ABSTRACT

Fracture liaison services are recommended as a model of best practice for organizing patient care and secondary fracture prevention for hip fracture patients, although variation exists in how such services are structured. There is considerable uncertainty as to which model is most cost-effective and should therefore be mandated. This study evaluated the cost-effectiveness of orthogeriatric (OG)- and nurse-led fracture liaison service (FLS) models of post-hip fracture care compared with usual care. Analyses were conducted from a health care and personal social services payer perspective, using a Markov model to estimate the lifetime impact of the models of care. The base-case population consisted of men and women aged 83 years with a hip fracture. The risk and costs of hip and non-hip fractures were derived from large primary and hospital care data sets in the UK. Utilities were informed by a meta-regression of 32 studies. In the base-case analysis, the orthogeriatric-led service was the most effective and cost-effective model of care at a threshold of £30,000 per quality-adjusted life years gained (QALY). For women aged 83 years, the OG-led service was the most cost-effective at £22,709/QALY. If only health care costs are considered, OG-led service was cost-effective at £12,860/QALY and £14,525/QALY for women and men aged 83 years, respectively. Irrespective of how patients were stratified in terms of their age, sex, and Charlson comorbidity score at index hip fracture, our results suggest that introducing an orthogeriatrician-led or a nurse-led FLS is cost-effective when compared with usual care. Although considerable uncertainty remains concerning which of the models of care should be preferred, introducing an orthogeriatrician-led service seems to be the most cost-effective service to pursue. © 2016 American Society for Bone and Mineral Research.

Introduction

Hip fractures are a major public health problem, with high morbidity, mortality, and health and social care costs.^(1–3) In the UK, hip fractures account for £1.1 billion per year in hospital costs,⁽⁴⁾ which is expected to rise to £1.5 billion by 2025⁽⁴⁾ when 104,000 annual cases are predicted.⁽³⁾ A previous study showed that acute hospital admission resulting from hip fracture was the largest component of hospital costs, with higher costs and length of stay for second compared with index hip fractures.⁽⁴⁾ There is therefore a strong economic incentive to identify and implement cost-effective measures for the provision of timely

patient care and secondary fracture prevention after an index hip fracture.

Fracture liaison services are recommended as a model of best practice for patients with hip fracture. This is supported by international guidance,^(5,6) patient organizations, the UK Department of Health,^(7,8) and several UK national bodies (British Orthopaedic Association,⁽⁹⁾ NICE,⁽¹⁰⁾ National Osteoporosis Society, and Age UK⁽¹¹⁾). The proposed model consists of two main stages of care: 1) orthogeriatric services focusing on achieving optimal recovery after hip fracture, and 2) nurse-led fracture liaison services focusing on secondary fracture prevention of fragility fractures.

The Glasgow Fracture Liaison Service⁽¹²⁾ reported that for every 1000 patients with a fragility fracture assessed by that FLS, 18 fragility fractures (including 11 hip fractures) were prevented. However, no firm evidence or evidence-based consensus exists as to which care model should be mandated across the NHS. As a result, current practice reflects significant variations across NHS hospital providers in the adoption and organization of FLS.⁽¹³⁾

We used large health care data sets based on deidentified computerized records, together with a detailed evaluation of hospital hip fracture services in a UK region,⁽¹⁴⁾ to estimate the “real-world” impact of the different models of care in terms of morbidity, survival, and costs, and to determine the cost-effectiveness of orthogeriatric (OG)- and nurse-led fracture liaison service (FLS) models of care after hip fracture compared with usual care in the English NHS.

Materials and Methods

Decision model and models of care

We estimated the cost-effectiveness of the following models of care for all patients with a hip fracture admitted to an NHS hospital: 1) Introduction of an orthogeriatrician-led (OG) model of post-hip fracture care; 2) Introduction of a nurse-led fracture liaison (FLS) model of post-hip fracture care; 3) Standard post-hip fracture care.

These models of care reflect the services provided in one regional area in the UK that comprises 11 hospitals receiving patients with acute hip fractures. Details on the OG and FLS models delivered within the region from 2003 to 2013 have been published elsewhere.^(14,15) Briefly, although there was variation across hospitals, the introduction of the OG model involved the appointment of an orthogeriatrician as the clinical lead, responsible for case finding, preoperative assessment, patient assessment, and treatment initiation, as well as having involvement in postoperative care. The average staff level of an OG for secondary fracture prevention services was estimated at 0.75 whole time equivalents (WTE) within region. The FLS model involved the appointment of a nurse specialist (osteoporosis or trauma) responsible for case finding, assessment, treatment recommendations, medication assessment, and preparation of the follow-up plan, as well as for providing additional support for management of bone health in hospital. In this region of the UK, treatment adherence monitoring was predominately delegated to primary care. Finally, standard care post-hip fracture care reflects care provided without the introduction and/or expansion of OG and FLS models of care.

The perspective adopted was that of the NHS in England and personal social services, including primary and secondary health care and care home costs. Primary care costs included GP and practice nurse contacts, visits to other community health care professionals (eg, health visitor, physiotherapist), laboratory tests, and drugs. Secondary health care costs included outpatient visits, accident and emergency contacts, day cases, and inpatient admissions. Primary and secondary care costs captured hip fracture-related costs as well as all other costs. We did not include the cost of walking aids, home adaptation costs, or home care costs funded by councils or local organizations (eg, live-in help, meals, nursing care, domestic help, etc.).

Given the natural history of hip fracture progression with recursive events, a Markov model was built to evaluate the lifetime costs (quality-adjusted) life expectancy and cost-effectiveness. The model structure was defined using an

iterative process involving discussions with clinical experts and epidemiologists involved in the REFRESH study and supplemented by a literature review of economic models in the disease area.

The Markov model, developed in Excel (Microsoft, Redmond, WA, USA), was used to simulate the natural history of individuals after an index hip fracture across health states representing: history of index hip fracture, second hip fracture; major non-hip fracture(s) (pelvic, spine, wrist, humerus, and rib) requiring hospitalization; living in patient’s own home or in a care home; and dead (within 30 days post-hip fracture or within year) (Fig. 1 and Supplemental Fig. S1). We assumed that if a patient transitioned to a care home they would not go back to their own home for the remainder of their life. A cycle length of one year was considered appropriate given the natural history of hip fracture patients, and half-cycle correction was performed.⁽¹⁶⁾ All costs and outcomes were discounted using the recommended annual rate of 3.5%. Costs are quoted in 2012/2013 prices.

Derivation of model inputs

Study subjects in Hospital Episode Statistics (HES) data set

We extracted all hospital records for 33,152 patients older than 60 years who had had an emergency hospital admission with a primary ICD-10 diagnosis code for hip fracture (S72.0, S72.1, S72.2, and S72.9) between April 2003 and March 2013 for a representative region of the UK (Fig. 2 and Supplemental Table S1).⁽⁴⁾ The HES data were used to develop the risk equations for the following events: time to second hip fracture, time to major non-hip fragility fracture requiring hospitalization, discharge to care home (nursing or residential) after hip fracture, and time to death. The data were also used to estimate the annual hospitalization costs for each health state of the model. See Supplemental Material and Leal and colleagues⁽⁴⁾ for details on the valuation of hospital resource use.

Study subjects in the Clinical Practice Research Datalink (CPRD) data set

We extracted all primary care contacts, laboratory tests, and prescribed drugs for 4063 patients registered in the CPRD GOLD database between April 1, 2003, and March 31, 2012, who had linked hospital use records indicating a hip fracture (Fig. 2 and Supplemental Table S2). Hip fracture was identified in primary care records using predefined READ codes (Supplemental Table S3). The data set was used to estimate the annual primary care costs for each health state of the model. Resource use was valued using national cost databases for the year 2012/13^(17–19) (see Supplemental Table S4 for more details).

Relative effectiveness of OG and FLS

Previous work using the HES cohort⁽¹⁵⁾ informed the relative effectiveness of the models of care measured by time to second hip fracture (hazard ratio [HR]) and time to death (HR) adjusted for confounding factors such as age, sex, deprivation, and Charlson comorbidity index (Table 1). In the base case, we assumed the effect of introducing OG or FLS relative to usual care on mortality after hip fracture was present only for the index fracture and in the year of the fracture, and the effect on second hip fracture was present only in the first 2 years after index hip fracture. These assumptions were explored in sensitivity analysis.

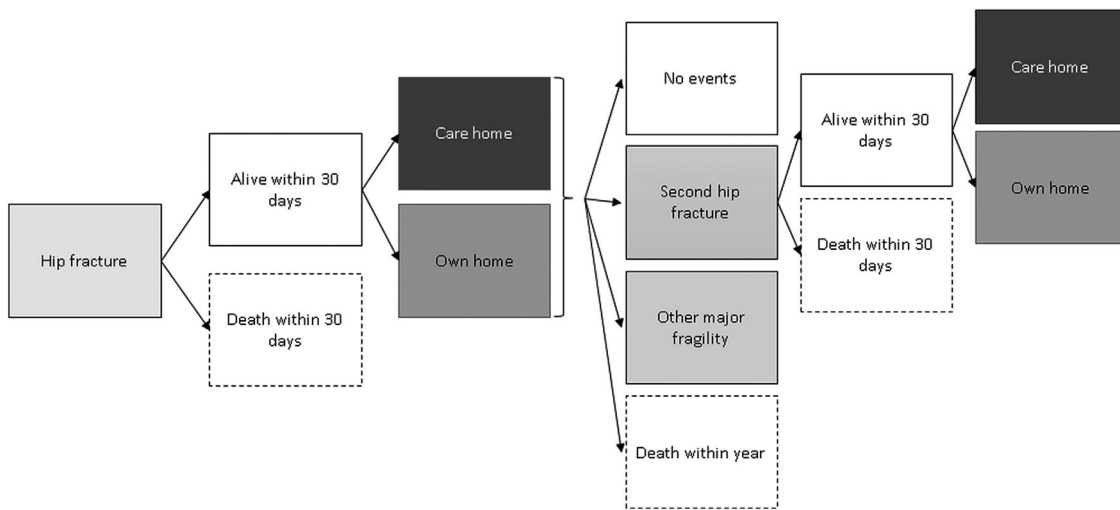

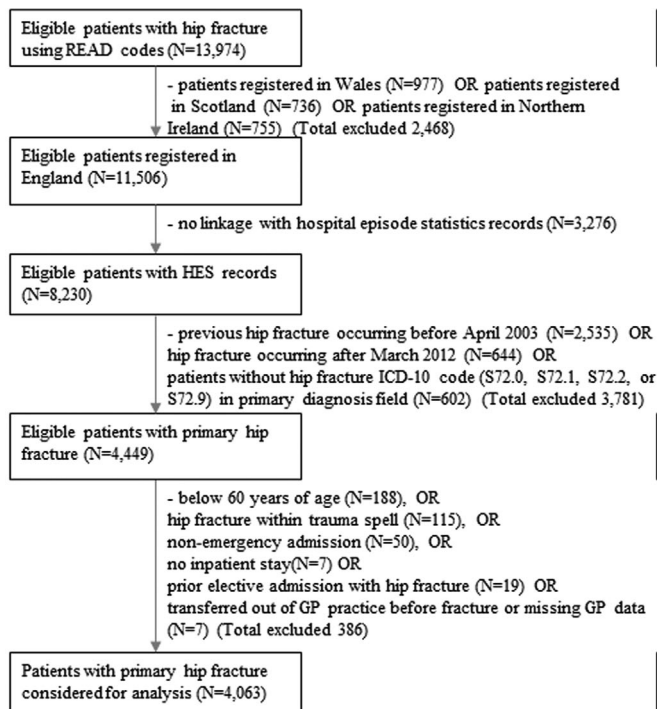

Fig. 1. Model structure and allowed transitions in the first year of simulation. The model simulated the transition of a cohort of patients with an index hip fracture through the health states over time to estimate expected costs and outcomes. At the start of the simulation, patients with a hip fracture could die within 30 days or be discharged home or to a care home (nursing or residential care home). In the same cycle, patients could then develop a second hip fracture, other major fragility fracture requiring hospitalization (non-hip such as pelvic, spine, wrist, humerus, and rib), have no further events, or die. If patients experienced a second hip fracture, they could die within 30 days or, if alive, be discharged to a care home or their own home.

Cost of introducing OG and FLS

Based on the survey of 11 hospitals in the UK region⁽¹⁴⁾ reporting staffing levels and non-clinical activities (eg, clinical leadership roles) of an orthogeriatrician and a nurse leading the FLS within the same region, an FLS was assumed to operate at 100%

capacity (whole time equivalent [WTE]), whereas an OG was assumed to operate at 75% capacity. The annual costs of an OG and an FLS per hip fracture patient were estimated by multiplying the respective WTE by the total annual costs⁽¹⁸⁾ and dividing these by 450 hip fracture patients (average patients seen per year across the 11 hospitals in the survey⁽²⁰⁾) (Table 1).

HES = Hospital Episode Statistics database; CPRD = Clinical Practice Research Datalink database.

^aIncludes salary, salary oncosts, qualification costs, management and non-staff overheads, and capital overheads.

^bNursing home at £39,000 per year (£750 per week times 52 weeks) and residential home at £27,664 per year (£532 per week times 52 weeks).

The OG- and FLS-specific costs were assumed to occur in the year of the index hip fracture, which was explored in sensitivity analysis.

Statistical analysis

The rate of second hip fracture or of major non-hip fracture requiring hospitalization after the index fracture was estimated using parametric survival models. Time to event was determined in continuous time from the onset of first hip fracture, using the censor date of death or the date of administrative censoring (March 31, 2013). All-cause mortality was derived using two logistic models to capture the high mortality in the first 30 days after first and second hip fracture (separate models) and a Gompertz proportional hazards survival model for the subsequent years. Time to death was modeled in continuous time, using each patient's current age as time at

risk to better extrapolate beyond the observed follow-up period.⁽²¹⁾ Logistic models estimated the probability of admission to care home (nursing or residential) after hip fracture (index and second). A generalized linear model (GLM), with a gamma distribution and identity link function, was used to predict the annual primary and hospital care costs by health state. Time-invariant covariates included sex, age, and Charlson comorbidity index at first hip fracture, and time-variant factors included occurrence or history of second hip fracture, occurrence or history of major non-hip fracture, and admission from care home or own home. The proportion of those discharged to a care home that go to a nursing home was derived from the National Hip Fracture Database report⁽²⁰⁾ and costed using a national cost database⁽¹⁸⁾ (Table 1). Statistical analysis was carried out using Stata v. 12 (StataCorp, College Station, TX, USA). See Supplemental Material for more methodological details.

Quality of life in patients with hip fracture

We used a meta-regression approach, with a linear mixed-effects model, to synthesize absolute utility data from 32 studies (21,085 patients) identified by literature review, which reported preference-based quality of life for patients with hip fracture (eg, EQ-5D, EQVAS, HUI2, etc.) (Supplemental Fig. S2 and Supplemental Table S5). The resulting model was used to predict the EQ-5D utility values of hip fracture patients at several time points (onset and 1, 6, 12, 18, 24 months) to estimate utility up to 2 years after hip fracture using the area under the curve (Table 1). We assumed that utilities remained constant after the first year after hip fracture (ie, 0.66) and that second hip fractures and major non-hip fractures requiring hospitalization had the same utility in the year of the event as those at the onset of hip fracture (0.46). These assumptions were varied in sensitivity analyses.

Analysis

Two cohorts of 1000 identical men and women were used to simulate a representative patient aged 83 years at hip fracture, with an average pre-admission Charlson comorbidity score of 1.2 and living in their own home before the fracture. We further assessed the cost-effectiveness of the models of care in several subgroups of hip fracture patients defined according to their age, sex, and Charlson comorbidity score at index hip fracture. A model of care was deemed to be cost-effective if the incremental cost-effectiveness ratio (ICER) was below £30,000 per quality-adjusted life years (QALY) gained.⁽²²⁾ The ICER was estimated by dividing the difference in mean costs by the difference in mean effects (life years and QALYs) for a given model of care compared with its next best alternative. Internal validity of the model was checked using sensitivity analysis (extreme values) and by comparing the model outputs with the data used to build the model. Model parameters and structural assumptions were evaluated in one-way and probabilistic sensitivity analysis and quantified using a cost-effectiveness acceptability curve (CEAC)⁽²³⁾ and analysis of covariance methods (ANCOVA)⁽²⁴⁾ (see Supplemental Material). Key uncertainties in the model structure were identified when developing the conceptual framework.

Results

Risk and cost equations

The mean follow-up time of patients in the HES data set was 2.6 years (SD 2.5) after index hip fracture, and 84,717 patient-years of data were available to estimate the risk equations. The number of patients reporting second hip fracture and major non-hip fractures were 2206 and 1464, respectively (Supplemental Table S7). Supplemental Tables S8 and S9 report the risk models, and Supplemental Tables S10–12 report the cost models. These models allow simulating the natural history of individuals and costs as well as patient heterogeneity. For example, being female was associated with higher risk of second hip fracture, higher risk of major non-hip fracture, lower risk of mortality (Supplemental Table S9), lower risk of hospitalization, and lower hospital costs (Supplemental Table S10), adjusting for other covariates. Patients living in a care home were associated with a higher risk of major non-hip fracture, higher risk of mortality (Supplemental Table S9), higher risk of hospital admission, and higher hospital costs if admitted, as well as higher primary care costs in the year of the hip fracture (Supplemental Tables S10 and S11), adjusting for other covariates.

Representative patient—male

Table 2 reports the total life years, QALYs, and costs associated with each of the three models of care. For our male cohort of 1000, the introduction of an OG and FLS would result in a reduction of 26 (95% confidence interval [CI] 17–35) and 19 (95% CI 9–29) deaths within 30 days of primary hip fracture, respectively, compared with usual care (Supplemental Table S13). Within 1 year of primary hip fracture, the reduction in deaths by introducing an OG and FLS, compared with usual care, would be 58 (95% CI 44–71) and 46 (95% CI 28–63), respectively. On average, over the lifetime of a patient, when compared with usual care, we would expect each patient to experience an increase of 0.18 (95% CI 0.14–0.23) and 0.14 (95% CI 0.08–0.19) life years (undiscounted) spent in their own home if an OG or FLS were to be introduced, respectively.

Relative to usual care, the mean discounted health care and care home costs would be £2610 (95% CI £2109–£3166) and £1975 (95% CI £1265–£2591) higher when an OG or FLS were introduced, respectively. Higher care home costs accounted for 35% and 44% of the additional costs of FLS and OG, respectively. This was a result of increased longevity due to OG or FLS being introduced. The discounted average QALYs gained by male patients, relative to usual care, were 0.13 (95% CI 0.09–0.16) and 0.10 (95% CI 0.06–0.14) if an OG or FLS were to be introduced, respectively.

At a £30,000 per QALY threshold, the most cost-effective model of care was introducing an orthogeriatrician, with an ICER of £23,407/QALY (Table 3). There was considerable uncertainty regarding the comparison between OG and FLS models of care with statistically nonsignificant difference in costs and QALYs being £635 (95% CI –£207 to £1496) and 0.03 (95% CI –0.02 to 0.07), respectively (Table 3 and Supplemental Fig. S3). However, the probability that introducing OG-led FLS was the most cost-effective option was estimated at 69%.

Representative patient—female

For our female cohort of 1000, mortality at 30 days and within 1 year was lower compared with the male cohort in the usual care (Supplemental Table S13). Hence, the introduction of an OG and FLS would result in a reduction of 16 (95% CI 11–22) and 12 (95% CI 5–18) deaths within 30 days of primary hip fracture, respectively, compared with usual care. Within 1 year of primary hip fracture, the reduction in deaths by introducing an OG and FLS, compared with usual care, was 42 (95% CI 31–51) and 33 (95% CI 21–45), respectively. On average, over a lifetime, when compared with usual care, we would expect each female to experience an increase of 0.17 (95% CI 0.13–0.21) and 0.13 (95% CI 0.08–0.18) life years (undiscounted) spent in their own home if an OG or FLS were to be introduced, respectively.

The mean discounted health care and care home costs were £2547 (95% CI £1993–£3035) and £1909 (95% CI £1272–£2515) higher by introducing an OG and FLS, respectively, relative to usual care. As a result of longer longevity relative to males, care home costs now accounted for 41% and 51% of the additional costs of FLS and OG, respectively. The discounted average QALYs gained by female patients, relative to usual care, were 0.12 (95% CI 0.09–0.15) and 0.09 (95% CI 0.06–0.13) if an OG or FLS were to be introduced, respectively.

At a £30,000 per QALY threshold, the most cost-effective model of care for females was introducing an orthogeriatrician, with an ICER of £22,709/QALY (Table 3). As with males, considerable uncertainty exists when comparing OG and FLS

Table 2. Mean Discounted Costs and Outcomes of the Differing Models of Secondary Prevention Care

LY = life years; QALY = quality-adjusted life years; ICER = incremental cost-effectiveness ratio; FLS = fracture liaison service; OG = orthogeriatrician.

largely associated with the uncertainty in the relative effectiveness of an OG-led model of care compared with FLS on 30-day (accounting for 25% of all uncertainty in incremental costs and QALYs) and 1-year mortality (52% to 58% of all uncertainty) after index hip fracture. The uncertainty in the natural history components of the model (eg, absolute mortality, probability of second hip fracture, or other major fragility fracture) was associated with 10% of all uncertainty in the incremental costs and QALYs. In terms of model structural assumptions, we tested the impact of changes to these assumptions on the cost-effectiveness results (Supplemental Table S14). Overall, at a £30,000/QALY threshold, the introduction of OG or FLS relative to usual care remained the most cost-effective options when the assumptions were changed. For example, assuming the effect of the interventions concerning second hip fracture extended over lifetime rather than 2 years resulted in OG becoming more cost-effective (£20,036/QALY). Also, assuming that the effect of the interventions on mortality extended over lifetime rather than 1 year after hip fracture resulted in OG being more cost-effective (£18,052/QALY). Excluding care home costs resulted in OG becoming more cost-effective (£13,039/QALY and £14,733/QALY for women and men, respectively). Assuming that the OG and FLS services resulted in additional £1000 per patient in management and test costs during the hip fracture admission relative to usual care resulted in OG becoming borderline cost-effective (£29,573/QALY). Finally, using the smallest hospital in the UK region (220 hip fractures per year) to estimate the intervention cost per patient (OG at £859 per patient and FLS at £409 per patient) resulted in FLS becoming the most cost-effective option (ICER of £22,922/QALY; Supplemental Table S14).

Subgroup analysis

For patients up to age 80 years, introducing an OG was the most cost-effective option (Supplemental Table S15). In contrast, introducing an FLS became the most cost-effective option for

Fig. 3. Orthogeriatrician- versus nurse-led fracture liaison service: ANCOVA analysis of proportion of sum of squares for incremental QALYs saved and incremental costs explained by the uncertainty in the model. The horizontal axis represents the variation in incremental costs and QALYs that is associated with the uncertainty in the model inputs.

patients aged 90 years if their Charlson comorbidity score at index hip fracture was 5 or above.

Discussion

Our cost-effectiveness analysis of models of hip fracture care found that the introduction and/or expansion of OG- and nurse-led FLS was more effective and cost-effective than usual care.

Two recent systematic reviews assessed the economic evidence concerning the prevention of osteoporotic fractures.^(25,26) Consistent with our findings, three previous economic evaluations, using Markov models, reported secondary fracture prevention interventions (ie, hospital osteoporosis case manager, outpatient-based FLS, and hospital nurse-led FLS) to be cost-effective in populations with fragility fracture.^(12,27,28) These analyses were limited by the use of data from single institutions and by a relatively short follow-up period (up for 1 year) or by the use of disparate data sources covering different populations of patients and time periods. Our study benefitted from the availability of large primary and hospital data sets to robustly estimate the impact of the models of care across a large representative population in terms of survival, prevention of second hip fracture, primary care and hospital care costs, and cost-effectiveness. For example, having incorporated into our modeling robust estimates of the time to second hip fracture and death and the short- and long-term costs associated with patients with hip fracture, we did not find the introduction and/or expansion of OG- or nurse-led services to be cost-saving compared with usual care, in contrast to previous work.^(12,27) This is largely explained by the added longevity that translates into higher costs and refractures compared with usual care.

Irrespective of how patients were stratified in terms of their age, sex, and Charlson comorbidity score at index hip fracture, our results suggest that it is cost-effective to introduce an orthogeriatrician or FLS compared with usual care. We find that these models of care produce greater gains in life years than QALYs, suggesting that the positive impact on survival was not necessarily accompanied by proportional gains in quality of life. This is an area that would repay closer investigation.

There is considerable uncertainty in the evidence informing the model, particularly concerning the relative effectiveness of an OG- compared with a nurse-led FLS on survival and prevention of second hip fracture and also concerning the natural history of hip fracture. The large number of hip fractures every year for which these interventions are potentially relevant suggests that caution is required about decisions based on the model results. Our findings highlight the need for further research to reduce decision uncertainty, with particular emphasis on undertaking clinical trials to obtain unbiased comparisons of the different models of secondary care services.

The translation of our findings into other types of acute fragility fractures requiring inpatient care is possible. However, the management of vertebral fractures requires additional components, different mechanisms for case finding (routine VFA, text mining radiology reports, rereading axial imaging) as well as treatment (analgesia, vertebral augmentation) relative to hip fractures. Although these types of care pathways can be delivered within an FLS system, they require layering of additional work flows and remain a priority for future service development.⁽²⁹⁾

Furthermore, the case-mix of patients seen by the OG- and nurse-led FLS services may vary by type of fracture and frailty of

patient; however, our qualitative evaluation of hip fracture services within the region did not detect differences in the types of patients that were seen by OG and FLS models of care.⁽¹⁴⁾

Our study had several limitations. First, although we improved on previous studies by basing our estimates of effectiveness on a very large administrative data set supported by a careful survey of the services provided in each hospital,^(14,15) there were no effectiveness data informed by clinical trials, and the limited range and number of services currently provided in England precluded considering some models of care, such as introducing a combined orthogeriatrician- and nurse-led FLS. Second, we did not separate the different types of fragility-related fractures that patients could suffer post-discharge. We focused on major non-hip fractures requiring hospitalization given their relative large impact in terms of health care costs. Furthermore, we did not separate non-hip fractures by type so that we could benefit from a larger sample to estimate the costs. Nonetheless, other fragility fractures not incurring hospitalization were still captured in the model in the primary and hospital care costs. Third, we did not have quality-of-life data from individual patient records and relied instead on a systematic review and meta-regression of published literature. This provided estimates of changes in EQ-5D-based utility conditional on time since hip fracture, but we could not reliably estimate utility values for non-hip fractures or the additional impact these may have on the quality of life of individuals with a history of hip fracture. The consequent assumptions were explored in sensitivity analysis, but future research could address this limitation. Furthermore, the use of a cohort-based Markov model made it difficult to capture the trajectory of utility values taking into account both time since primary hip fracture and history of events such as non-hip fractures and second hip fracture. An individual-based (ie, microsimulation) Markov model would have facilitated tracking of each individual's history and time-varying utility values, but would have been more time-consuming to construct and computationally intensive to run.⁽³⁰⁾ Finally, we only included health care and care home costs, and so excluded some important economic considerations for people with hip fracture and their families, such as unpaid care provided by friends and family, walking aids, and home adaptation costs as a consequence of the fracture, as well as locally funded home social care (eg, provision of meals, nursing care, live-in help, etc.). Future research using UK-based populations of hip fracture patients is needed to assess the use and costs of these resources as well as the impact on informal care.

In conclusion, our work suggests that it is cost-effective to introduce an orthogeriatrician or FLS secondary care service for patients with a hip fracture, predominantly because of their effects on mortality rather than on refracture. Further research is needed to make more informed decisions with a focus on estimating the effectiveness of these models of care informed by clinical trials.

Disclosures

JL, AM, DPA, NKA, CC, MKJ, and AJ received grants from NIHR HS&DR during the conduct of the study. Outside the submitted work, MKJ reports personal fees from Lilly UK, Amgen, Servier, Merck, Medtronic, Internis, and Consilient Health and serves on the Scientific Committee of the National Osteoporosis Society and International Osteoporosis Foundation. DPA received grants from Bioiberica S.A. and Amgen Spain S.A. CC received personal fees from Servier, Amgen, Eli

Lilly, Merck, Medtronic, and Novartis. NKA reports personal fees from Merck, Smith and Nephew, Q-Med, Nicox, Flexion, Bioiberica, and Servier and grants and personal fees from Roche. AJ has received consultancy, lecture fees, and honoraria from Servier, UK Renal Registry, Oxford Craniofacial Unit, IDIAP Jordi Gol, and Freshfields Bruckhaus Deringer, has held advisory board positions (which involved receipt of fees) from Anthera Pharmaceuticals, Inc., and received research sponsorship from Roche. SH and AD state that they have no conflicts of interest.

Acknowledgments
