rules the asymptotic form for each block of \mathbf{A} is (to leading order),

$$\mathbf{A}_{ij} = (a\delta_{ij} + b)\mathbf{I} + (c\delta_{ij} + d)\mathbf{B}_i\mathbf{B}_i^T + d\mathbf{B}_j\mathbf{B}_j^T, \quad (\text{A6})$$

where

$$\begin{aligned}
a &= \frac{2}{\pi\sqrt{1+2T}} - \frac{2}{\pi(1+T)}, & b &= \frac{2}{\pi(1+T)}, \\
c &= \frac{4}{\pi(1+T)^2} - \frac{4}{\pi(1+2T)^{3/2}}, & d &= -\frac{2}{\pi(1+T)^2}.
\end{aligned}$$

Block (i, j) in the inverse of \mathbf{A} is then given by

$$\mathbf{A}_{ij}^{-1} = \left(\frac{1}{a}\delta_{ij} - \frac{b}{a(a + bK)} \right) \mathbf{I} + \sum_{n=1}^K \Gamma_{ij}^n \mathbf{B}_n \mathbf{B}_n^T, \quad (\text{A7})$$

Substituting these expressions into Eq. (A4) and using the orthogonality of the teacher weight vectors ($T_{nm} = T\delta_{nm}$) we obtain a matrix equation for $\mathbf{\Gamma}^n = [\Gamma_{ij}^n]$,

$$\mathbf{\Gamma}^n = \mathbf{P}^{-1} \mathbf{X}, \quad (\text{A8})$$

where

$$\mathbf{P} = a\mathbf{I} + \begin{pmatrix} \mathbf{e}_n \\ \mathbf{u} \end{pmatrix}^T \begin{pmatrix} cT & -dT \\ -dT & b \end{pmatrix} \begin{pmatrix} \mathbf{e}_n \\ \mathbf{u} \end{pmatrix},$$

$$\mathbf{X} = \frac{1}{a} \begin{pmatrix} \mathbf{e}_n \\ \mathbf{u} \end{pmatrix}^T \begin{pmatrix} -c & (da - bc)/(a + bK) \\ d & -db/(a + bK) \end{pmatrix} \begin{pmatrix} \mathbf{e}_n \\ \mathbf{u} \end{pmatrix}.$$

Here, we have defined \mathbf{e}_n to be a K -dimensional row vector with a one in the n th element and zeros everywhere else, while \mathbf{u} is a row vector of ones. Solving for $\mathbf{\Gamma}^n$ we find

$$\mathbf{\Gamma}^n = \frac{1}{\Delta} \begin{pmatrix} \mathbf{e}_n \\ \mathbf{u} \end{pmatrix}^T \mathbf{\Theta} \begin{pmatrix} \mathbf{e}_n \\ \mathbf{u} \end{pmatrix}, \quad (\text{A9})$$

where

$$\begin{aligned}
\mathbf{\Theta} &= \begin{pmatrix} K(d^2T - bc) - ac & d^2T - bc - ad \\ d^2T - bc - ad & (d^2T(a + b) - 2abd - b^2c)/(a + bK) \end{pmatrix}, \\
\Delta &= a^2(a + bK) + a^2T(c - 2d) + aT(K - 1)(cb - d^2).
\end{aligned}$$

APPENDIX B: EQUATIONS OF MOTION

Using the definition of \mathbf{A}^{-1} given in Eq. (9) we find

$$\frac{dR_{in}}{d\alpha} = \eta \sum_j \left(\theta_{ij} \phi_{jn} + \sum_{kl} \Theta_{kl}^{ij} R_{kn} \psi_{jl} \right),$$

$$\begin{aligned}
\frac{dQ_{ir}}{d\alpha} &= \eta \sum_j \left(\theta_{ij} \psi_{jr} + \theta_{rj} \psi_{ji} + \sum_{kl} \psi_{jl} (\Theta_{kl}^{ij} Q_{kr} + \Theta_{kl}^{rj} Q_{ki}) \right) \\
&\quad + \eta^2 \sum_{jk} \theta_{ij} \theta_{rk} v_{jk}.
\end{aligned} \quad (\text{B1})$$

Here $\phi_{in} \equiv \langle \delta_i y_n \rangle_{\{\xi\}}$, $\psi_{ik} \equiv \langle \delta_i x_k \rangle_{\{\xi\}}$ and $v_{ik} \equiv \langle \delta_i \delta_k \rangle_{\{\xi\}}$

where $x_i \equiv \mathbf{J}_i^T \boldsymbol{\xi}$ and $y_n \equiv \mathbf{B}_n^T \boldsymbol{\xi}$ are activations of the i th student and n th teacher hidden nodes, respectively, and $\delta_i^\mu \equiv g'(x_i^\mu) [\sum_{n=1}^M g(y_n^\mu) - \sum_{j=1}^K g(x_j^\mu) + \rho^\mu]$. The brackets denote averages over inputs that can be written as averages over the multivariate Gaussian distribution of student and teacher activations. The explicit expressions for ϕ_{in} , ψ_{ik} , v_{ik} depend exclusively on the weight overlaps (the covariances of the activation distribution) and are given in [9].

1. Site-symmetric system

We substitute the definition of the inverse Fisher information for a symmetric system from Eq. (A2) into Eq. (3) to get the weight update equation:

$$\mathbf{J}_i^{\mu+1} = \mathbf{J}_i^\mu + \frac{\eta}{N} \left[s \delta_i^\mu + t \sum_j \delta_j^\mu \right] \boldsymbol{\xi}^\mu + \sum_{jkl} \Gamma_{ij}^{kl} \delta_j^\mu x_l^\mu \mathbf{J}_k^\mu, \quad (\text{B2})$$

where $s = 1/a$ and $t = -b/a(a + bK)$. Differential equations for the order parameters can then be derived by the methods described in [9] and for the reduced dimensionality system we find

$$\frac{dR}{d\alpha} = \eta [s \phi_s + t(\phi_s + (K-1)\phi_a) + v_R + w_R + z_R R],$$

$$\frac{dS}{d\alpha} = \eta [s \phi_a + t(\phi_s + (K-1)\phi_a) + w_R + z_R S],$$

$$\begin{aligned} \frac{dQ}{d\alpha} = & \eta [s \psi_s + t(\psi_s + (K-1)\psi_a) + 2(v_Q + w_Q + z_Q Q)] \\ & + \eta^2 [s^2 v_s + (2st + t^2 K)(v_s + (K-1)v_a)], \end{aligned}$$

$$\begin{aligned} \frac{dC}{d\alpha} = & \eta [s \psi_a + t(\psi_s + (K-1)\psi_a) + 2(w_Q + z_Q C)] \\ & + \eta^2 [s^2 v_a + (2st + t^2 K)(v_s + (K-1)v_a)], \end{aligned} \quad (\text{B3})$$

where

$$\mathbf{M} = \frac{1}{\Delta} \begin{pmatrix} c_1 & c_2 & -6(K-1)c_3 & 3(K-1)c_3 \\ -\frac{16}{\sqrt{3}}c_3 & c_4 & -12(K-1)c_3 & 6(K-1)c_3 \\ 8\sqrt{3} & -4\sqrt{3} & c_5 & -9(K-1) \\ 16\sqrt{3} & -8\sqrt{3} & 2c_4 & -\frac{8}{\sqrt{3}}c_3 \end{pmatrix},$$

$$\Delta = \pi(25 - 16\sqrt{3} + K(8\sqrt{3} - 9)),$$

$$c_1 = 2[32\sqrt{3} - 41 - K(16\sqrt{3} - 9)],$$

$$c_2 = [57 - 48\sqrt{3} + K(24\sqrt{3} - 9)]/2,$$

$$v_R = (\gamma_4 + \gamma_6)(R - S)(\psi_s - \psi_a),$$

$$\begin{aligned} w_R = & (\gamma_4 + \gamma_6)[(R - S)\psi_a + S(\psi_s + (K-1)\psi_a)] \\ & + (R + (K-1)S)[(\gamma_2 + \gamma_3 + K\gamma_7)\psi_s \\ & + (2\gamma_8 + \gamma_9 + \gamma_{10} + K\gamma_{11})[\psi_s + (K-1)\psi_a]], \end{aligned}$$

$$z_R = (\gamma_1 + \gamma_5 K)\psi_s + (\gamma_2 + \gamma_3 + K\gamma_7)[\psi_s + (K-1)\psi_a],$$

and v_Q , w_Q and z_Q are the same except that R and S are replaced by Q and C respectively everywhere they appear explicitly. Here, $\boldsymbol{\gamma} = [\gamma_i]$ is defined in Eq. (A5) and we have defined

$$\langle \delta_i y_n \rangle_{\{\xi\}} = \delta_{in} \phi_s + (1 - \delta_{in}) \phi_a,$$

$$\langle \delta_i \delta_j \rangle_{\{\xi\}} = \delta_{ij} v_s + (1 - \delta_{ij}) v_a,$$

$$\langle \delta_i x_j + \delta_j x_i \rangle_{\{\xi\}} = \delta_{ij} \psi_s + (1 - \delta_{ij}) \psi_a,$$

where δ_{ij} with two indices denotes the Kronecker δ and brackets denote averages over the inputs. These averages can again be calculated in closed form [9].

2. Asymptotic dynamics

The asymptotic dynamics for GD with an annealed learning rate have recently been solved under the statistical mechanics formalism and the optimal generalization error decay is known in this case [16]. Here we extend those results to NGD.

Following the notation in [16] we define $\mathbf{u} = (R - T, Q - T, S, C)^T$ to be the deviation from the asymptotic fixed point. If the learning rate decays according to some power law then the linearized equations of motion around this fixed point are given by

$$\frac{d\mathbf{u}}{d\alpha} = \eta_\alpha \mathbf{M} \mathbf{u} + \eta_\alpha^2 \sigma^2 \mathbf{b}, \quad (\text{B4})$$

where $\eta_\alpha \mathbf{M}$ is the Jacobian of the equations of motion to first order in η while the only nonvanishing second order terms are proportional to the noise variance. For $T = 1$ we find

$$c_3 = 2(2\sqrt{3} - 6 + 3K),$$

$$c_4 = 7 - 16\sqrt{3} + K(9 + 8\sqrt{3}),$$

$$c_5 = 16\sqrt{3} - 43 + K(27 - 8\sqrt{3}),$$

and the two nonzero entries in \mathbf{b} are

$$b_2 = \frac{\pi(38\sqrt{3} - 66 + K(51 - 30\sqrt{3}) + K^2(6\sqrt{3} - 9))}{[2 + (K-1)\sqrt{3}](\sqrt{3}-2)^2},$$

$$b_4 = \frac{-3\pi(7 - 4\sqrt{3} + K(2\sqrt{3} - 3))}{[2 + (K-1)\sqrt{3}](\sqrt{3}-2)^2}.$$

The solution to Eq. (B4) with $\eta_\alpha = \eta_0/\alpha$ is

$$\mathbf{u}(\alpha) = \sigma^2 \mathbf{V} \mathbf{X} \mathbf{V}^{-1} \mathbf{b}, \quad (\text{B5})$$

where $\mathbf{V}^{-1} \mathbf{M} \mathbf{V}$ is a diagonal matrix whose entries λ_i are eigenvalues of \mathbf{M} . We have defined the diagonal matrix \mathbf{X} to be

$$\mathbf{X}_i^{\text{diag}} = -\frac{\eta_0^2}{1 + \lambda_i \eta_0} \left[\frac{1}{\alpha} - \alpha^{\lambda_i \eta_0} \alpha_0^{-(1 + \lambda_i \eta_0)} \right], \quad (\text{B6})$$

where annealing begins when $\alpha = \alpha_0$. For natural gradient learning we find two degenerate eigenvalues $\lambda_{1,2} = -1$, $\lambda_{3,4} = -2$ and by substituting Eq. (B6) into a first-order expansion of the generalization error it is straightforward to show $\eta_0 = 1$ to be optimal. In this case the modes corresponding to $\lambda_{1,2}$ do not contribute to the asymptotic generalization error and for all values of T we find

$$\epsilon_g = -\frac{\sigma^2 \eta_0^2 K}{2\alpha(1 + \eta_0 \lambda_{3,4})} = \frac{\sigma^2 K}{2\alpha}. \quad (\text{B7})$$
