### ABSTRACT

In recent decades, Boa Viagem beach located in the city of Recife-PE and Piedade in Jaboatão dos Guararapes-PE (Brazil) has seen urbanization near the coastline causing changes in social, economic and morphological aspects, where coastal erosion problems are observed. This study uses GNSS (global navigation satellite system) shoreline monitoring approach, which is quicker, and provides continuously updatable data at cm-level accuracy to analyze and determine temporal positional shifts of the shoreline as well as annual average rates through EPR (end point rate). To achieve this, kinematic GNSS survey data for the years 2007, 2009, 2010 and 2012 were used. The results show sectorial trends over the years, with the highest annual retreat rate of 8.16 m /year occurring during the period 2007-2009. Variety of different patterns over the shoreline were also observed. These findings could be essential for decision making in coastal environments.

**Keywords:** Shoreline, monitoring, GNSS, coastal erosion, coastal settlement.

### RESUMO

Nas últimas décadas, a praia de Boa Viagem localizada no município de Recife-PE e de Piedade no município de Jaboatão dos Guararapes-PE vem sendo urbanizadas próximas à linha de costa provocando grandes transformações nas relações sociais, econômicas e morfológicas, onde problemas de erosão costeira são observados. O presente trabalho faz uso monitoramento da linha de costa utilizando o GNSS (*global navigation satellite system*) que oferece rapidez, repetibilidade e acurácia centimétrica para determinar e analisar os deslocamentos temporais da linha de costa assim como as taxas de deslocamento médias através do EPR (*end point rate*). Para isso, foram utilizados dados obtidos através de levantamentos geodésicos relativos cinemáticos para os anos de 2007, 2009, 2010 e 2012. Os resultados representam tendências setoriais através dos anos onde a maior taxa de recuo encontrada foi de 8,16 m/ano encontrada no período de 2007-2009. Uma variedade de diferentes padrões sobre a linha de costa foram observados. Os resultados obtidos são considerados fundamentais para tomada de decisão em ambientes costeiros.

**Palavras-chave:** Linha de Costa, monitoramento, GNSS, erosão costeira, ocupação costeira.

### 1. INTRODUCTION

A shoreline is one of the most dynamic geomorphological features of our planet. Several studies involving its concept and modeling have been developed both nationally in Brazil (Tanajura et al., 2011; Gonçalves et al., 2010; Almeida, 2008; Rocha et al., 2008; Ribeiro, 2005; Angulo, 1996), and globally (Smith and Cromley, 2012; Jackson et al., 2012; Baptista et al., 2011; Stockdon et al., 2002; Thieler and Danforth, 1994, among others). The shoreline monitoring is necessary for the purpose of integrating coastal zone management (ICZM), where the positional and dynamical information are fundamental for territorial planning, as well as for learning the process of coastal evolution providing information to protect, plan, and make decisions in relation to coastal environment (Veloso-Gomes et al., 2008; Tzatzanis et al., 2003).

Shoreline monitoring at higher temporal resolution is essential for mitigating the impacts of coastal erosion that has recently featured prominently in the Brazilian news. Coastal erosion in Brazilian beaches, e.g., Boa Viagem beach in the city of Recife-PE and Piedade in Jaboatão dos Guararapes-PE are known to cause socio-economic problems, whereby they usually result from a combination of natural and human factors. In temporal terms, it is common to find coastal changes classified as long-term and short-term. Long-term may be related to changes in average sea level, sediment transport, wave energy, geological controls (contemporaries and antecedents) causing changes in its position over a period of hundred or thousands of years. Short-term, however, may occur on time scales of decades or smaller and are related to daily movement, monthly or seasonal changes in tidal currents, wave climate and episodic events (see e.g., Harley et al., 2011; Galgano and Douglas, 2000; Galgano et al. 1998; Demarest and Leatherman, 1985).

The challenge with temporal monitoring of shoreline at higher resolution is the lack of temporal cartographic information, which makes it difficult to determine the variability of the shoreline as well as its prediction. This shortage in temporal cartographic information is due to that fact that the techniques used for data collection such as photogrammetric restitution are either expensive or poor in terms of spatial resolution (see e.g., Gonçalves et al., 2012a). More modern techniques such as LiDAR (*Light Detection and Ranging*) that are useful for monitoring coastal areas with vertical accuracy of 8-15 cm and a set of points spaced at least 1 m (without taking into account the processes of extraction of shoreline) are way out of reach for developing nations such as Brazil (e.g., Gonçalves et al., 2012b). To circumvent shoreline monitoring problems at shorter temporal spans that are of benefit to coastal planning, GNSS are rapidly coming up as efficient tools that can provide *quicker, all-weather, highly accurate and continuously updatable* shoreline positional time series relevant for monitoring, thus enabling quicker management decisions to be undertaken, which may be of benefit to coastal engineering applications (see e.g., Awange and Kiema 2013; Gonçalves et al., 2012a,b; Ahmad and Lakhan 2012; Awange 2012; Krueger et al. 2009; Tanajura 2011 and Ruggiero et al., 1999).

Use of GNSS to monitor Brazilian coastal areas, such as, Pernambuco have been reported, e.g., in Mendonça (2005) and Mendonça et al. (2006) who applied GNSS technology to measure the shoreline for morphological studies of Coroa do Avião in Itamaracá, Mallmann (2008) who studied the vulnerability on the beaches of the southern coast of Pernambuco, Rollnic (2008) who analyzed the dynamics of waves, circulation and transport of sediments in the coastal zone of the beaches in the metropolitan area of Recife, and Gregório (2009) who analyzed some aspects of shoreline in Recife. More recently, Gonçalves et al., (2012a,b) studied the trend of simple linear regression, robust estimation, and artificial neural networks using temporal data from different sources and demonstrated the importance of choosing a probabilistic model. Silva et al. (2013) used fuzzy logic to model and produce a thematic map containing the vulnerability of coastal erosion, while Gonçalves et al., (2013) simulated the effect of the shadows of the buildings constructed near the shoreline showing the importance of preserving distances between urban beaches and shorelines.

As a contribution to studies of monitoring of the shoreline based on GNSS techniques, this paper describes a consistent, low cost, and accurate monitoring approach that can detect different sectors with similar characteristics of evolution. The study area is the beach of Piedade and Boa Viagem where GNSS surveys were conducted during the years 2007, 2009, 2010 and 2012 for the purpose of preservation and enhancement of the coastal environment in-line with the aims of Coastal Management Act of the State of Pernambuco (Brazil) of promoting and supporting the conservation, restoration, and control of areas that are representative ecosystems of the coastal zone.

This study is organized as follows: In section 2, the study area is presented along with its geographical coastal characteristics, census data, and sectorial division. Section 3 presents data and methodology used to undertake the shoreline change analysis. The results and analysis are presented in section 4, and the study conclusion in section 5.

## 2. STUDY AREA

With a range of 187 km of Atlantic ocean shoreline, Pernambuco coast was divided into 21 municipalities based on their geographic location. In the northern and southern boundaries are respectively the municipalities of Goiás and São José da Coroa Grande. The coast of Pernambuco has a diversity of ecosystems such as plain segments covered by coconut trees, remnants of Atlantic forest, estuaries with extensive mangroves, coral reefs, islands, among others, (Manso et al., 2006).

The coast of Pernambuco is divided into three sectors: Northern sector, located between Olinda and Paraíba State, with a narrow plain. Eastern sector, between Olinda and Cabo de Santo Agostinho, characterized by Quaternary sedimentation that lies between the city of Recife and sandbanks of Barra da Jangada, Candeias and Brasília Teimosa. The Southern sector that lies between Cabo de Santo Agostinho and the extreme south of the State, represented by the sediments of Cretaceous, Cabo and Estivas formations and the volcanic formations of Ipojuca (Coutinho et al., 1997).

In the middle sector are Pleistocene marine terraces (7-11 m high) and Holocene (1-5 m high) designed during the last marine transgression. In addition to swamp's deposits, banks of sandstone or *beachrocks* are in some sectors (Dominguez et al., 1990). The *beachrocks* have a width average of 20 to

60 m and are 3-4 m in thickness. The *beachrocks* that are arranged parallel to shoreline protect the coast from the wave energy effect but can also generate erosion process at their ends (Dominguez et al., 1990, Manso et al., 1995).

The study area includes the beaches of Pina and Boa Viagem, located in the southern Recife coast and Piedade that is situated in the northern coast of Jaboatão Guararapes, which together represents approximately 13 km of extension. Those beaches are urbanized and have suffered coastal erosion in recent decades.

Figure 1 shows a location map of Pernambuco state in northeastern Brazil, the extension of the state and in particular a polygon that define the municipalities of Recife and Jaboatão dos Guararapes.

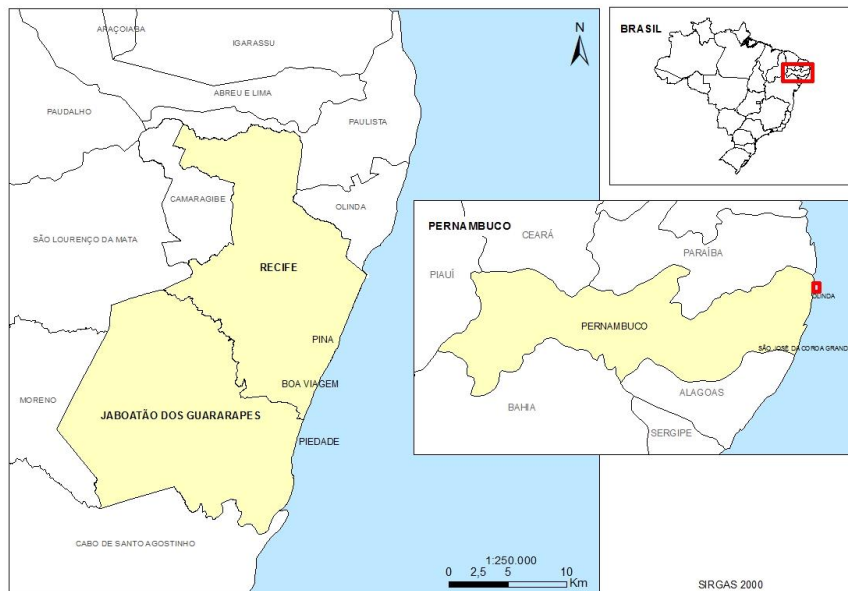

Figure 1- Localization Map: Recife and Jaboatão dos Guararapes.

According to Manso et al., (2006) the exponential population growth of Pernambuco state coastal zone accompanied by uncontrolled explosion of tourism activities precipitated its mischaracterization, which in some sectors around several municipalities is considered irreversible. Manso et al., (2006) report that the development and expansion of Recife was mainly along rivers and coastal zone. Over time, the beaches of Candeias, Piedade and south of Boa Viagem, which presented a stable shoreline began to have coastal erosion problems. It is believed that the erosion is related to the settlement done very close to the shoreline. According Aureliano (2000), characterization of the urbanization of the city was through residential subdivisions, commercialization and industrialization. Since the last decades there has been a large rise in building constructions, condominiums and hotels along the waterfront.

Recife, according to the 2010 census, had a population of 1,537,704 inhabitants and has a land area of 218.498 km<sup>2</sup>, thus Recife has a very high population density of 7,037.61 inhabitants/ km<sup>2</sup>. The area and population for 2010 in the urban municipalities of Recife and Jaboatão dos Guararapes are presented in Table 1, totaling approximately to three and a half million inhabitants (IBGE, 2010).

Table 1 - Total area and population in the urban area of Recife metropolitan region (Source: IBGE (2010)).

Municipalities	Population (hab)	Area (km <sup>2</sup> )
Cabo de Santo Agostinho	185,025	446.578
Camaragibe	144,466	51.194
Jaboatão dos Guararapes	644,620	258.566
Moreno	56,696	196.071
Olinda	377,779	41.659
Paulista	300,466	97.364
Recife	1,537,704	218.498
São Lourenço da Mata	102,895	262.157
<b>Total</b>	<b>3,349,651</b>	<b>1,572.087</b>

## 2.1 Sectorial division

Figure 2 shows a satellite image of 2011 denoting the study area that was divided into specific sectors. The criterion used in the division was the behavior of the region's post-beach, whereby the data was analyzed according to five sectors located and distributed from north to south: Sector 1, Pina Beach and North Beach of Boa Viagem; Sector 2 - the center zone of Boa Viagem; Sector 3 - south of Boa Viagem beach until the beginning of riprap, Sector 4 - south of Boa Viagem riprap to the limit with Jaboatão dos Guararapes and Sector 5 - located north of Jaboatão dos Guararapes (beach of Piedade) until the beginning of the South riprap. Figure 2 (in red) shows an area covering 2.4 km in length that interrupts the two paths by the riprap (boulders of granite). This location was not mapped because it is in direct contact with an area of urban construction, demonstrating that within this stretch, coastal erosion problems are already part of society and require constant maintenance and rehabilitation works.

Sector 1 begins at the end of Brasília Teimosa riprap and continues southward with 2,905 m to a water flow channel at the building Canopus nº 2594 of Boa Viagem Avenue. This sector is characterized by a well developed post-beach, with the presence of vegetated dunes, with a distance of ~120-140m between the shoreline and the first urban obstacle. Going southwards, the post-beach becomes narrower without the presence of foredunes, which is the starting of Sector 2 and heads south to 1340 m to the intersection of Boa Viagem Avenue with Bruno Veloso street. Sector 2 is characterized by a post-beach without undergrowth and occurrence of coastal erosion. The average distance between the shoreline and the first urban obstacle is approximately 40 meters. There is also a steepening of the beach environment with the presence of berm and beachrocks on the beach face.

Sector 3 starts at the intersection of Boa Viagem Avenue with Bruno Veloso street and heads south for 440 m to the beginning of the Boa Viagem riprap. It is characterized by a post-beach reduction to less than 10 m, and at some points with the high tide reaching the wall of the containment, with clear indication of coastal erosion. Sector 4 is south of Boa Viagem riprap still in Recife following the direction of Jaboatão dos Guararapes (Piedade Beach) for a length of 2835 m. A sandy beach without evidence of coastal erosion nor vegetation and foredunes characterized this sector. Sector 5 located north of Jaboatão dos Guararapes (beach of Piedade) heads towards south for about 880 m to the beginning of riprap. In this sector the post-beach is not limited by a pavement street but by the buildings that were built too close to the shoreline.

Figure 2 - Sectorial division.

### 3. METHODS

The spatial positioning of the shoreline trajectory benefits from GNSS using both the American GPS (Global Positioning System) and the Russian system GLONASS (Global Navigation Satellite system). The shoreline position trajectory was extracted using kinematic relative positioning method of GNSS, details of which can be found in Awange (2012), Monico (2008), El-Rabbany (2006), Seeber (2003) and Hoffman-Wellenhof et al. (2001, 2008). In this method, the base receiver is placed at a base station of known coordinates, while the rover receiver is moved by a person walking on foot (or vehicle) on the feature of interest, in this case the shoreline. During data collection, a geodetic dual frequency receiver was placed at a base station at a location known as the Terceiro Jardim on Boa Viagem Avenue whose coordinates are latitude  $08^{\circ} 06' 30.16493''$ S, longitude  $34^{\circ} 53' 17.32463''$ W (SIRGAS-2000), geometric altitude -1.433 m and orthometric height 4.533 m (IMBITUBA-SC). The base station receiver was configured to collect raw data every 3 seconds. The roving receiver was configured to store information in a data recording interval of 3 seconds in kinematic mode, with elevation mask of  $10^{\circ}$  to reduce multipath and atmospheric related errors. The field team consisted of 4 or more members of LACCOST (Laboratory of Coastal Cartography) formed by graduate students in Cartographic Engineering or Geodetic Sciences and Technology of Geoinformation Post Graduation Program at UFPE with knowledge on geodetic survey. The staff were trained in advance to perform the mapping of the shoreline. For planning the survey, the team searched in the DHN (*Diretoria de Hidrografia e Navegação*) tide forecasts available to the State of Pernambuco site analyzing the day and the time for maximum high tide in the month chosen as shoreline indicator. In the case of Recife, the maximum tide is around 2.5 to 2.7 m depending of the month. The 2.4 km extension of shoreline takes around 3 hours for mapping generating more than 3,500 points with a horizontal accuracy better than 7.0 cm.

Figure 3 shows the use of GNSS receivers in the study area on Boa Viagem beach. This type of survey has been effective and accurate for small areas of study as exemplified for the island of Ilha do Mel and the city of Matinhos in Paraná State, Brazil (Krueger et al., 2009) and also here in this case where the distance between the base station and the receiver in the study area is less than 5 km.

Figure 3 - Base and rover receiver in the study area.

The data collected in the field are stored simultaneously in the two receivers (base and rover) and post-processed with the use of Topcon processing software. The level of accuracy of the method with relative kinematic post-processing is about 10 cm and may reach a few centimeters if conditions are favorable (good satellite geometry, no multipath, short distance from the base line processing, etc.) (Seeber, 2003).

The calculation of the rate of change of shoreline considering the processes of advances and retreats were performed automatically in the free extension of ArcGIS software called Digital Shoreline Analysis System - DSAS (Thieler, 2009). This was done across distances of cross sections between the baselines, with intervals of 5 m. Figure 4 shows an example of the shoreline and transects selected as base.

Figure 4 - Cross sections between shoreline of 2007 and 2012.

### 3.1 Evaluation Criteria

The displacements were evaluated for each sector using the following statistical methods:

(1) The arithmetic mean of the variation of the shoreline from the cross section the samples collected for each sector from the following pairs of years (2007 and 2009), (2009 and 2010) and (2010 and 2012 ) were calculated using:

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n (SL_{Previous_i} - SL_{Back_i}), \quad (1)$$

where  $(SL_{Previous_i} - SL_{Back_i})$  is the distance between shorelines considering the years studied in the  $i$ th cross section, and  $n$  is the number of sections.

(2) The standard deviation was obtained by taking the square root of the variance of the shoreline position as:

$$\sigma = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (SL_{Previous_i} - SL_{Back_i}) - \bar{x}^2}. \quad (2)$$

(3) The maximum value in meters found in cross sections.

(4) The minimum value in meters found in cross sections.

(5) The shoreline rates of variations by the endpoint (EPR - end pont rate) method. The EPR method uses two points to determine the shoreline rate of change. In this case, we calculated the variations of the distance between the cross sections using the base line by pairs (2007 and 2009), (2009 and 2010) and (2010 and 2012). For example, between 2007 and 2009 is 2 years, and this is the number considered as dividend to be taken in this specific comparison. The rate is expressed in m / year. Examples of papers discussing and using this method are Genz et al., (2007), Crowell et al., (1997, 1999) and Dolan et al., (1991).

#### 4. RESULTS AND DISCUSSION

Table 2 presents the results observed for the five sectors and show; the number of cross sections at each 5 m, the minimum and maximum displacement, the arithmetic mean, the standard deviation of observations and rates of changes by end point method.

Table 2 Values of the displacements (m) of shorelines by sectors, between the years 2007/2009, 2009/2010, 2010/2012

Sectors (S)/Year	Number of cross sections each 5 m	Arithmetic Mean (m)	Minimum displacement (m)	Maximum displacement (m)	Standard deviation (m)	Annual average displacement (m/year)
S1 2007 - 2009	581	-2.38	-14.88	13.04	6.48	-1.19
S2 2007 - 2009	268	-8.03	-13.94	5.76	5.12	-4.02
S3 2007 - 2009	88	-9.48	-14.98	1.48	3.74	-4.74
S4 2007 - 2009	567	-1.61	-12.96	10.42	7.36	-6.48
S5 2007 - 2009	176	-16.33	-29.98	0.38	7.77	-8.16
S1 2009 - 2010	581	1.60	-4.60	10.61	2.58	1.60
S2 2009 - 2010	268	1.14	-4.67	10.96	3.55	1.14
S3 2009 - 2010	80	2.62	-1.06	6.98	2.34	2.62
S4 2009 - 2010	567	1.19	-8.34	7.40	3.03	1.19
S5 2009 - 2010	123	0.32	-4.79	5.22	2.43	0.32
S1 2010 - 2012	581	2.38	-3.30	13.48	2.81	1.19
S2 2010 - 2012	268	1.09	-5.78	9.68	3.47	0.55
S3 2010 - 2012	80	-0.07	-5.72	3.76	2.18	-0.04
S4 2010 - 2012	567	0.79	-10.92	10.08	4.39	0.40
S5 2010 - 2012	123	-6.02	-11.50	-2.04	2.66	-3.01

In Table 2, it is possible to analyze the behavior of the sectors for 5 years divided by intervals. During the interval 2007-2009 the average position of the shoreline was negative indicating retreat in the analyzed period with values ranging from 16.33 m in sector 5 to 1.61 m in sector 4. The interval 2009-2010 yielded positive values indicating advances of shoreline ranging from 0.32 m in sector 5 until 2.62 m in sector 3. Interval 2010-2012 is observed to have stretches of backward and forward highlighting the decline in average of 6.02 m in section 5 and further advancement average for the sector 1 with 2.38 m.

In Table 2, in the column number of cross sections for the sector 3 of 2007-2009 there were 88 cross sections, that number goes to 80 cross sections in the same sector for the periods 2009-2010 and 2010-2012. This reduction is due to the increase in erosion at the site, leading to an increase in (riprap), thereby decreasing the shoreline spatial monitoring since this is done at a range of sandy beach. The same happened also in sector 5 whit containment occurring north of the increase in erosion and decreasing the number of cross sections from 176 to 123.

Figure 5 shows a bar chart built from the observed results of the shoreline rates of changes by end point method presented in the last column of Table 2. From the analysis of this bar chart we can observe the variation of the rate by the method of endpoint (EPR) represented in m/year. In sector 1 between 2007-2009, a retreat of shoreline by a value of 1.19 m/year is seen. Then for the years 2009-2010 and 2010-2012 they advance (positive value) reaching of 1.60 m/year and then slightly decrease to 1.19 m/year respectively. The situation for 2007-2009 intervals in all sectors shows a period of shoreline retreat rates reaching around 8 m/year in sector 5. On the other hand, for 2009-2010, the opposite behavior characterized by the advance in the sectors analyzed reached 2.6 m/year. For the 2010-2012

interval, sectors 1, 2 and 4 shows positive values (advance), stability in sector 3 and a retreat of 3.01 m/year for the sector 5.

Figure 5 - Shorelines average annual rate of displacement by sectors, between the years 2007/2009, 2009/2010, 2010/2012

For a representative analysis of the values found in the average annual rates of displacement (m / year), Table 3 presents a model for classifying the advances and retreats of the shoreline according to Thieler and Hammar-Klose (2000), and also show the classification of shoreline rates obtained.

Table 3 - Classification of average annual rates of shoreline according to Thieler and Hammar-Klose (2000).

Classification of mean shoreline annual rates					
Classification	Retreat		Stability	Advance	
	Very High	High	Moderate	Low	Very Low
Shoreline advance/retreat (m/year)	< -2.0	-2.0 - -1.0	-1.0 - 1.0	1.0 - 2.0	> 2.0
Sectors/interval					
S1 (2007 - 2009)		High			
S1 (2009 - 2010)				Low	
S1 (2010 - 2012)				Low	
S2 (2007 - 2009)	Very High				
S2 (2009 - 2010)				Low	
S2 (2010 - 2012)			Moderate		
S3 (2007 - 2009)	Very High				
S3 (2009 - 2010)					Very Low
S3 (2010 - 2012)			Moderate		
S4 (2007 - 2009)	Very High				
S4 (2009 - 2010)				Low	
S4 (2010 - 2012)			Moderate		
S5 (2007 - 2009)	Very High				
S5 (2009 - 2010)			Moderate		
S5 (2010 - 2012)	Very High				

Table 3 illustrates fluctuations in classification of shoreline rates over the sectors and periods. For sector 2 (2007-2009), sector 3 (2007-2009), sector 4 (2007-2009) sector 5 (2007-2009) and sector 5 (2010-2012) the rates of shoreline retreated and was considered as a very high retreat. On the other hand considering advances' rates as low and very low, there are five cases found in sector 1 (2009 - 2010), sector 1 (2010 - 2012), sector 2 (2009 - 2010), section 3 (2009 - 2010) and sector 4 (2009 - 2010). Finally there was no change classified as moderate (considered stable) in sector 2 (2010 - 2012), sector 3 (2010 - 2012), sector 4 (2010 - 2012) and sector 5 (2009 - 2010).

The seasonal shoreline transport change processes possibly are related to the granulometry characteristics of Pina and Boa Viagem beaches. During the rainy seasons for example, a very thin until medium size of sediments is found. The medium sand lies in the beach in the central part of the Boa Viagem, while the thin sand is observed at the edges, and very thin sand in north of Pina. During dry seasons sediments are dominantly composed of thin sand (Gregório et al., 2004a). But the thin sand sediments is composed mostly of these beaches (Gregório, 2009). The sediment characteristics of the Pina and Boa Viagem beaches showed a moderate energy sedimentary environment (Gregório, 2009, Gregório et al., 2004a, 2004b). The predominance of thin sand in the study area is easily mobilized by the action of waves and tides, influencing the shoreline positional variation toward the mainland or in the opposite direction, toward the ocean.

## CONCLUSIONS

The kinematic GNSS method used for shoreline monitoring in this study has the advantages of being able to produce consistent data for temporal analysis, be applied in the field by a small team, be quick for small areas and have low operating costs when compared with **LiDAR** (*Light Detection and Ranging*) for example. LiDAR needs an airplane team, whose shoreline data can also be detected from digital terrain models applied to coastal zones and are much more expensive than GNSS but remains very important for coastal applications, see e.g., Awange and Kiema (2013, chapter 24), Gibeaut et al., (2001), and Gorman et al. (1998). The GNSS disadvantages are; it can become unfeasible for coastal mangroves, rocky shores or, for example, for monitoring very large areas can become costly.

Through a short term temporal analysis of five years for Boa Viagem and Piedade beaches, it was possible to verify that the shoreline is constantly changing. These changes were characterized by sectors that may experience different periods of advances, stability and retreats. Sector 4 (2007-2009) for instance showed retreat rate considered as very high, then between (2009-2010) changed to low, and over the period (2010 -2012) fell to moderate.

During the time series monitoring that began in 2007, the field team also notice the increase in containment works in the case of riprap (boulders of granites) indicating human intervention in sectors with serious problems of coastal erosion such as in the central part of the Boa Viagem beach with a length of 2.4 km (2012) that requires constant maintenance. For this specific site of the beach, where riprap shoreline rates were not calculated (on purpose), erosion appears to be increasing over time detected from the decreasing extension of monitoring, which is a worrying trend for urban planning. The purpose of this structure made with rocks is to protect the coast with the mission of removing the wave energy and protect the urban area. This can generate a problem since it can affect the dynamics of the beach and sediment transports. The contention of the sea, sometimes, without planning can become a problem because it requires constant care over time.

It is recommended that shoreline monitoring for the study area be continued since this area will in future receive sand replenishment according to Pernambuco State and possibly develop a complex shoreline behavior such as observed in this study.

## ACKNOWLEDGMENTS

The authors are grateful to the support of: FACEPE/CNPq, PPP/APQ-1242-1.07/10 – “Monitoramento e mapeamento costeiro do uso e ocupação do solo nos municípios de Recife e Jaboatão dos Guararapes” Project; the laboratory of coastal cartography (LACCOST), the Department of Cartographic Engineering (UFPE); the Department of Spatial Sciences (Curtin University). RMG acknowledge the support of Post-Doctoral CNPq scholarship (233170/2013-8). This is a TiGER No. 573.
