**Abstract:** Although the Wilson cycle is usually considered in terms of wide oceans floored with normal oceanic crust, numerous orogens result from the closure of embryonic oceans. We discuss how orogenic and post-orogenic processes may be controlled by the size/maturity of the inverted basin. We focus on the role of lithospheric mantle in controlling deformation and the magmatic budget. We describe the physical properties (composition, density, rheology) of three types of mantle: inherited, fertilized and depleted oceanic mantle. By comparing these, we highlight that fertilized mantle underlying embryonic oceans is mechanically weaker, less dense and more fertile than other types of mantle. We suggest that orogens resulting from the closure of a narrow, immature extensional system are essentially controlled by mechanical processes without significant thermal and lithological modification. The underlying mantle is fertile and thus has a high potential for magma generation during subsequent tectonic events. Conversely, the thermal state and lithology of orogens resulting from the closure of a wide, mature ocean are largely modified by subduction-related arc magmatism. The underlying mantle wedge is depleted, which may inhibit magma generation during post-orogenic extension. These end-member considerations are supported by observations derived from the Western Europe–North Atlantic region.

The paradigm now called the Wilson cycle (Dewey & Burke 1974) refers to the rift–drift–subduction–collision–collapse evolution occurring repeatedly along particular deformation belts. The model originates from the work of Wilson (1966), who first recognized that the distribution and evolution of the palaeofaunal assemblages of North America and Western Europe required the existence of a major ocean basin separating these continents during the lower and middle Paleozoic, whereas this ocean no longer existed from the late Paleozoic to the middle Mesozoic. Wilson’s theory has been widely used to describe the repeated opening and closure of continent collision zones, the conjugate pre-collision margins of which are implicitly considered to be separated by zones of normal oceanic crust.

Embryonic oceans and abandoned hyperextended rift systems are common geological features

(e.g. the Porcupine Basin and the Rockall Trough in the North Atlantic) and it is generally recognized that a significant number of orogens involved the closure of such immature rift systems – for example, the Alps (Sengör 1991), the Pyrenees (Boillot & Capdevila 1977) and most of the Variscides of Western Europe (Franke 2006). However, only a few researchers have attempted to distinguish between orogens resulting from narrow versus wide ocean basins (Sengör 1991; Chenin *et al.* 2017) and the question of whether minor oceans experience a Wilson cycle comparable with that of wide oceans has not been widely explored.

We focus here on immature extensional systems, which we define as extensional systems whose development stopped before a steady-state seafloor spreading system was initiated. Based on thought experiments and relying on recent data/concepts

and currently developed numerical models, we investigate how the characteristics of orogenic and post-orogenic processes resulting from the closure of such an immature extensional system may differ from those following the closure of a wide oceanic domain (Fig. 1). In particular, we investigate the evolution of the lithospheric mantle during extension and emphasize its impact on the localization of deformation and on the magmatic budget of subsequent tectonic events (i.e. orogenic collapse and/or rifting). We discuss how shortened or incomplete Wilson cycles may differ from the classical Wilson cycle in the light of natural examples from the well-studied Western Europe–North Atlantic region. This region is of particular interest because it consists of orogens resulting from the closure of both narrow (<500 km) and/or immature hyperextended rift systems (the Variscides of Western Europe) and wide mature oceans (the Scandinavian Caledonides).

## Characteristics of extensional systems

### *First-order characteristics*

Extension of the lithosphere, from orogenic collapse to hyperextension and eventual seafloor spreading, is usually achieved through a succession of deformation phases, which form a series of domains with relatively consistent characteristics (Peron-Pinvidic *et al.* 2013; Sutra *et al.* 2013; Chenin *et al.* 2017). Note that we use the term hyperextension to refer to the stage starting when the crust has been stretched to full embrittlement, usually at a crustal stretching factor of *c.* 3–4 (Perez-Gussinyé & Reston 2001), and ending either when subcontinental mantle starts to be exhumed or when steady-state seafloor spreading initiates. As extension progresses, the crust and the lithospheric mantle are increasingly modified by strain localization, thermal perturbations, magmatic additions and phase transformations. However, as rifting is generally a localization process progressively focusing deformation until the onset of steady-state seafloor spreading, the specific characteristics formed during the successive stages of extension are preserved from the proximal to the distal part of rifted margins (Fig. 2b; Manatschal *et al.* 2015).

We consider three major stages of extension, each being associated with the formation of specific physical characteristics (Fig. 2a): (1) the orogenic collapse and early rifting stage, also called the stretching phase; (2) the hyperextension and possible exhumation stage; and (3) the oceanic stage.

*Orogenic collapse.* The orogenic collapse stage is characterized by gravitational (i.e. topographic) re-equilibration of an over-thickened lithosphere after the termination of orogeny (Dewey 1988; Rey *et al.* 2001). Orogenic collapse is usually more or

less radial, characterized by extension achieved via normal and low-angle detachment faulting in the high-elevation domain (over-thickened crust), compression expressed as thrusting towards the lower elevation surrounding area and strike-slip faulting at all elevations (Dewey 1988; Andersen 1998). These result in an intense structural inheritance. In some cases, orogenic collapse is accompanied and/or followed by intense magmatic activity, as evidenced by widespread mafic to acidic intrusions – for instance, in the crust in the Variscan area, in the Basin and Range Province and in the Canadian Cordillera (Costa & Rey 1995; Vanderhaeghe *et al.* 1999; Rey *et al.* 2001; Petri *et al.* 2016). These former orogenic areas display a flat Moho and a strong seismic layering of the lower crust (Bois *et al.* 1989; Rey 1993; Vanderhaeghe 2009), interpreted as mafic underplating resulting from the partial melting of the underlying asthenosphere (Goodwin & McCarthy 1990; Costa & Rey 1995) or as sheared, formerly ductile or partially molten lower crust (Vanderhaeghe 2009). We use the term magma-poor orogenic collapse to refer to (classical) orogenic collapse that is devoid of extensive magmatic activity (e.g. the Caledonian orogenic collapse; Meissner 1999; Fossen *et al.* 2014) and magma-rich orogenic collapse for the opposite case.

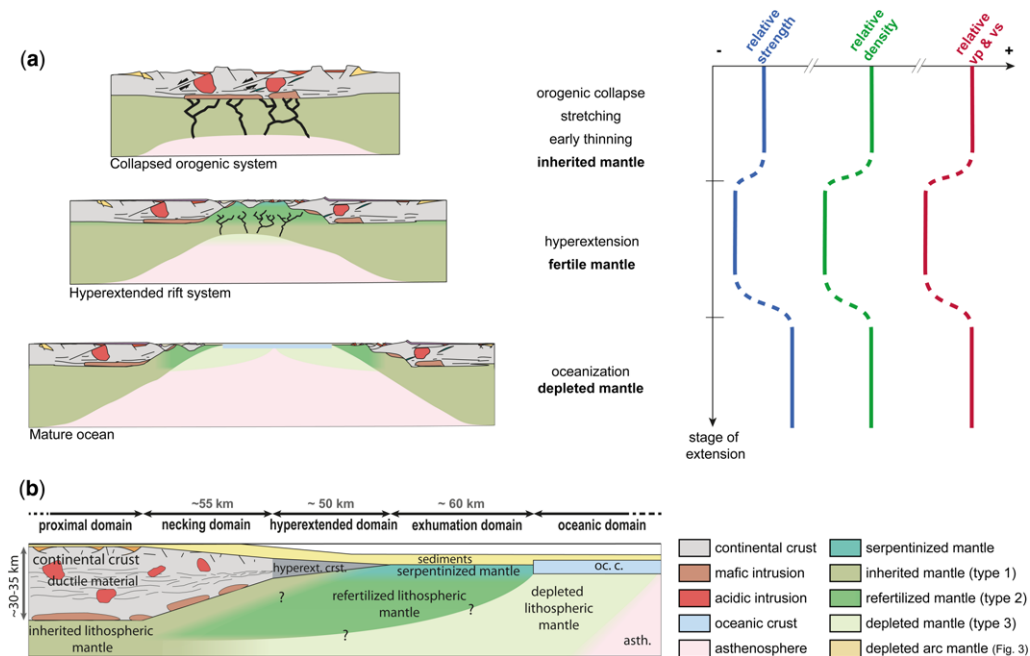

After orogenic collapse, the thermal heterogeneities are rapidly re-equilibrated (in a few tens of millions of years; see Jaupart & Mareschal 2007). By contrast, most of the structural and lithological features inherited from orogenic collapse are essentially preserved. During the early stages of a subsequent rifting event (stretching and necking stages), extension does not significantly modify the lithology of the crust or lithospheric mantle (Picazo *et al.* 2016; Chenin *et al.* 2017). Thus the lithology of the crust and lithospheric mantle in the proximal and necking domain of continental margins are comparable (Fig. 2b).

*Hyperextension/continental mantle exhumation.* On further extension, a rift system may reach the stage of hyperextension (Sutra *et al.* 2013; Doré & Lundin 2015) and possibly the stage of mantle exhumation. These stages correspond, respectively, to thinning of the fully embrittled crust from *c.* 10 km to the exhumation of the subcontinental lithospheric mantle at the seafloor. In these domains, the entire remaining crust and the shallowest part of the subcontinental mantle undergo intense hydrothermal circulation, which forms sericite and illite in crustal rocks (Manatschal 1999, 2004; Pinto *et al.* 2015) and serpentine, chlorite and talc up to 4–6 km depth in the lithospheric mantle (Hess 1955; Christensen 1970; Früh-Green *et al.* 2004; Picazo *et al.* 2012).

In addition to the hydrothermal alteration processes, hyperextension may lead to decompressional

**Fig. 1.** Classic view of the Wilson cycle and possible short-cuts (light grey arrows). Figure modified after Petri (2014).

**Fig. 2.** (a) Main characteristics of extensional systems at various stages of extension and corresponding physical properties of the lithospheric mantle at the centre of the rift (modified after Petri 2014). (b) First-order architecture and lithology of a typical magma-poor rifted margin (modified after Chenin *et al.* 2017 and Picazo *et al.* 2016).

melting of the underlying asthenospheric mantle (Latin & White 1990). At the stage of hyperextension and exhumation, the resulting mid-ocean ridge basalt (MORB)-type melts are not, or are only partially, extracted and tend to stagnate in the overlying lithospheric mantle, fertilizing it (Müntener *et al.* 2010 and references cited therein). This process tends to progressively homogenize (on a large scale) the continental lithospheric mantle into plagioclase-bearing lherzolite in the uppermost *c.* 30 km of the mantle (Müntener *et al.* 2010; Picazo *et al.* 2016 and references cited therein). Thus orogenic and post-orogenic inheritance in the mantle and remnant continental crust are largely obliterated in the hyperextended and exhumation domains and their lithology is essentially controlled by rift-induced processes (Fig. 2b).

**Oceanization.** Ultimately, upwelling of the asthenosphere may generate a self-sustaining spreading system for moderate to high seafloor spreading rates (Mutter & Zehnder 1988; Huisman *et al.* 2001). In this case, a *c.* 6–7 km thick mafic oceanic crust with a remarkably homogeneous composition (e.g. Gale *et al.* 2013) is formed (Bown & White 1994; Dick *et al.* 2003). At the same time, the underlying asthenospheric source mantle is generally thought to evolve from a lherzolite depleted only in highly

incompatible elements to a harzburgite composition depleted in both major and trace elements (see Saunders *et al.* 1988, their fig. 7). Figure 2b illustrates the first-order architecture, lithology and mantle types at the rifted margins of a typical ocean.

### Evolution of the lithospheric mantle

Experimental studies, thermomechanical numerical modelling and flexure observations generally support the view that most of the strength of the lithosphere resides in the mantle (e.g. Chen & Molnar 1983; Burov & Watts 2006), although Maggi *et al.* (2000) and Jackson (2002) questioned the dominant strength of the upper mantle based on the focal depth of intraplate earthquakes. Thus during lithospheric-scale deformation, the lithospheric mantle appears to have a dominant role in controlling the localization of deformation (e.g. Gueydan *et al.* 2008; Rosenbaum *et al.* 2008). Anderson (2006) and Meyer *et al.* (2007) suggested that compositional heterogeneities within the mantle may control the nature and volume of magmatic activity. However, the mantle is still very poorly known and its impact on the characteristics of tectonic systems has been largely ignored. In the following analysis, we attempt to integrate the most recent knowledge – from small-scale petrological studies to large-scale geophysical studies – into a

## LITHOSPHERIC MANTLE AND THE WILSON CYCLE

coherent, first-order model of the evolution of the lithospheric mantle in extensional systems. Based on the petrological data from Western Europe reviewed by Picazo *et al.* (2016) and using the algorithms of Hacker *et al.* (2003), we provide estimates of the density and seismic velocities for the three types of mantle – namely, inherited (subcontinental), fertilized (hyperextended rift systems) and oceanic (steady-state seafloor spreading) mantle.

*Highly heterogeneous inherited mantle (mantle type 1).* There is growing evidence that the upper mantle is highly heterogeneous ‘in all parameters and at all scales’ (Anderson 2006), essentially as a consequence of tectonic and magmatic processes. These processes include, for example, subduction and the partial melting of hydrated and altered oceanic crust and the overlying sediments, the delamination and partial melting of thickened continental crust, and decompression and/or flux melting at subduction zones, all of which cause large-scale heterogeneities (Jagoutz *et al.* 2011). Partial melting of the upper mantle may also occur during both orogenic and post-orogenic evolution, such as in the Variscides (Timmerman 2004), contributing to regional compositional heterogeneities that are internally relatively homogeneous (Picazo *et al.* 2016). Interaction with possible rising plumes from the lower mantle may also modify the composition of the upper mantle (Baker *et al.* 1998). Therefore the lithospheric mantle in a former orogenic domain can be expected to be highly heterogeneous, which is supported by observations from the Variscan orogenic domain of Western Europe (Picazo *et al.* 2016) as well as regional density and P-wave velocity anomalies (Artemieva *et al.* 2006).

Table 1 provides end-member modal compositions for the inherited type of mantle (mantle type 1) based on the modal composition of peridotites in the Western and Central Alps (Müntener *et al.* 2010) and assuming that the compositional variability of the subcontinental mantle is comparable across Western and Central Europe (Picazo *et al.* 2016). We distinguish between a fertile end-member (mantle type la; Table 1) and a depleted end-member (mantle type lb; Table 1) that underwent an intense episode of partial melting – namely, the thermal event that followed the collapse of Variscan topography. Note that this type of mantle is rarely exhumed (McCarthy & Müntener 2015). The density of the fertile and depleted end-members are comparable at pressures <2.5 GPa (80 km), but at 2.5 GPa the depleted end-member (mantle type lb) is denser by 2% than the fertile end-member (mantle type la; Table 2 and Fig. 3b). P- and S-wave seismic velocities are faster by *c.* 1.2 and 1.5%, respectively, in mantle type lb than in mantle type la at pressures

**Table 1.** Modal compositions of different types of mantle

Mantle type	Pressure (GPa)	ol (%)	ol Mg#	spi (%)	spi Mg#	cpx (%)	cpx Mg#	opx (%)	opx Mg#	plg (%)	plg An%	grt (%)	py (%)	alm (%)	gro (%)

We consider the mineralogical variation due to depth (i.e. pressure); values highlighted in grey represent rare or unlikely existence in natural systems. Inherited mantle (mantle type 1) is highly heterogeneous, therefore we consider its composition ranges between a fertile (mantle type la) and a post-orogenic collapse depleted (mantle type lb) end-member. The composition of the fertilized and oceanic types of mantle are average and/or ideal compositions.  
 cpx, clinopyroxene; grt, garnet; ol, olivine; opx, orthopyroxene; plg, plagioclase; spi, spinel; An%, anorthite mole per cent content; Mg#, Mg number = Mg/(Fe<sub>tot</sub> + Mg); py%, alm% and gro% and gro% of mantle are and grossular garnet mole per cent content.

Values highlighted in grey represent rare or unlikely existence in natural systems.

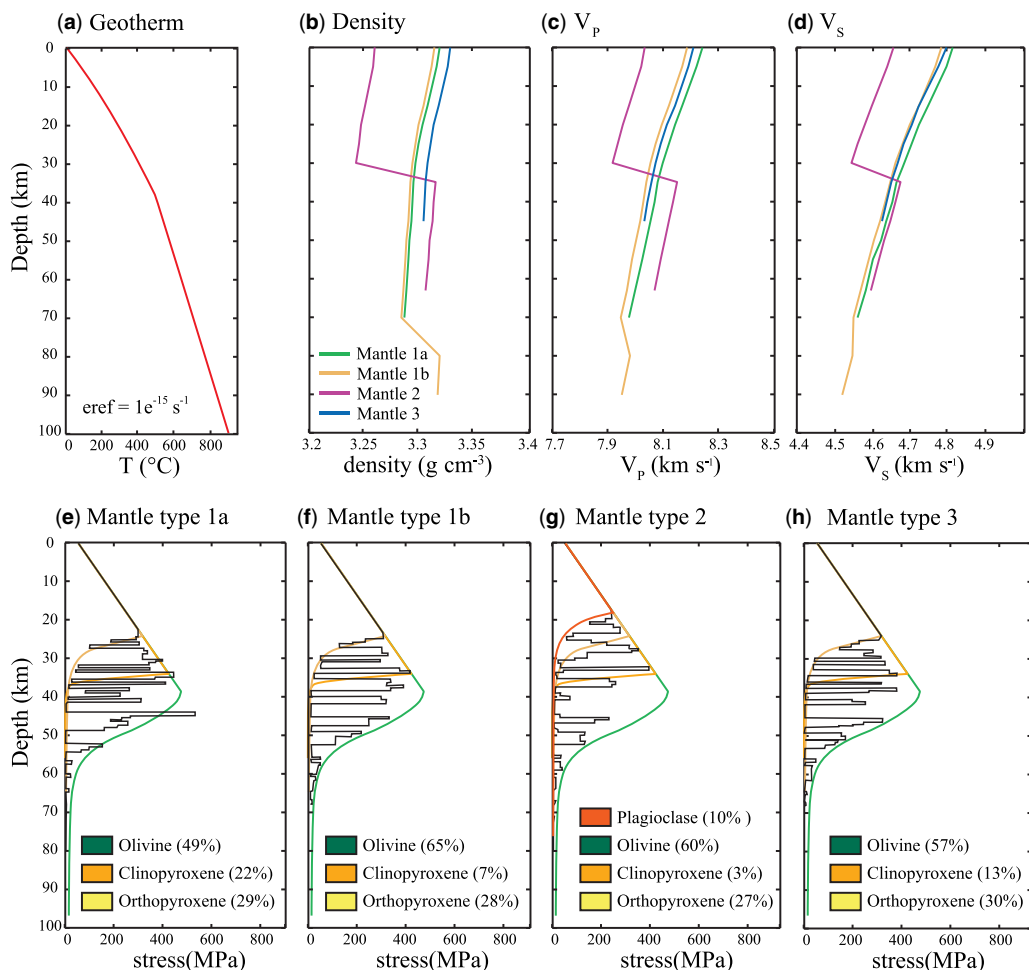

<2.5 GPa and comparable for pressures >2.5 GPa (Table 3, right-hand side of Fig. 2a and Fig. 3c, d).

To estimate the relative strength of the different types of mantle (Fig. 3), we built a depth-dependent stress profile based on average mineralogical compositions (Table 1) using the polymineralic parametrization developed by Jammes *et al.* (2015) and Jammes & Lavier (2016). The polymineralic rheology is created by randomly distributing the mineral phases and their rheological properties among the elements of numerical grids. For each phase, the parameters of the viscous flow law are obtained from laboratory measurements. We use dry olivine (Goetze & Poirier 1978), clinopyroxene (Hier-Majumder *et al.* 2005), orthopyroxene (Raleigh *et al.* 1971) and plagioclase (Shelton & Tullis 1981) in different proportions depending on the mantle type (see Table 1 for percentages). For each mineral phase, the transition from brittle to ductile behaviour depends on the plastic strain, temperature and pressure in the corresponding element. Therefore, under certain conditions of pressure and temperature, the polymineralic material generated is semi-brittle because one or two phases deform in a brittle manner while the other phase exhibits a ductile behaviour, or semi-ductile when all phases deform in a ductile manner, but present an important difference in strength (Jammes *et al.* 2015; Jammes & Lavier 2016). Because the distribution of the mineral phases in this type of model is random, we built the depth-dependent stress profile for one

$x$ -coordinate using the geothermal gradient shown in Figure 3a and a strain rate equal to  $10^{-15} \text{ s}^{-1}$ . The comparison between the depth-dependent stress profile obtained for the polymineralic material (black curve in Fig. 3) and each mineral phase (olivine, clinopyroxene, orthopyroxene and plagioclase; see corresponding coloured curves in Fig. 3e–h) allows us to identify the different rheological behaviours (brittle, semi-brittle, semi-ductile, ductile) as a function of the depth in the mantle.

Figure 3e, f show the depth-dependent stress profile of the fertile inherited mantle end-member (mantle type 1a) and the depleted inherited mantle end-member (mantle type 1b). The depth-dependent stress profile of olivine, clinopyroxene and orthopyroxene are also plotted for comparison. For mantle types 1a and 1b, we observe that below 25 km depth the mantle is characterized by a brittle behaviour. Between 25 and 40 km, only olivine is in the brittle regime, so that the mantle is characterized by a semi-brittle behaviour. Numerical models predict that, in this case, deformation is accommodated by localized anastomosing shear zones (Jammes *et al.* 2015; Jammes & Lavier 2016). Between 40 and 60 km depth, the three mineral phases are in the ductile regime, but there is still an important strength contrast between olivine and pyroxene. The rheological behaviour is then described as semi-ductile and numerical models predict the formation of localized anastomosing shear zones (Jammes *et al.* 2015; Jammes & Lavier 2016). Beyond 60 km depth, the

## LITHOSPHERIC MANTLE AND THE WILSON CYCLE

**Fig. 3.** (a) Geothermal gradient and strain rate ( $\epsilon_{ref}$ ) used for calculation of the different profiles shown in this Figure, (b) Density, (c) P-wave and (d) S-wave seismic velocities of the four types of mantle along the geotherm shown in panel (a); (e–h): Depth-dependent stress profile of the different types of mantle designed using the parametrization of Jammes *et al.* (2015). We consider only the main minerals (proportion >5%), namely olivine, pyroxene and plagioclase feldspar, (e) Mantle type 1a: Inherited mantle – fertile end-member (f) Mantle type 1b: Inherited mantle – depleted end-member; (g) Mantle type 2: Fertilized mantle; (h) Mantle type 3: Depleted oceanic mantle.

deformation is fully ductile and numerical models predict the formation of distributed shear zones (Jammes *et al.* 2015; Jammes & Lavier 2016).

The main difference between the fertile inherited (1a) and depleted inherited (1b) mantle is the relative proportion of olivine and clinopyroxene. The work by Jammes *et al.* (2015) suggests that this variation affects the localization of the deformation. A decrease in the percentage of weak phases (orthopyroxene and clinopyroxene) in favour of strong phases (olivine) localizes strain, which may lead to the formation of localized shear zones. As a consequence,

we expect that deformation will localize earlier in an inherited depleted mantle than in an inherited fertile mantle.

*Fertilized mantle (mantle type 2).* Growing evidence supports that, during hyperextension, the infiltration and stagnation of melt resulting from asthenospheric decompression melting fertilizes the overlying sub-continental lithospheric mantle (e.g. Müntener *et al.* 2004). Observations by Picazo *et al.* (2016) support the view that fertilized mantle evolves progressively from a highly heterogeneous composition

**Table 3.** Seismic velocities corresponding to the composition of the different mantle types defined in *Table 1* calculated using the algorithm by *Hacker et al. (2003)*

## LITHOSPHERIC MANTLE AND THE WILSON CYCLE

with essentially inherited mantle (mantle type 1) characteristics in the proximal part of the hyperextended domain towards an ideally homogeneous plagioclase-bearing peridotite in more distal parts of the domain (mantle type 2; see Table 1).

To calculate the density of fertilized mantle (mantle type 2), we use the modal composition of Western and Central Alps ophiolites from Müntener *et al.* (2010) and assume that the composition of fertilized mantle is comparable (Picazo *et al.* 2016). Fertilized mantle is characterized by a density reduced by *c.* 1.4% relative to mantle type 1 for pressures <1 GPa (*c.* 35 km) (Table 2, Fig. 3b; see also Simon & Podladchikov 2008). Fertilized mantle becomes denser at greater depths due to higher amounts of modal garnet. However, because the amount of fertilized mantle is extremely limited compared with that of inherited mantle, this effect can be neglected.

Fertilized mantle is also characterized by seismic velocities that are reduced by *c.* 1% for pressures up to 1 GPa and by >2% at greater pressures (Table 3, Fig. 3c, d). This difference may partly explain the anomalous (i.e. not only due to temperature) decrease in seismic velocity commonly observed in the mantle underlying immature basins (incipient or abandoned rift systems) or at hyperextended rifted margins – for example, beneath the southern part of the Porcupine Basin (O'Reilly *et al.* 2006) and beneath the hyperextended part of the Iberian margin (Afilhado *et al.* 2008), Newfoundland margin (Lau *et al.* 2006) and Flemish Cap (Funck 2003). Although serpentinization is presumably the main cause of the decrease in velocity up to 6 km beneath the seafloor, it cannot account for the decrease at greater depths because serpentine becomes unstable. The existence of fertile mantle may account for reduced velocity up to 10 km beneath the seafloor.

The existence of plagioclase in the fertilized mantle (mantle type 2) strongly affects the depth-dependent stress profile. Figure 3g shows that plagioclase is weaker than both pyroxene and olivine. As a result, the fertilized mantle has a semi-brittle behaviour between 18 and 40 km. The domain where deformation can be accommodated along localized anastomosing shear zones is consequently wider than in the inherited mantle, which favours decoupling of the deformation. Because the rheology and thickness of the decoupling layer strongly control contractional deformation processes (Beaumont *et al.* 1994; Pfiffner *et al.* 2000; Jammes & Huisman 2012), the weaker rheology of fertilized mantle may have major consequences for the localization of deformation at the onset of basin reversal.

*Homogeneous mid-ocean ridge mantle (mantle type 3).* During steady-state seafloor spreading, the asthenospheric mantle is undergoing decompression melting and produces a remarkably homogeneous

oceanic crust (MORB). Even if it was initially heterogeneous, the remaining mantle source becomes uniformly depleted because of the relatively high degree of partial melting (Anderson 2006). In contrast to fertilization, depletion related to seafloor spreading has a limited effect on density (<0.5% variation; Table 2, Fig. 3b) and on seismic velocity (mantle type 3 faster by *c.* 0.6% than mantle type 1; Table 3, Fig. 3c, d; Schutt & Lesher 2006). Note that density and velocity variations related to thermal anomalies and to the presence of melt are thought to be much more important than those related to composition in the upper mantle (Sobolev *et al.* 1996; Goes *et al.* 2000; Cammarano *et al.* 2003).

### Reversal and collision of extensional systems

Any extensional system may be reversed when the background stress changes to relative compression. We describe how the characteristics of the resulting orogen and possible subsequent extensional events (orogenic collapse and/or rifting) may be influenced by the size/maturity of the extensional system involved.

#### *Collapsed orogenic systems*

During the reversal of a collapsed system or of a rift basin that never reached the stage of hyperextension, shortening is presumably not sufficient to cause significant thermal or compositional modification of the crust or mantle. The reversal of systems with small extensions (rifts) is dominantly a mechanical process, governed by structural, lithological and thermal inheritance (Sengör 1991; Chenin *et al.* 2017).

In the case of a magma-poor orogenic collapse, structural inheritance dominates largely over thermal and lithological inheritance. Structural inheritance provides immediate and long-term weaknesses, which are usually reactivated during subsequent tectonic events when appropriately oriented with respect to the stress direction (Ring 1994; Withjack *et al.* 2010).

However, in the case of a magma-rich collapse, the thermal and lithological inheritance may dominate over structural heterogeneities. In the early stages of orogeny or orogenic collapse, the orogenic domain is characterized by a high heat flow due to high radiogenic production in the over-thickened crust and/or from percolating melts caused by the partial melting of the lower crust and/or the asthenosphere. This hot thermal state results in weakening of the orogenic region, favouring the localization of deformation during subsequent tectonic events (see Huisman & Beaumont 2011; Brune *et al.* 2014; Petersen & Schiffer 2016).

When most of the topography has been eroded and the lithosphere has thermally recovered, a significant proportion of the crust may consist of mafic intrusions and granulite facies rocks, which result from the magmatic event or from deep burial. After the termination of magmatic activity and associated heat advection, these rocks contribute to lower geothermal gradients because their radiogenic production is lower than that of average continental crust (for a review, see [Krabbendam 2001](#)). Mafic intrusions have a stronger rheology than the encompassing quartzo-feldspathic crust (e.g. [Kohlstedt \*et al.\* 1995](#)). As a result, the former orogenic region becomes relatively strong and is less deformed during subsequent tectonic events ([Yamasaki & Gernigon 2009](#); [Chenin \*et al.\* 2015](#)).

### *Hyperextended rift systems to embryonic oceans*

Examples of orogens resulting from the closure of a hyperextended rift system or immature ocean include the Pyrenees ([Lagabrielle & Bodinier 2008](#); [Tugend \*et al.\* 2015](#)) and the Alps ([Mohn \*et al.\* 2014](#)). In both cases, orogeny was essentially a mechanical process largely devoid of subduction-related magmatic activity, thus the architecture of the initial margins is relatively well preserved ([Beltrando \*et al.\* 2014](#); [Mohn \*et al.\* 2014](#); [Tugend \*et al.\* 2015](#)).

In the Pyrenees, the Alps and the southern Iberian abyssal plain, compressional deformation initiated at the limit between either the hyperextended and the exhumation domains, or within the exhumation domain ([Peron-Pinvidic \*et al.\* 2008](#); [Tugend \*et al.\* 2014](#)). [Peron-Pinvidic \*et al.\* \(2008\)](#) and [Lundin & Doré \(2011\)](#) proposed that serpentine may act as a stress guide during subduction initiation because it is weaker than peridotite, continental crust and oceanic crust (e.g. [Ulmer & Trommsdorff 1995](#); [Escartm \*et al.\* 2001](#); [Hilairt \*et al.\* 2007](#)). However, because serpentinization affects only the upper 6 km of the mantle in the exhumation domain, its effect may be restricted to a relatively superficial level. We suggest that the difference in density and strength ([Table 2](#), [Fig. 3](#)) between fertile mantle (mantle type 2) and inherited mantle (mantle type 1) or between fertile mantle and depleted mid-ocean ridge mantle (mantle type 3) may act as a stress guide for subduction initiation at greater depths (6–30 km).

The lack of significant subduction-related magmatism in the Pyrenees and the Alps was interpreted by, respectively, [Boillot & Capdevila \(1977\)](#) and [Sengör \(1991\)](#) as a consequence of the narrow width of the closing ocean, which did not allow for significant decompression and/or flux melting. As a result, the mantle underlying orogens resulting

from the closure of a hyperextended rift system or a narrow embryonic ocean is likely to be fertile. It is presumably hydrated and enriched by mobile components from subducting sediments, oceanic crust and dehydrating serpentinite ([Anderson 2006](#)). This fertile composition may add to the already fertile sub-lithospheric mantle preserved from the rift-related melt impregnation and provide fusible components for subsequent magmatic events ([Fig. 2b](#); [Chenin \*et al.\* 2017](#)).

### *Wide/mature oceans*

In contrast with the quasi-amagmatic closure of hyperextended rift systems, protracted subduction associated with the closure of a wide ocean is accompanied by intense magmatic activity, which forms volcanic arcs ([Uyeda 1981](#)). Subduction-related magma is generated by flux melting of the wet mantle wedge resulting from slab dehydration, and decompression melting of the hot asthenosphere, which rises to compensate the down-dragging of mantle wedge material by the slab ([Iwamori 1998](#); [Sisson & Bronto 1998](#); [Jagoutz \*et al.\* 2011](#)). These melting processes deplete the source mantle wedge, as recognized by [Martinez & Taylor \(2002\)](#) in the Lau and Mariana back-arc regions. This observation suggests that the incoming asthenosphere does not bring enough fertile material to equilibrate with the amount of fertile material that is taken out by arc magmatism and therefore orogens resulting from the closure of a wide ocean are potentially underlain by relatively depleted mantle ([Chenin \*et al.\* 2017](#)).

The extraction of mafic melts towards the surface also strongly affects the lithology and the thermal state of the hanging wall ([Miyashiro 1961, 1967](#); [Ernst \*et al.\* 1970](#); [Gerya 2011](#)). If the magmatic arc is intra-oceanic, it will be accreted in the orogenic wedge, whereas if the arc is built on the upper plate continental margin, it will affect the continental crust inboard of the future suture zone. In both cases, strong inheritance is expected in the orogenic domain.

## **Hyperextended rift systems versus mature oceans and the Wilson cycle in the North Atlantic**

The Wilson cycle states that ocean basins open and close following roughly the same lines, which suggests a major structural control of inheritance. Among the inherited features supposed to facilitate extension and rifting, we can mention structural weaknesses or fabric (e.g. [Ring 1994](#); [Vauchez \*et al.\* 1997](#)), compositional inheritance (e.g. [Ryan & Dewey 1997](#); [Yamasaki \*et al.\* 2006](#); [Petersen & Schiffer 2016](#)) and thermal inheritance (e.g.

## LITHOSPHERIC MANTLE AND THE WILSON CYCLE

Yamasaki & Gernigon 2009; Vanderhaeghe 2012), which can exist in the crust as well as in the mantle. However, although complete Wilson cycles have been recognized in several places, occurring sometimes repeatedly along the same region (Thomas 2006), the theory is challenged in other regions (Krabbendam & Barr 2000). In particular, in Western Europe, most of the Variscan sutures were not reactivated during the Mesozoic extensional phases, either by the North Atlantic rift, or by the Alpine

Tethys rift system (Frizon de Lamotte *et al.* 2011). This implies that either orogenic inheritance and/or post-orogenic processes vary among orogens.

The work by Chenin *et al.* (2015) and references cited therein highlighted major differences in the behaviour of the North Atlantic rift system, depending on whether it affects the Caledonian or Variscan orogenic lithosphere. In the northern North Atlantic, the rift parallels the Caledonian suture, rifting is protracted and polyphase and break-up is accompanied

**Fig. 4.** Illustration of the two end-members proposed for the Wilson cycle in the North Atlantic. See Figure 2 for colour legend.

by intense magmatic activity. By contrast, in the southern part of the North Atlantic, the rift circumvents the Variscan orogenic domain in Western Europe, the duration of rifting is much shorter than in the north and the break-up is magma-poor. They also noted that the orogenic collapse of the Scandinavian Caledonides was largely devoid of magma (Meissner 1999; Fossen *et al.* 2014), whereas the collapse of the Variscides was followed by intense magmatic activity (Costa & Rey 1995; Schaltegger 1997; Petri 2014).

One major difference between the Scandinavian Caledonides and the Variscides of Western Europe is the number and size of ocean basins involved. The Scandinavian Caledonides resulted from the closure of the wide Iapetus Ocean between the two large Laurentian and Baltic cratonic shields, with only the limited accretion of magmatic arcs or terranes between Norway and Greenland (Roberts 2003; van Staal *et al.* 2012). By contrast, the Variscides of Western Europe resulted from the closure of a series of narrow oceans (<500–1000 km; McKerrow *et al.* 2000), in addition to the closure of the wide Rheic Ocean (Franke 2006; Kroner & Romer 2013).

As highlighted in the previous sections, major differences in the characteristics of orogens can be expected, depending on whether they arise from the closure of a narrow hyperextended rift system or a wide and mature ocean. In particular, we focused this study on the role of the lithospheric mantle because it is often regarded as the strongest lithospheric layer and thus would largely control most tectonic events (e.g. Burrov & Watts 2006).

During a Wilson cycle, the mantle lithosphere may be modified by three different processes: (1) thermal processes, which may affect any part of the lithosphere, but with transient effects; (2) mantle depletion or enrichment due to the interactions of mantle rocks with melt – these compositional modifications may arise across the entire mantle lithosphere; and (3) serpentinization due to the hydration of mantle rocks, which is limited to shallow depths (with the exception of supra-detachment systems). These processes affect both the rheology and the melting potential of the mantle. For instance, the relatively fertile mantle presumed to underlie orogens resulting from the closure of narrow hyperextended rift systems may explain the magma-rich collapse of the Variscides of Western Europe. By contrast, the magma-poor collapse of the Scandinavian Caledonides could be explained by the depleted mantle that may underlie orogens formed after long-lasting subduction and arc magmatism systems.

The magmatic budget of orogenic collapse may have a strong influence on the localization of future extension. Although Caledonian orogenic and post-orogenic structures were largely reactivated during the rifting of the northern North Atlantic between

Norway and Greenland, illustrating the classic Wilson cycle, possible thermally equilibrated mafic underplating of the crust in the Variscan domain would have formed a strong core, which the subsequent Alpine Tethys and southern North Atlantic rifts circumvented.

Thus we propose two end-members for the Wilson cycle in the North Atlantic, depending on the maturity of the extensional system involved (Fig. 4). The classic Wilson cycle applies to the Scandinavian Caledonides. It involves: (1) the formation of a wide ocean; (2) protracted subduction of the oceanic domain forming magmatic arcs and depleting the mantle wedge beneath the orogen; (3) magma-poor orogenic collapse preserving both orogenic and post-orogenic structures; and (4) rifting within the former orogenic area when renewed extension takes place.

An incomplete Wilson cycle applies to the Variscides of Western Europe. It is characterized by: (1) the formation of a series of narrow oceans or hyperextended rift systems; (2) their closure, which is essentially mechanical and largely devoid of magmatic activity; (3) magma-rich orogenic collapse causing widespread underplating of the continental crust; (4) a long relaxation time leading to strengthening of the orogenic area; and (5) rifting outside the orogenic area during subsequent extension.

## Conclusions

During the reversal of an extensional system and ultimate collision, the size and maturity of the basin/ocean involved presumably have a major control on the orogenic and post-orogenic evolution. In particular, the fertilization processes of the lithospheric mantle during hyperextension, together with the lack of depletion caused by subduction-related magmatism during the closure of a narrow/immature ocean, allow for a relatively fertile mantle composition beneath the orogen. By contrast, the underlying mantle is proposed to be relatively depleted beneath orogens resulting from the closure of wide/mature oceans, both due to the depleted composition of the slab and the arc-related partial melting of the mantle wedge. Because the composition of the mantle controls both its rheology and its ability to melt, it probably influences both the localization and magmatic budget of subsequent tectonic events. This may help to explain the different behaviour of the North Atlantic rift depending on whether it affected the orogenic lithosphere of the Scandinavian Caledonides or the Variscides of Western Europe.

Despite its potential first-order control, the lithospheric mantle remains very poorly known and therefore further studies on the characteristics and evolution of the subcontinental mantle in various

## LITHOSPHERIC MANTLE AND THE WILSON CYCLE

tectonic settings, from outcrop to regional scales, are desperately required.
