**Automated computer-based CT stratification as a predictor of outcome in hypersensitivity pneumonitis**

**ABSTRACT**

**BACKGROUND:** Hypersensitivity pneumonitis (HP) has a variable clinical course. Modelling of quantitative CALIPER-derived CT data can identify distinct disease phenotypes. Mortality prediction using CALIPER analysis was compared to the interstitial lung disease gender, age, physiology (ILD-GAP) outcome model.

**METHODS:** CALIPER CT analysis of parenchymal patterns in 98 consecutive HP patients was compared to visual CT scoring by two radiologists and functional indices including forced vital capacity (FVC) and diffusion capacity for carbon monoxide (DLco) in univariate and multivariate Cox mortality models. Automated stratification of CALIPER scores was evaluated against outcome models.

**RESULTS:** Univariate predictors of mortality included visual and CALIPER CT fibrotic patterns, and all functional indices. Multivariate analyses identified only two independent predictors of mortality: CALIPER reticular pattern ( $p=0.001$ ) and DLco ( $p<0.0001$ ).

Automated stratification distinguished three distinct HP groups (log-rank test  $p<0.0001$ ).

Substitution of automated stratified groups for FVC and DLco in the ILD-GAP model demonstrated no loss of model strength (C-Index=0.73 for both models). Model strength

improved when automated stratified groups were combined with the ILD-GAP model (C-  
Index=0.77).

**CONCLUSIONS:** CALIPER-derived variables are the strongest CT predictors of mortality in HP.  
Automated CT stratification is equivalent to functional indices in the ILD-GAP model for  
predicting outcome in HP.

7 **INTRODUCTION**  
8  
9

10 Recently developed sophisticated computer analytic tools such as CALIPER are able to  
11 quantify a range of parenchymal pattern extents in a whole lung CT dataset [1].  
12  
13 Considerable ~~morphologic~~ information is generated by such tools, including quantitation of  
14 parenchymal patterns that ~~have no~~ cannot be similarly characterised using visual CT  
15 analysis, visual such as the volume of intraparenchymal vessels equivalent [2]. To date  
16  
17 however, there has been a paucity of computer-based analytic studies in non-idiopathic  
18  
19 fibrosing lung diseases such as hypersensitivity pneumonitis (HP). Yet quantitative analysis  
20  
21 has the potential to estimate disease burden in a condition such as HP that may present  
22  
23 with highly variable morphological [3] and histopathological features [4; 5] ~~features~~.  
24  
25  
26  
27  
28  
29  
30

31 Traditionally, the evaluation of disease severity in patients with interstitial lung disease (ILD)  
32 has focused on the identification of individual CT parenchymal patterns that predict  
33 mortality. The result has been the identification of a few key features such as honeycombing  
34 [6; 7] and traction bronchiectasis [8; 9] that are associated with a worse outcome.  
35  
36  
37  
38  
39  
40

41 In tandem with the development of computer quantitation, mathematical modelling has  
42 also evolved. New advanced automated computational techniques are able to analyse  
43 information contained within an entire CT dataset and identify patient groups that share  
44 common or idiosyncratic disease phenotypes [10; 11]. By examining the spectrum of  
45 morphological appearances on an individual patients CT, the resulting analysis facilitates  
46 individualised medicine. Automated stratification of patients into phenotypically similar

groups has been shown to correlate well with functional indices [12]. However, the association between stratified patient subgroups and differing patient outcomes has not been validated.

In the current study, CT imaging scored visually and by CALIPER in patients with HP was analysed to identify variables predictive of mortality using proportional hazards regression analysis. The population was also stratified using advanced automated computational techniques. Patient subgroups derived using automated stratification were evaluated against mortality and an alternative risk prediction model - the interstitial lung disease gender, age physiology (ILD-GAP) model [13]. The ability of automated stratification to substitute for functional indices in the ILD-GAP model was also explored.

7 **MATERIALS AND METHODS**  
8

9  
10 Study population

11  
12 A previously defined cohort of consecutive patients diagnosed with subacute and chronic HP  
13 was identified using the clinical coding database of the **Royal Brompton**  
14 **Hospital** \_\_\_\_\_ for the period January 2000 to December 2006- [14]. All  
15  
16 patients with a non-contrast, interspaced supine HRCT (1mm sections at 10mm intervals)  
17  
18 reconstructed with a Siemens B70 edge-enhancing algorithm were chosen for analysis  
19  
20 (Figure 1)[n=98]. Patients were diagnosed by multidisciplinary team clinical, radiological and  
21  
22 when available pathological consensus. 68/98 patients (69%) had both a positive exposure  
23  
24 history and serum precipitants to relevant antigens. The remainder were diagnosed using  
25  
26 broncho-alveolar lavage lymphocytosis results, appropriate CT findings [15; 16] and  
27  
28 histopathological confirmation- [17; 18]. Eleven cases with concurrent volumetric CT  
29  
30 imaging were evaluated with CALIPER to analyse differences in interpretation of interspaced  
31  
32 and volumetric scans (Figure 1, Supplementary appendix). Approval for this study of  
33  
34 clinically indicated CT and pulmonary function index (PFI) data was obtained from the  
35  
36 Institutional Ethics Committee of the **Royal Brompton Hospital** \_\_\_\_\_ and the  
37  
38 Institutional Review Board of the **Mayo Clinic** \_\_\_\_\_.

45 CT, CALIPER and PFI protocols

46  
47 Protocols are described in detail in the supplementary appendix. PFI's analysed included  
48  
49 forced expiratory volume in one second (FEV1), forced vital capacity (FVC), total lung  
50  
51 capacity (TLC), residual volume (RV), transfer coefficient of the lung for carbon monoxide

9

#### 10 11 12 13 14 CT evaluation

15  
16  
17 Visual CT evaluation on a lobar basis was performed independently by two radiologists  
18 (MM, WM) each with 3 years thoracic imaging experience, blinded to all clinical  
19 information. CT parameters evaluated included: ground glass opacity, reticular pattern,  
20 honeycombing, and consolidation which were summed to calculate total ILD extent- [2].  
21  
22 Total fibrosis extent represented the sum of reticular pattern and honeycombing.  
23  
24 Emphysema, mosaicism (decreased attenuation component) and traction bronchiectasis  
25 were scored as previously described- [2].

33

#### 34 CALIPER CT evaluation

35  
36 CALIPER segmented the lung into 6 zones: right and left upper, middle and lower zones,  
37 demarcated with reference to the lung hilum, with each of the 6 zones further divided into  
38 an inner half (central region) and outer half (peripheral region). 8 initial CT patterns were  
39 classified by CALIPER, (described below) were evaluated for all the 12 areas (see  
40 supplementary appendix)- however preliminary analyses demonstrated that honeycombing  
41 was not identified as a distinct pattern on CALIPER evaluation of interspaced datasets as  
42 honeycombing requires three-dimensional information for characterisation. Consequently,  
43 CALIPER honeycombing was not further analysed in the study. In the final analysis therefore.

seven CT patterns (described below) were evaluated for all 12 anatomic areas of the lung (see supplementary appendix).

CALIPER evaluation of the lungs was pictorially expressed as volume rendered three-dimensional images or as a glyph (Figure 2). Each glyph comprised six wedges, or zones, the size of which reflected the volume of the zone relative to the total lung volume. Within each lung zone, every voxel was classified into one of 8 separately colour coded CALIPER parenchymal patterns: ground glass opacity=yellow, reticular pattern=orange, honeycombing=brown, Grade 1 decreased attenuation (DA)=light green, Grade 2 DA=light blue, Grade 3 DA=dark blue, Normal lung=dark green, pulmonary vessel volume (PVV)[pulmonary arteries and veins, excluding vessels at the lung hilum]=white. The relative volumes of the patterns within a zone determined the proportions of each colour in a zone.

Honeycombing was not identified as a distinct pattern on CALIPER evaluation of interspaced datasets as honeycombing requires three dimensional information for characterisation. Consequently, CALIPER honeycombing was not further analysed. All CT variables were expressed as a percentage of the total lung volume. CALIPER ~~gradetype~~ 2 and 3 DA lung were corresponded to areas of emphysema, [2], whilst ILD extent represented the sum of ground glass opacity and reticular pattern.

Automated stratification of CALIPER-variables:

Global and regional dissimilarities in distribution of the 8 patterns quantified by CALIPER within 12 zones were evaluated by a dissimilarity metric as previously described- [12].

Regional dissimilarities were discerned using 3 components. Within a single lung, differences in regional lung volume as a proportion of the total lung volume were calculated. Between any two lungs, dissimilarities in the proportions of absolute lung volumes in corresponding regions and dissimilarities in the proportions of specific parenchymal patterns in the corresponding regions were calculated.

The dissimilarity metric was used to compare all 98 HP cases in a pairwise manner and the resultant 98x98 matrix was stratified using unsupervised affinity propagation [20] to identify unique clusters representing patient groups with shared parenchymal characteristics. An a priori specification of the number of expected clusters was not imposed, as affinity propagation derives naturally occurring clusters using real-valued message exchange- [20].

#### Statistical analysis:

Data are given as means with standard deviations, or numbers of patients with percentages where appropriate. Interobserver variation for the visual scores was calculated using the single determination standard deviation- [21]. CALIPER analysis of 11 interspaced and volumetric CTs was compared using the independent samples T test, (significance = $p < 0.05$ ). Univariate and multivariate Cox regression analyses were used to investigate relationships within and between: CALIPER and visual CT evaluation and PFIs. [Linear regression analyses](#)

were used to characterise relationships between cardinal pulmonary function indices and CT scores of ground glass opacity and reticular pattern.

Comparisons of functional and morphological indices between automated stratified groups were examined using one-way analysis of variance (ANOVA) and post-ANOVA pairwise T test analyses using the Bonferroni correction for multiple analyses. Cox regression analysis and Kaplan Meier survival curves were used to identify survival differences between automated stratification results and the ILD-GAP staging system. Survival distributions were compared using the Log rank test, and bootstrapped with 1000 randomly generated samples. The automated stratified groups were then substituted for PFIs in the ILD-GAP staging system resulting in the creation of a Stratified-CT model containing the following weighted variables: automated stratified group score, patient age and gender. Finally the automated stratified groups were combined with the ILD-GAP model to form a third final model termed the Stratified-GAP model. Model strength for the ILD-GAP, Stratified-CT and Stratified-GAP models was compared using receiver operating characteristic (ROC) curves, and measuring the area under the ROC curve (AUROCC) and Harrells C-Index- [22]. Statistical analyses were performed with STATA (version 12, StatCorp, College Station, TX, USA).

7 **RESULTS**  
8

9  
10 Baseline results

11  
12 The median age of the cohort was 59 years, with 52% having died during the average follow  
13 up period of 69 months. Demographic data and average visual and CALIPER CT scores and  
14 PFI data are provided in Table 1. Interobserver variation for the visual scores is  
15 demonstrated in Supplementary Table 1. On average, visual scores identified more ILD than  
16 CALIPER. ILD mainly compromised reticular opacities on visual scoring as opposed to ground  
17 glass opacities as scored by CALIPER. CALIPER scores for ground glass opacity and reticular  
18 pattern correlated more strongly with cardinal pulmonary function indices than equivalent  
19 visual CT scores (Supplementary Table 3).  
20  
21

22 ~~Honeycombing was not identified as a distinct pattern on CALIPER evaluation of interspaced~~  
23 ~~datasets as honeycombing requires three dimensional information for characterisation.~~  
24 ~~Consequently, CALIPER honeycombing was not further analysed.~~ Evaluation of the 11 cases  
25 with concurrent interspaced and volumetric CT imaging demonstrated a significant  
26 difference in PVV extent between groups (p=0.03), with CALIPER classifying more vessels on  
27 interspaced images than volumetric scans (Figure 2)[Figure 1, Supplementary appendix].

46 Mortality analyses

47  
48 On univariate visual CT analysis reticular pattern, honeycombing, mosaicism and traction  
49 bronchiectasis were strongly predictive of mortality. All CALIPER-scored patterns except  
50  
51  
52  
53

1  
2  
3  
4  
5  
6  
7 emphysema and all PFIs were predictive of mortality on univariate analysis (Table 2). [The](#)  
8  
9 [results were maintained after adjusting for patient age and gender \(Supplementary Table 2\).](#)

10  
11 When visual parameters alone were analysed in a multivariate model, reticular pattern  
12  
13 (HR=1.05, CI 1.02-1.08, p=0.001) and ILD extent (HR=1.03, CI 1.01-1.04, p=0.01) were  
14  
15 independent predictors of mortality. Reticular pattern (HR=1.10, CI 1.02-1.18, p=0.02) and  
16  
17 PVV (HR=1.08, CI 1.01-1.15, p=0.02) were independently predictive of mortality on  
18  
19 multivariate analysis of CALIPER variables. Of the PFIs, DLco alone best described mortality  
20  
21 on multivariate analysis. When CALIPER, visual and PFI variables were analysed together in a  
22  
23 multivariate model, DLco and CALIPER reticular pattern were the only two independent  
24  
25 predictors of mortality (Table 2). [The results were maintained after adjusting for patient age](#)  
26  
27 [and gender \(Supplementary Table 2\).](#)

28  
29  
30  
31  
32 Automated stratification of CALIPER-derived groups:

33  
34 Automated stratification of HP patients identified 3 distinct groups with similar distributions  
35  
36 of CALIPER parenchymal patterns within each group (represented as glyphs in Figure 3).

37  
38 With progression from group 1 to 3, the proportion of the lung comprised of reticular  
39  
40 pattern, ground glass density and PVV increased, while the extent of normal lung and grade  
41  
42 1 DA decreased (Table 1). Mean PFIs also worsened with progression from group 1 to 3  
43  
44 (Table 1).

45  
46  
47  
48  
49 Significant functional differences across all groups were identified with FVC, TLC and CPI,  
50  
51 with differences in at least two groups identified with FEV1 and DLco ([Figure 4 and](#) Table 3).

1  
2  
3  
4  
5  
6  
7 Visual CT parameters demonstrated good separation between group 1 and groups 2 and 3  
8  
9 for parenchymal patterns indicative of fibrosis, and for mosaicism. However only ILD and  
10  
11 consolidation extents identified group separations between groups 2 and 3. CALIPER scores  
12  
13 for patterns indicating ILD and PVV demonstrated clear differences across all three  
14  
15 automated stratified groups. When the eleven cases with concurrent interspaced and  
16  
17 volumetric imaging were analysed by CALIPER and stratified, the volumetric cases mapped  
18  
19 to the same outcome groups as the interspaced cases (Figure 1, Supplementary appendix).  
20  
21  
22  
23

24 Survival distributions between automated stratified groups are demonstrated in Figure [45a](#)  
25  
26 ( $p < 0.0001$  Log rank test). Cox regression analysis demonstrated that separation of patients  
27  
28 into automated stratified groups was strongly predictive of mortality (HR=2.74, CI 1.86-4.05,  
29  
30  $p < 0.0001$ ). A mortality effect from automated stratification was maintained following  
31  
32 correction for age, gender and baseline disease severity using the CPI (group stratification =  
33  
34 HR 1.95, CI 1.15-3.29,  $p = 0.01$ ) and DLco (group stratification = HR 2.05, CI 1.23-2.41,  
35  
36  $p = 0.006$ ). When automated stratified groups were evaluated against DLco tertiles in a Cox  
37  
38 proportional Hazards analysis, both DLco tertiles ( $p = 0.001$ ) and automated stratified groups  
39  
40 ( $p = 0.002$ ) were equivalent in their ability to predict outcome following bootstrapping of  
41  
42 1000 samples.  
43  
44  
45

46  
47 The ILD-GAP model separated patients according to age, gender, FVC and DLco values  
48  
49 (scored on a nine point scale) into four outcome groups (Figure [45b](#)). A bivariate Cox  
50  
51 regression analysis, bootstrapped with 1000 samples demonstrated no difference between  
52  
53  
54

8 0.36-1.22).  
9

10  
11  
12  
13  
14 To compare the ability of the automated stratified groups to substitute for FVC and DLco in  
15 the ILD-GAP model, the three-point automated stratified group scale was converted into a  
16 five-point scale analogous to the five point scale for FVC (0-2) and DLco (0-3) in the ILD-GAP  
17 model. Automated stratified group 1 was converted to a score of 0, group 2 remained  
18 unchanged, whilst group 3 was converted to a score of 4. When the five-point automated  
19 stratified group scale was combined with patient age and gender (weighted on a three (0-2)  
20 and two-point (0-1) scale respectively, in accordance with the ILD-GAP model) an eight point  
21 scale was derived and converted into a four point automated stratified model (Stratified-CT  
22 model) using the same group divisions as the ILD-GAP model (scores of 0-1=1; scores of 2-  
23 3=2; scores of 4-5=3; scores >5=4) with good separation of outcome groups (Figure 45c; Log  
24 rank test  $p<0.0001$ ).

31  
32  
33  
34  
35  
36  
37  
38

39 The ordinal predictive power of the four-point Stratified-CT model was 0.73 as judged by  
40 Harrells C-Index, which was identical to the C-Index value of the ILD-GAP model (0.73).  
41

42  
43 When the three-point scale of the automated stratified groups were combined with the  
44 four-point scale of the ILD-GAP model, the new Stratified-GAP model had a C-Index value of  
45 0.77. Sensitivity and specificity for mortality prediction using the three models are  
46 demonstrated using ROC curves analysis in Figure 56, and was greatest with the Stratified-  
47 GAP model.

**DISCUSSION**

In the current study, a computer derived variable, CALIPER reticular pattern was stronger than all visual CT scores at predicting mortality in patients with HP. The current study has demonstrated for the first time that in conjunction with computer quantitation, automated stratification techniques can separate HP patients into prognostic groups that are functionally distinct and comparable to the ILD-GAP model for risk prediction. When automated stratification is combined with functional indices, patient age and gender, the resulting model is stronger than the ILD-GAP model alone at predicting mortality. Furthermore, survival across groups defined using automated stratification remains independent of baseline disease severity.

Automated stratification identified 3 unique HP groups that had distinct functional characteristics. The recognition of disease sub-groups is clinically desirable if it allows identification of high-risk patients that may benefit from aggressive interventions, yet limits unnecessary treatment in patients with quiescent disease- [23]. Computer analysis of CT imaging is attractive as a tool to generate repeatable and reproducible information across disease cohorts given its lack of interobserver variation and reproducibility. Furthermore, quantitative tools such as CALIPER can evaluate the entirety of a CT dataset providing a comprehensive analysis of an individual patient’s CT. Computer analysis has been used in emphysema cohorts with the aim of identifying distinct phenotypic groups [12; 24] with limited success- [25], but similar studies in individual ILD populations are sparse- [26].

The benefits of combining CT quantitation with automated stratification techniques lie in the emphasis on data to drive the identification of distinct phenotypic groups which can then be assessed to identify functional and prognostic similarities. The automated stratified groups in the current study were generated without any innate bias. The numbers and types of phenotypic clusters were not predetermined but were generated by the automated stratification process itself. Consequently, phenotypic features that might be overlooked with visual scores can be identified, and may be used to uncover populations with shared outcomes.

The comparable strength in risk stratification between the the ILD-GAP model and the automated stratification model suggests that computer analysis and automated modelling could have a role as outcome measures in clinical trials. For example discrete therapeutic responses or adverse reactions may become apparent, with a sensitivity potentially surpassing functional indices alone.

Against the complexity of stratified mathematical modelling, the simplicity of a glyph representation translates dense numerical datapoints into a format with clinical pertinence. Patients can use a glyph to understand the nature and extent of their particular disease. For clinicians meanwhile, the combination of a glyph mapped to a stratified group allows the characterisation of a patients disease phenotype at a glance in a busy clinic setting.

The difference in quantitation of ground glass opacity and reticular pattern between visual and CALIPER scores was largely secondary to differences in classification of a pattern where ground glass opacity is overlaid by reticular pattern. Visual scorers often disagree on such a pattern, and in the current study the visual scorers considered the pattern to represent reticular pattern, whilst as previously described [2], CALIPER classifies such a pattern as ground glass opacity.

The prognostic implications of an increasing CT reticular pattern extent identified in the current analysis confirms findings from a previous HP study; [27]. Fibrosis extent [27-30] and the decreased attenuation component of a mosaic attenuation pattern; [27], also demonstrated in the current study, have similarly been previously implicated as prognostic variables in HP. Conversely however, CALIPER grade 1 DA which partly corresponds to air trapping on CT, demonstrated a mild protective effect on univariate analysis. Traction bronchiectasis, in contrast to previous studies in HP [14] was not found to be a powerful multivariate predictor of mortality.

There were limitations to the current study. CALIPER was unable to classify honeycombing on interspaced imaging. Nevertheless, despite the loss of a strong prognostic variable, a CALIPER variable, reticular pattern, remained an independent predictor of mortality across the entire HP cohort. PVV was over-represented on interspaced imaging secondary to its requirement, like honeycombing, for three-dimensional patterns for optimal characterization. PVV is recognized by CALIPER as contiguous tubes followed to the lung

edge using tubular filters and three-dimensional region growing software. The PVV signal in the current study may have related to linear tubular structures that were predominantly “in plane” on a single interspaced image. However it is also possible that some of the characterized vessels may have represented reticular densities that were in fact misclassified as vessels. Nevertheless, whilst there appears to be a degree of overlap in CALIPER scoring of reticular pattern and vessels, both factors remained independent predictors of mortality when CALIPER variables were analysed. A final limitation lies in the lack of an external validation cohort with which to confirm the study findings. The scarcity of large HP populations even within tertiary referral centres made validation of our results challenging, but remains an important aim for future studies.

In conclusion, we have shown for the first time that computer quantitation and automated stratification of CTs (by CALIPER) generate variables that are powerfully predictive of mortality in HP. Automated stratification is able to distinguish patients with differing disease phenotypes that correspond to discreet functional groups, and is equivalent to functional indices in the ILD-GAP model in their ability to risk stratify patients with hypersensitivity pneumonitis. When combined with quantitative CT analysis, prognostication using the ILD-GAP model was found to improve.

**FIGURE LEGENDS:**

Figure 1. CONSORT diagram illustrating the selection of patients for the final study population. HP = hypersensitivity pneumonitis, HRCT = high resolution computed tomography, CT = computed tomography.

Figure 2. Coronal three-dimensional rendering ~~and~~ accompanying glyph of parenchymal patterns scored by CALIPER using interspaced imaging and corresponding colour overlay axial images at the lung bases using interspaced imaging (top images) and volumetric imaging (lower images). ~~The~~ Within the glyph the dark line separates right and left lungs and concentric circles overlying the glyph represented quintiles of lung volume. Examination of the glyph generated by the volumetric dataset demonstrates a shrunken left lung and right lower lobe both of which contain honeycombing. A greater volume of decreased attenuation lung is also evident in the right middle lobe when compared to the glyph generated from interspaced data. Dark green=normal lung, light green=grade 1 decreased attenuation, light and dark blue=emphysema, yellow=ground glass opacity, orange=reticular pattern, brown=honeycombing, white=pulmonary vessel volume.

Figure 3. Glyphs demonstrating the compositions of the three hypersensitivity pneumonitis groups (Group 1= left, group 2=middle, ~~group~~-3=right) derived following CALIPER CT analysis. Dark green=normal lung, light green=grade 1 decreased attenuation, light and dark blue=emphysema, yellow=ground glass opacity, orange=reticular pattern, brown=honeycombing, white=pulmonary vessel volume.

Figure 56. Receiver operating characteristic curves demonstrating sensitivity and specificity for mortality prediction using three models: ILD-GAP (blue, area under curve (AUC)=0.72, Confidence Interval (CI) 0.61-0.82,  $p=0.0002$ ); Stratified-CT (green, area under curve (AUC)=0.76, CI 0.66-0.85,  $p<0.0001$ ); Stratified-GAP (yellow, area under curve (AUC)=0.77, CI 0.6
