ABSTRACT

An experimental study is carried out to investigate the unsteady pressure exerted on the surface of a round cylinder in the subcritical Reynolds number range. Results are presented for the surface pressure fluctuations, spanwise coherence, lateral correlation length and peripheral coherence. Discussions are provided for the dominance of the first three vortex shedding tones at different regions of the cylinder and the size of the flow structures around the cylinder. The dataset provided have shed new light on the unsteady aerodynamic loading acting on cylinders and provides the impetus for further research on the aerodynamics and aeroacoustics of bluff bodies.

Keywords: *Circular cylinder, surface pressure fluctuations, Aeolian tone, vortex shedding*

1. INTRODUCTION

The aerodynamics of circular cylinders placed in a laminar cross-flow has extensively been

studied as it involves some very interesting physics and is of great importance in many engineering

applications, including risers in marine engineering, buildings, bridges, tubular heat exchangers, power

transmission lines, chimneys, towers and so on. The noise generation mechanism and methods to reduce

the noise from bluff bodies are also of great academic and industrial interest. While the aerodynamics of

bluff bodies has been the subject of much experimental studies, there still exists a need for high-quality

measurement of the quantities important for the understanding of the noise generation mechanism.

The broadband and tonal characteristics of the noise generated by circular cylinders depend on

the Reynolds number of the flow [1]. At the Reynolds numbers below 50, the separation of the

boundary layer on the cylinder causes a pair of vortices, but no shedding behind the cylinder. Within the

Reynolds number range of 50 to 10^5, known as the subcritical flow regime, the boundary layer over the

cylinder remains laminar, but periodic shedding of vortices occur in the wake region. At higher

Reynolds numbers, the boundary layer becomes turbulent, followed by flow separation, leading to

strong random flow fluctuations as well as the emergence of period shedding structures in the wake

region. A complete review of the different flow regimes, vortex shedding structures and the Reynolds

number dependency of the vortex shedding phenomenon can be found in [2].

The sound generated as a result of the flow interaction with circular cylinders can be

characterized as both tonal, due to the period aerodynamic forces acting on the cylinder due the vortex

shedding, and broadband, because of the presence of strong three-dimensional random fluctuations

within the boundary layer and the near-wake. The sound generation due to the vortex shedding has

received considerable attention since the pioneering research of Strouhal [3] in 1878, who made the first

quantitative measurement of the sound generated from air-flow over stretched wires. Strouhal's

measurements showed that the frequency of the tonal noise produced as a result of flow interaction with

the wires is independent of the wire length and that it can be described using a non-dimensional

frequency relationship, now known as the Strouhal number ($St = fD/U_\infty$). The wake measurements for

round cylinders von Karman [4] also confirmed the emergence of such tones. These experimental

observations, in conjunction with some flow stability analysis [4], led to the association of the flow

induced tones to the periodic vortex shedding within the wake region of the cylinder [5]. Rayleigh also showed that the vortex shedding Strouhal number is a function of Reynolds number. The Reynolds number dependency of the radiated tonal noise or vortex shedding frequency was further confirmed by later experiments [6]. Other experimental studies in the low Reynolds number regime have shown the emergence of periodic vortex shedding structures at a Reynolds number of 40 [7] and appearance of more three-dimensional irregular and turbulent structures for $Re \geq 300$ [8].

The Aeolian tones, i.e. the tonal noise generated due to the vortex shedding, are known is a basic and important characteristic of the aerodynamic of bluff bodies. Stowell and Doming [6] were the first to measure the directivity of the noise radiated by circular cylinders and demonstrated that the sound field has a dipolar character, with peaks normal to the freestream flow direction and the cylinder axis. The mathematical model developed by Curle [9] showed that the fluctuating forces acting on the cylinder, as a result of the solid-flow interaction, leads to a dipolar radiation. Curle's dimensional analysis also showed that theoretically the sound intensity scales with the sixth-power of the velocity. The experimental work Yudin [10], however, found that the sound power scaling law can vary significantly with flow condition and Reynolds number.

The prediction of the sound radiated by an isolated cylinder in a crossflow has been the subject of many studies over the past few decades, a summary of which can be found in the work by Blevins [11]. Assuming an acoustical dipole in a moving medium and by modelling the vortex shedding as an externally exerted body force, Etkin and Keefe developed a model for the prediction of the radiated noise [12]. Lighthill's Acoustic Analogy has also been extended by Curle [9] and Ffowcs Williams and Hawkings [13] to allow for the effects of external solid bodies and their motion, respectively. Based on the mathematical models developed, it has become evident that the far-field noise can be predicted using some of the flow quantities, namely the vortex shedding frequency, the aerodynamic loading acting on the cylinder, and the spanwise correlation length of the flow structures as a function of

1   frequency. While the aerodynamic loading, i.e. lift and drag response, shows the strength of the

2   oscillation and therefore the noise radiation, the spanwise correlation length represents the three-

3   dimensional character of the flow and the coherence level of the flow structure, particularly at the

4   vortex shedding frequency and it harmonics.

5   Based on Curle's mathematical model for the prediction of noise from stationary solid bodies in

6   a flow, one can infer that the far-field sound from a circular cylinder is directly related to the surface

7   integral of the unsteady pressure exerted on the body of the cylinder as a result of the interaction with

8   the boundary layer and wake structures [14]. Therefore, for proper understanding of the noise

9   generation mechanism from external bodies in a flow, it is important to study the flow-field around the

10   object and the unsteady forces exerted by flow structures. The most conventional and effective method

11   for measuring the unsteady surface pressure fluctuations acting on the surface in a flow field is the use

12   of miniature pressure transducers. Using such a method, one can obtain reliable measurement of the

13   unsteady pressure over a wide range of frequencies. A potential shortcoming of the method, on the other

14   hand, is that the spatial resolution, i.e. the distance between the transducers, is restricted to the physical

15   size of the transducers. This can cause problems with pressure coherence studies and resolving high-

16   frequency structures. A comprehensive study of vortex shedding noise from a single cylinder using this

17   method was carried out by Schlinker et al. [15]. Results had confirmed that vortex shedding is

18   dependent on the surface roughness and the effective Reynolds number. It was also shown that the

19   vortex shedding noise is particularly strong in the subcritical Reynolds number range and that in the

20   supercritical regime the far-field noise becomes more broadband. The wall pressure fluctuation

21   measurements using in-situ pressure transducers were also reported in the work by Casalino and Jacob

22   [16] for understanding of the statistical characteristics of the wake flow structures. Two-point coherence

23   measurements were also performed using a limited number of angular and spanwise pressure sensors. In

24   this research, the Aeolian tones were detected at each observation angle corresponding to the typical

1 Strouhal number of 0.2. It was also argued that both the fundamental vortex shedding frequency and the

2 second harmonic correspond to the lift fluctuations of the cylinder, while the first harmonic is related to

3 the drag fluctuation force acting on the cylinder. Using the same measurement technique, Fujita et al.

4 [17] carried out an investigation on the properties of the Aeolian tone and the surface pressure

5 fluctuations for a wide range of Reynolds numbers between 2.5×10^5 and 2×10^6. According to the

6 experimental data obtained in [17], the wake flow experiences significant changes at $Re = 3 \times 10^5$,

7 leading to sudden increase in the Strouhal number of the Aeolian tone from 0.2 to 0.45. The Strouhal

8 number of the Aeolian tones were found to remain at around 0.45 up to $Re = 7.5 \times 10^5$, followed by a

9 decrease to 0.2 at higher Reynolds numbers. The spanwise correlation studies between the surface

10 pressure fluctuation and the Aeolian tones had also shown that in the sub-critical range, the vortex

11 shedding structures are more two-dimensional than those in the super-critical flow range.

12   In addition to the conventional methods, such as the miniature pressure transducers, for the

13 measurement of the surface pressure fluctuations, new non-intrusive methods based particle image

14 velocimetry (PIV) has opened a new field of research. The pressure field can be extracted from the PIV

15 velocity field and used in the context of aerodynamic noise diagnosis. Such PIV-based methods have

16 recently been used for some fundamental problems, such as the flow over circular cylinders [14]. The

17 noise sources were then identified and assessed through cross-correlation analysis of the pressure

18 fluctuations. The pressure field results obtained using the PIV method had shown that the noise sources

19 can be found mainly at the flow separation point on the cylinder and within the near-wake region. The

20 pressure field obtained based on the PIV method was also found to be in good agreement with that

21 measured using an embedded pressure transducer. The PIV technique has also been widely used for

22 studying flow control around circular cylinder using permeable plates and porous covers [18, 19].

23   As reviewed above, there exists an extensive body of research on the generation of aerodynamic

24 noise from cylinders and the prediction of the radiated noise. However, no comprehensive study has

been carried out to investigate the surface pressure fluctuations over the circumference of the cylinder and along its span. This paper aims to provide an extensive study of the unsteady pressure exerted on the surface of circular cylinders in a laminar cross-flow in the subcritical flow regime, perform comprehensive near-field correlation studies and improve our understanding of the noise generation mechanisms from bluff bodies. We will make use of in-situ unsteady pressure measurements and will provide a large database, which can be used both for better understanding of the noise generation and as a benchmark case for future numerical studies. The remainder of the paper is organized as follows: Section 2 describes the test-rig, model instrumentation and data processing methods. Section 3 details the experimental data collected as part of this research work and provides discussions on the surface pressure fluctuations, spanwise coherences, correlations lengths, and peripheral coherence analysis. Finally, Section 4 concludes the paper and provides suggestions for future research.

2. EXPERIMENTAL SETUP

The Experiments were performed in an open-jet subsonic wind tunnel with an exit cross-sectional area of $460 \, mm \times 460 \, mm$. A low-noise forward-blade type centrifugal fan powers the wind tunnel, providing a maximum reliable wind speed of 25 m/s, with an incoming turbulence level of less than 0.3%. To further improve the noise performance of the tunnel and avoid noise contamination due to the fan background noise, the internal walls of the tunnel were replaced with a highly absorbing porous layer [20], which resulted in the reduction of the fan background noise by about 15 dB over a wide range of frequencies.

2.1. Test Model

The cylinder model tested in the present work has an outer diameter of 22mm and a span length of 460mm. In order to simplify the instrumentation of the model with in-situ pressure sensors, the circular

1   cylinder model is made of three parts, namely one middle section with the static and dynamic pressure

2   instrumentations and two side parts to extend the span length of the model to that of the wind tunnel

3   exit, as shown in Fig. 1. The blockage ratio of the test rig is less than 5%. The model also has an aspect

4   ratio (span-length to diameter) of over 20 and therefore the wind tunnel walls effects on the measured

5   quantities can be assumed negligible [21]. The cylinder is placed within the potential core of the exiting

6   jet flow and supported by two parallel rectangular end-plates downstream of the contraction nozzle. The

7   model is properly fixed to the side-plates to eliminate the possibility of vibration. The cylinder is

8   mounted on a turning-table to enable data collection using the static pressure taps and pressure

9   transducers in fine angular increments. The details of the experimental setup are provided in Fig. 1.

10   **2.2. Static Pressure Measurement**

11   In order to study the cylinder flow-field and measure the pressure distribution around the cylinder (C_p),

12   the model is instrumented with 18 static pressure taps, distributed evenly with 20° spacing over the

13   circumference of the cylinder, as shown in Fig. 1. The pressure taps have a diameter of 0.55 mm. Each

14   tap-hole is tightly fitted with a 5 mm long brass tube, with the inner and outer diameters of 0.4 mm and

15   0.6 mm, respectively. The brass tubes are then connected to a series of polyurethane tubes with the

16   diameters of 1mm, 3 mm and 4 mm, and finally connected to the pressure scanner ports outside the

17   cylinder. The static pressure measurements are carried out using a Honeywell electronic differential

18   pressure measurement unit with 16 channels and a range of ±1.25 kPa. An uncertainty analysis of the

19   pressure measurement, based on the method described in [22], showed a maximum uncertainty of 2.2%.

20   As mentioned above, while the pressure taps are spaced at every 20°, the cylinder can be rotated in 5°

21   increments using the turning-table, providing the possibility of pressure measurement with fine angle

22   (θ) resolution.

23   **2.3. Surface Pressure Microphone Array**

The layout of the pressure transducers used for the measurement of the dynamic pressure acting on the surface of the cylinder is depicted in Fig. 1. The locations of the pinholes are also summarized in Table 1. A total number of 15 microphones are distributed in the spanwise and peripheral directions. A set of microphones (p1-p8) are installed on a straight line along the span of the cylinder to verify the two-dimensionality of the flow and also to measure the spanwise length-scale at different frequencies. Special care has been taken for the distribution of the spanwise pressure transducers. To fully resolve the flow structures, the spanwise transducers must be distributed over at least 5D-7D, as reported in the literature [17, 23, 24]. At the same time, the transducers must be kept outside the boundary layer developed by the wind tunnel side-plates. The maximum thickness of the boundary layer created on the side-plates at the flow velocity of 20m/s is found to be 8 mm. In this study, the pressure transducers are distributed over 6D (132 mm) along the span and are always outside the side-plate boundary layer. The minimum distance between the transducers is limited by the physical dimension of the transducers. The pressure transducers are distributed along the span of the cylinder according to a potential function, with an unequal spacing. This is to provide a non-redundant population of sensor spacing, maximum number of spatial distance combinations and therefore more accurate cross-correlation and spanwise length-scale calculations. Another set of pressure transducers (p9-p15) are distributed around the circumference of the model at the mid-span plane with an angular spacing of 45°, to provide information on the flow structures and shedding at different peripheral angles. The turning-table has been used to collect data at every 5° degrees.

2.4. Surface Pressure Instrumentation

Unsteady surface pressure measurements are made using Panasonic electret condenser pressure transducers (series WM-61A). The transducers have a diameter of 2.5mm, height of 3.4 mm and circular sensing area of 2 mm. The same type of pressure transducers had previously been used in

similar studies [23] and has shown to deliver reliable pressure recording in the frequency range relevant

to the current study. The accurate measurement of the dynamic pressure due to the flow interacting with

the cylinder requires the use of extremely small pressure transducers. This is, however, not possible in

practice. At low frequencies, when the sensing area of the pressure transducers is smaller than the sound

or hydrodynamic field wavelength, accurate pressure measurements can be achieved. At high

frequencies, on the other hand, when the wavelength is smaller than the pressure transducer sensing

area, the pressure fluctuation measurement is spatially integrated, leading to inaccurate measurement of

the dynamic pressure, as reported in [25, 26]. In order to reduce the attenuation effects at high

frequencies, pressure measurements are made via a small pinhole at the surface of the cylinder. Also, as

reported by Bull and Thomas [27] and Afshari et al. [28], the discontinuity on the surface of the model

due to the presence of the pinholes can cause flow disturbance and errors in the measurement at high

frequencies. Such errors can be minimized to a large extent by employing pinholes with very small

diameters [29].

As shown in Fig. 2, the pressure transducers are placed inside the cylinder, underneath a small

pinhole mask of 0.55 mm diameter, and fixed in place using a fully sealed holding mechanism. The

pinholes are made using an accurate drill machine. The geometrical dimensions of the pinholes and the

pressure transducer holding mechanism are shown in Fig. 2. Moreover, the cavity between the pressure

transducer and the pinhole mask can cause cavity resonance, which is an undesirable consequence of

such in-situ measurement techniques. The most important parameters determining the cavity resonance

frequencies for the pinhole configuration are the pinhole diameter, pinhole neck length and volume

between the microphone and the mask surface [30]. Analytical and experimental investigations have

been carried out as part of our test-rig design and manufacturing to ensure that the resonance

frequencies associated with the pinhole configuration are outside our frequency range of interest, i.e. up

to 20 kHz.

1   The microphone calibration was performed before each test in the following manner. In order to

2 acquire the transfer function of the pressure transducers a purpose-built calibrator was used. A bespoke

3 calibrator was designed and made as part of this research, consisting of a high-quality loudspeaker,

4 connected to a cone-shaped extension with a 110mm long tube with a diameter of 10 mm, microphone

5 chamber, and an acoustic termination see Fig. 3. The cone was designed with a shallow angle and filled

6 with a dense porous material to ensure plane wave propagation and suppression of high-order modes.

7 An extension tube connects the cone to the microphone chamber, with a microphone holder that aligns

8 the reference microphone to the pinhole of the embedded pressure sensor. In order to ensure the proper

9 sealing during the calibration, the area around the pinhole is covered by a thin silicone ring during the

10 calibration process. A ¼-inch 40BP GRAS microphone, calibrated with a GRAS Sound Calibrator

11 (Type 42AB), was used as the reference microphone. A long and very highly absorptive plastic tube is

12 also used for the termination of the sound field from the microphone chamber and suppression of

13 reflected waves. All pressure sensors installed in the test rig were calibrated in-situ with a white noise

14 excitation signal over the frequency range of 10 Hz to 20 kHz. A 16-channel power module was used to

15 power the Panasonic pressure transducers and the data were collected using a 16-channel NI PCI-6023E

16 data acquisition system. The pressure data have been collected over 20 seconds at a sampling frequency

17 of $f_s = 40$ kHz. Figure 4 shows the amplitude and phase of the transfer function for one of the

18 embedded Panasonic pressure transducers in the pinhole configuration. As shown, the microphone

19 delivers a linear and smooth response at all frequencies and the pinhole cavity does not produce any

20 resonances within the frequency range of interest (100-10kHz). The main source of uncertainty in the

21 measurement of the unsteady surface pressure here is due to the statistical convergence error, and is

22 inversely proportional to the number of sample records [31], i.e. $1/\sqrt{N_r}$, with N_r being the number of

23 records. In the present study, the spectra have been calculated as the average of the spectra of individual

24 data records obtained from dividing the pressure time series into a sequence of records to reduce the

10

1   statistical convergence error. A total number of $N_r = 800$ records have been used, resulting in an

2   uncertainty of about 3.5%.

3   **3. RESULTS AND DISCUSSIONS**

4   **3.1. Aerodynamic Characteristics**

5   The results of the pressure distribution around the cylinder model are presented in this section. The

6   results here also serve as the validation of the experimental setup and wind tunnel used for the present

7   study. The experiments were carried out at three different freestream velocities, $U_\infty = 10, 15$, and 20

8   m/s, corresponding to the Reynolds numbers of $Re = 14.7 \times 10^3$, 22×10^3 and 30×10^3,

9   respectively, based on the diameter of cylinder. This Reynolds number range is limited to subcritical

10   regime, as reported by Zdravkovich [2]. Figure 5 compares the data measured as part of our

11   experimental campaign against some other experimental data available in the literature with similar

12   flow condition. It is well recognized that the pressure coefficient can be greatly affected by the wind

13   tunnel blockage ratio (B) and the cylinder span-length to diameter ratio [32]. To show the validity of the

14   current measured data, results have been comp`1ared against those from previous works with similar

15   blockage ratios (Weidman [33], Fage and Falkner [34], Sade and Sharon [35], Sun et al. [36] and Gu et

16   al. [37]). The pressure results are presented only for the top side of the model ($\theta = 0° - 180°$). As

17   shown in the figure, the pressure distribution is almost independent of the Reynolds number in the

18   subcritical flow regime, which is consistent with the results in the literature [2]. The comparison has

19   also shown that our measured data is in good overall agreement with those in the literature. The pressure

20   coefficient minimum occurs at the angular position $\theta_m = 70°$ and the base region, i.e. the region of

21   nearly constant pressure, extends from $\theta = 80°$ to $180°$ at all Reynolds numbers, consistent with the

22   values reported in [33-37]. In the base region, the deviation of the pressure coefficient with respect to

23   the base pressure coefficient C_{P_b} (i.e. pressure coefficient at $\theta_b = 180°$) is approximately 3%, which is

1 similar to the base pressure values reported in [33, 34]. In the present study, the skin friction was not

2 measured since in the subcritical regime the friction drag is negligible compared to the total drag.

3 Therefore, the separation angle θ_s (i.e. the angle at which skin friction is zero and in considered as the

4 beginning of the base region [34]) is estimated using the pressure coefficient distribution and is found to

5 be about 80° for the three subcritical Reynolds numbers considered in this study.

6 **3.2. Pressure Power Spectral Density**

7 The surface pressure power spectral density (PSD) has been measured using microphone p1 at several

8 peripheral angles, at $Re = 30 \times 10^3$. The surface pressure PSD results are presented in both line-plot

9 and contour-map formats in Fig. 6 as a function of the Strouhal number. The PSD calculations are

10 performed in Matlab using the Pwelch function. Hamming windowing with 50% overlap is applied to

11 obtain smoother and more accurate results. The frequency resolution was set to 64 Hz. The pressure

12 PSD data are referenced to 20 μPa. The PSD results are presented only when the surface pressure

13 fluctuations are at least 10dB higher than the background noise due to the freestream flow. In addition

14 to the fundamental vortex shedding frequency ($St \approx 0.2$), the first four harmonics are also visible in the

15 PSD results, thanks to the good signal to the background noise ratio. For the pre-separation angles ($\theta \leq$

16 θ_s), results show that both the broadband and tonal content of the PSD spectra increase with the angle.

17 The increase in the broadband energy content can be due to the increase in the boundary layer thickness

18 and emergence of larger flow structures, while the increase at the tonal frequencies is due to its distance

19 from the vortex shedding region. For the post-separation locations ($\theta > \theta_s$), the tonal frequencies are

20 found to have a very high energy level, protruding well above the broadband part of the surface pressure

21 spectra. It can also be seen that the broadband energy content of the pressure spectra generally increases

22 with the angle. An interesting observation here is that at $\theta = 180°$, the fundamental frequency

23 disappears, and the 1st harmonic ($f_1 = 2f_0$) remains as the only noticeable tonal peak. The

1   disappearance of the fundamental tone will be further discussed later in Section 3.3. One can also see

2   from the results that the slope of the surface pressure PSD changes greatly with frequency and angle. At

3   small angles and low frequencies, the PSD spectra are dominated by the tonal peaks and it is not easy to

4   find a slope for the broadband content of the surface pressure energy field. At larger angles, particularly

5   beyond the separation point, the broadband content of the surface pressure PSD begins to increase and

6   follows certain f^{-n} decay gradients. At large angles ($\theta > 135^o$), and particularly at the cylinder base

7   ($\theta = 180^o$), the surface pressure PSD spectra follow a gradient of about f^{-1} within $0.1 < St < 0.4$,

8    $f^{-1.5}$ after the 1st harmonic (f_1) and f^{-3} at very high frequencies ($St > 6$).

9   In order to gain a better understanding of the surface pressure PSD variation with the angle, the

10   amplitude of the fundamental vortex shedding frequency and its first and second harmonics (f_1 and f_2),

11   are extracted from the data Fig. 6 and presented in Fig. 7. The results show that the amplitude of the

12   fundamental peak (f_0) increases with the angular position of the pressure transducers between $\theta = 0° -$

13   75°. The f_0-amplitude remains nearly constant within $75° < \theta \leq 105°$ and then decreases for $\theta >$

14   105°. At $\theta = 180°$, the fundamental tone disappears completely, shown as the hollow circles in the

15   figure, which are simply the values of the broadband noise at $St = 0.2$. The same trend can be observed

16   for the peak values of the 2nd harmonic ($f_2 = 3f_0$), although in this case the tones disappear for

17   angles $\theta > 135°$, presented as the hollow triangle markers. For the 1st harmonic ($f_1 = 2f_0$), the

18   magnitude of the tone increases uniformly from $\theta = 0°$ to 180°, with two small plateau regions between

19   $0° < \theta \leq 20°$ and $40° < \theta \leq 90°$. Results also show that both the f_0 and f_2 tones peak at around $\theta =$

20   80°, while that for f_1 occurs at $\theta = 180°$. This indicates that the fundamental and 2nd harmonic reach

21   their peak values near the separation point, while the 1st harmonic continues to grow into the fully

22   separated flow and peaks at the cylinder base ($\theta = 180°$). These observations are consistent with the

23   general understanding of the unsteady aerodynamic loads acting on isolated cylinders and that the odd

24   ($f_0, 3f_0, ...$) and even ($2f_0, 4f_0, ...$) harmonics correspond to the cylinder unsteady lift and drag

13

1 fluctuations, receptively [16]. It is well known that the axial oscillation frequency of a cylinder, due to

2 the unsteady drag force, is twice the vertical oscillation frequency, due to the unsteady lift force, but the

3 amplitude of the vertical fluctuating forces are often larger than the forces in the streamwise direction

4 [16]. These observations are particularly important for the better understanding of the noise generation

5 mechanism from bluff bodies.

6 **3.3. Lateral and Azimuthal Coherence**

7 *3.3.1. Lateral Coherence*

8 The results in the previous section showed the changes to the surface pressure PSD and the vortex

9 shedding frequencies at different peripheral angles. In this section, we shall investigate the changes to

10 the shape of the flow structures by studying the spanwise and azimuthal coherences between different

11 pressure transducers. The measurement of coherence can help gain a better understanding of the

12 physical size and also lifespan of flow structures. The coherence between two pressure transducers

13 along the span can be defined as:

$$\gamma^2_{p_i,p_j}(\eta_z,f) = \frac{\left|\Phi_{p_i,p_j}(\eta_z,f)\right|^2}{\Phi_{p_i,p_i}(\eta_z,f)\Phi_{p_j,p_j}(\eta_z,f)} \tag{1}$$

14 where $\Phi_{p_i,p_j}(\eta_z,f)$ denotes the cross-spectrum between the two pressure signals, $\Phi_{p_i,p_i}(\eta_z,f)$ is the

15 auto-spectrum of each individual signal, and η_z is the spanwise separation distance between the

16 transducers.

17 Figure 8 shows the line-plots and contour-maps of the lateral coherence measured between the

18 spanwise microphones p1 and p2, with a separation distance of $\eta_z/D = 0.68$ at different angular (θ)

19 positions. Results indicate that at all angles around the cylinder, the maximum lateral coherence occurs

20 at the fundamental shedding frequency and its harmonics (i.e. f_1 and f_2). Moreover, in all cases,

21 except $\theta > 170°$, the lateral coherence value at the fundamental frequency is greater than those at

14

1   f_1 and f_2. For $\theta > 170°$, the lateral coherence is dominated by the tonal component at f_1, while the

2   coherence values at f_0 and f_2 reduce to nearly zero. The coherence results at $\theta = 0°$ show a rather

3   broadband behavior, *i.e.* with no sign of distinct tones behavior at f_0, f_1 and f_2. At $\theta = 180°$, the

4   coherence is purely tonal, with a dominant peak at f_1. In the case of the 1st harmonic (f_1), the coherence

5   value at small angles ($\theta < 30°$, *i.e.* within the stagnation and the onset of the laminar boundary layer) is

6   very small and close to the broadband level, but then increases gradually with the angle. Similarly, the

7   coherence at the 2nd harmonic becomes more tonal at the angles larger than 30°, but then rapidly

8   decreases at large angles ($\theta > 130°$), see Fig 8-c. The results presented in Fig. 8 are summarized in Fig.

9   9, by extracting the peak coherence values measured at the fundamental frequency (f_0) and its

10   harmonics (f_1 and f_2) at different angular positions. As can be observed, the lateral coherence for f_0 is

11   very small at $\theta = 0°$ but increases quickly to one by $\theta = 20°$ and remains almost fully coherent

12   ($\gamma^2_{p_1,p_2} \approx 1$) up to $\theta = 140°$. The f_0 spanwise coherence amplitude then reduces gradually to 0.6

13   at 175° and ultimately zero at 180°. The spanwise coherence at the f_1 and f_2 frequencies is found to be

14   low at small angles, increasing gradually and reaching their maximum value at about $\theta = 40°$ to 60°,

15   respectively. The peak value for the 1st harmonic (f_1) then varies between 0.6 and 0.8 between $\theta = 60°$

16   to 180°, while that for the f_2 harmonic drops with θ and reaches zero at $\theta = 180°$.

17   As discussed above, the results presented in Figs. 8 and 9 were obtained using two pressure

18   transducers with a fixed spanwise separation distance of $\eta_z/D = 0.68$. Figure 10 shows the lateral

19   coherence results for several spanwise spacings and can provide some useful information about the

20   broadband content of the coherent flow structures formed around the cylinder and the length-scale of

21   the structures at different frequencies. Results are presented for the lateral spacings in the range of

22    $\eta_z/D = 0.41$ to 5.95, which should be sufficient for capturing the two- and three-dimensional flow

23   structures. It can be generally seen that the spanwise coherence level between the transducers decreases

24   with η_z/D at all angles. The more interesting issue, however, is that, in addition to the distinct strong

15

1   peaks at f_0, f_1 and f_2, the coherence for small lateral spacings of up to $\eta_z/D = 0.68$ has a relatively

2   strong broadband content. However, with increasing the spacing, the lateral coherence becomes entirely

3   tonal and reaches zero at other frequencies. This indicates that the three-dimensional flow structures

4   lose their coherence within a short lateral distance (within $\eta_z/D = 0.68 - 2.6$), while the two-

5   dimensional structures, *i.e.* vortex shedding structures, retain their coherence over a much longer

6   spanwise distance. The coherence results at the stagnation point ($\theta = 0°$) show a broadband behavior

7   with only a tonal peak at the f_0 frequency, indicating that the lift fluctuations can be realized at the

8   stagnation point. Progressing downstream, the strongest broadband coherence occurs at $\theta = 45°$, which

9   can be due to the growing laminar boundary layer and development of larger flow structures. However,

10   at the angles of $\theta = 90°$ and $\theta = 135°$, which correspond to the post-separation regions and turbulent

11   flow, the broadband coherence decreases gradually and approaches zero at $180°$. One interesting

12   phenomenon observed here is the emergence of a double-peak coherence behavior near f_0 ($St \approx 0.2$)

13   for the post-separation angles, between $\theta = 90°$ and $135°$, with a spanwise characteristic length of

14   between $\eta_z/D = 2.6$ and 4.54, which indicates the emergence of some new large coherent structures

15   near the fundamental tone. This characteristic length is longer than the three-dimensional turbulence

16   structures, but shorter than the two-dimensional vortex shedding structures at the fundamental

17   frequency. The nature of this double-peak phenomenon is not quite clear and requires further

18   investigation. As seen previously in Figs. 8 and 9, the spanwise coherence at $\theta = 180°$ is nearly zero

19   over the entire frequency range and for all lateral distances, except at the f_1-harmonic.

20   The spanwise coherence results can also be presented in terms of the separation distance (η_z)

21   with the aim to calculate the spanwise length-scales of the structures at different frequencies. Figure 11

22   presents the coherence between the microphones distributed in the spanwise direction at the

23   fundamental shedding and the 1st and 2nd harmonics at different angular positions. The plot shows that

24   in all cases the coherence level decays uniformly with the separation distance (η_z/D). As expected, the

1   coherence is approximately one for small separation distances as the two fluctuating pressure signals are

2   perfectly correlated. The coherence level and the decay rate of the coherence of the surface pressure

3   fluctuations along the span of the cylinder can be described by an equivalent correlation length L_c. The

4   correlation length is commonly defined as the spanwise distance over which the coherence drops to 0.5

5   [38]. In order to find the equivalent correlation length (L_c), the experimental data are fitted with a

6   Gaussian function, i.e. $exp(-a(\eta_z/D)^2)$, where a is the exponents constant and determines the

7   coherence decay rate. Although Gaussian data-fitting is a very common approach, the use of Laplacian

8   data-fitting for modelling of the coherence decay rate has also been reported in the literature [16]. The

9   results in Fig. 11 show that the Gaussian function fits well with the coherence data at the vortex

10   shedding frequency and its harmonics at all angels. It is clear from the results that at the fundamental

11   vortex shedding frequency, the surface pressure remains highly coherent over a long distance along the

12   span of the cylinder (Fig. 11-a), while for the first (Fig. 11-b) and the second harmonics (Fig. 11-c) the

13   coherence decay occurs much faster and over a much shorter span length. Also, as expected, the

14   spanwise coherence level for the pressure signals at the base of the cylinder ($\theta = 180°$) at the

15   fundamental frequency (f_0) drops much more rapidly compared to $\theta = 45°$, 90° and 135° (within the

16   laminar boundary layer and turbulent region). The results for the first harmonic (f_1) show that the

17   spanwise correlation length is much smaller than that of the fundamental frequency (f_0), but the largest

18   structures are observed from the measurements at $\theta = 180°$. Finally, the general trend of the results for

19   the second harmonic (f_2) are similar to the fundamental frequency (f_0), but with a much higher decay

20   rate and smaller correlation length. The curve-fitting coefficient (a) and the equivalent spanwise

21   correlation length values (L_c) extracted from Fig. 11 are summarized in Tables 2 and 3.

22   In order to better understand the structure of the flow passing over the cylinder, the frequency

23   dependent spanwise length-scale of the flow structures are studied. The spanwise length-scale can be

24   calculated using the surface pressure fluctuations measured along the span in the frequency domain, as

1 [39]

$$\Lambda(f) = \int_0^\infty \sqrt{\gamma^2_{p_i,p_j}(f,\eta_z)} \, d\Delta z \qquad\qquad (2)$$

2   The frequency dependent spanwise length-scale results at different angels are presented in Fig.

3 12. The results for $\theta = 45°$, 90° and 135°, show similar trends with distinct tonal peaks at the

4 fundamental vortex shedding frequency (f_0) and its harmonics f_1 and f_2. The value of the spanwise

5 length-scale at the fundamental frequency for $\theta = 45°$ reaches about $\Lambda(f_0) = 8.1D$, while that for the

6 1st and 2nd harmonics are, respectively, $\Lambda(f_1) = 3.6D$ and $\Lambda(f_2) = 2.5D$. These values for the flow

7 structures at $\theta = 90°$ and 135°, are slightly less than those 45°, with much smaller values of length-

8 scale at other frequencies, indicating the emergence of more three-dimensional flow structures. Another

9 interesting result here is the appearance of a small tonal peak before the fundamental frequency in the

10 case of $\theta = 90°$ and 135°, similar to the results in Fig. 10, which shows the emergence of a turbulent

11 structure with a slightly different shedding frequency than that of the main vortex shedding structure

12 and a smaller length-scale of about $3.5D$. The results presented here can be of great use for the

13 development of new CFD-based aeroacoustic models for the calculation of noise from bluff bodies.

14 *3.3.2. Peripheral Coherence*

15 The results in Figs. 8 to 12 show the peripheral coherence of the flow structures as they travel over the

16 cylinder. While the lateral coherence can provide useful information on the spanwise extend of the

17 coherent flow structures, studying the coherence of the pressure signals at different polar locations on

18 the cylinder may give some insight into the evolution of the flow structures as they travel over the

19 cylinder from the stagnation point, to the onset of the laminar boundary layer, to the separation point

20 and into the wake region. Figure 13 shows the changes in the peripheral coherence measured between

21 the circumferential pressure transducers p1, p9, p10, p14 and p15, with 45° angular spacings. As

22 expected, the pressure signals collected within the laminar and turbulent boundary layers, i.e. pre- and

1   post-separation locations ($p_{45°} - p_{90°}, p_{45°} - p_{135°}, p_{90°} - p_{135°}$), have the highest level of coherence,

2   while those made with respect to the impingement point ($\theta = 0°$) and the base pressure ($\theta = 180°$)

3   have the lowest level of coherence. The coherence results obtained between the 45°, 90°, and 135°

4   pressure transducers, have strong broadband content, as well as distinct peaks at the fundamental and

5   harmonic frequencies. The coherence results obtained with respect to the $\theta = 0°$ pressure transducer

6   show only tonal components at the fundamental and first harmonic and are nearly zero at all other

7   frequencies. This, of course, makes sense as the broadband components, due to the boundary layer and

8   wake flow structures generated around the cylinder, only have local effects, while the vortex shedding

9   tonal components, can propagate upstream as a hydrodynamic field and reach the $\theta = 0°$ pressure

10   transducer. As a result, in the coherence data measured with respect to the $\theta = 0°$ location, the f_0 and f_1

11   peaks can be seen clearly. The $90° - 180°$ coherence is also purely tonal, with the coherence at f_1 much

12   stronger than that at f_0, unlike the other cases. Finally, the lowest coherence has been observed between

13   the $\theta = 0°$ and $\theta = 180°$ locations, with the coherence level of only 0.2 at f_0 and f_1.

14   *3.3.3. Surface Pressure Autocorrelation*

15   The autocorrelation of the dynamic pressure data collected at different peripheral locations can provide

16   information about the time-scales of the flow structures responsible for the most energetic pressure

17   fluctuations. The pressure can be found from

$$R_{p,p}(\theta) = \frac{\overline{p(\theta,t)p(\theta,t+\tau)}}{p_{rms}^2(\theta)} \qquad (3)$$

18   where p_{rms} is the root-mean-square of the pressure signal and τ denotes the time delay. The surface

19   pressure autocorrelation results are presented in Fig. 14 for a selected number of angles over a long

20   period of non-dimensional time ($\tau U_\infty/D$). Results have been obtained for the pressure signals collected

21   at $Re = 30 \times 10^3$. The autocorrelation results are presented as solid lines and the dashed lines show the

22   decay rate of the autocorrelation envelop and are based on the Laplacian distribution function,

1    $\exp(-b(|\tau|U_\infty/D))$, where b signifies the decay rate. The results for the stagnation point ($\theta = 0°$)

2   shows a relatively rapid decay within $-20 < \tau U_\infty/D < 20$ and very weak oscillation about the mean

3   autocorrelation line. At $\theta = 5°$, the results show some signs of weak oscillations, but decaying fast with

4   time. The oscillations correspond to $St \approx 0.2$, close to the fundamental vortex shedding frequency. The

5   autocorrelation amplitude increases significantly for angles greater than $\theta = 10°$ and peaks at

6   about 45°. The autocorrelation decay rate increases between $\theta = 45°$ and 90°. The decay rate (b)

7   remains almost constant within 90° to 170° and then experiences a rapid decay and a switch in the

8   coherence periodicity to the first vortex shedding harmonic $f_1 = 2f_0$. The contour plot results also show

9   some changes to the data periodicity at $\theta = 45°$ and 135°. This is believed to be due to some flow

10   transition processes occurring in these two locations, but the underlying physics of these changes is not

11   yet well understood and requires further research.

12   **4. CONCLUSION**

13   A comprehensive study of the surface pressure fluctuations acting on a cylinder in a cross-flow in the

14   subcritical region has been presented. A highly instrumented test rig was designed and built to enable

15   the work. The surface pressure power spectral density results have been presented for different

16   peripheral angles, showing the variations in the dominance of the fundamental vortex shedding

17   frequency and its harmonics in different flow regimes over the cylinder. Results have shown that the

18   fundamental vortex shedding frequency and the second harmonic, characteristic of the cylinder lift

19   fluctuations, peak at around the flow separation angle, while the first harmonic peaks at the base of the

20   cylinder. The lateral coherence studies have also been performed to study the extend of the two-

21   dimensionality of the vortex shedding structures along the span of the cylinder. Results have shown that

22   the structures responsible for the vortex shedding can retain their coherence along the span for about 8

23   diameters at the fundamental frequency and 3.6 and 2.5 at the first and second harmonics. A secondary

1   vortex structure has been identified at a frequency slightly lower than the fundamental vortex shedding

2   frequency, with a spanwise characteristic length of about 3.5D. The results in this paper have shown

3   that there is still a need for more fundamental research on the aerodynamics of round cylinders,

4   especially in the context of noise generation mechanism. This experimental work can also provide the

5   impetus for more high-quality computational research on the aerodynamics and aeroacoustics of bluff

6   bodies.
