(Received 23 November 2009; published 23 March 2010)

We analyze the dipole spectrum of a two-level atom excited by a nonresonant intense monochromatic field under the electric dipole approximation and beyond the rotating wave approximation. We show that the apparently complex spectral structure can be completely described by two families: harmonic frequencies of the driving field and field-induced nonlinear fluorescence. Our formulation of the problem provides quantitative laws for the most relevant spectral features: harmonic ratios and phases, nonperturbative Stark shift, and frequency limits of the harmonic plateau. In particular, we demonstrate the locking of the harmonic phases at the wings of the plateau opening the possibility of ultrashort pulse generation through harmonic filtering.

I. INTRODUCTION

Two-level atoms are essential blocks for the understanding of basic processes in quantum physics. In particular they are the keystone of quantum optics as the harmonic oscillator is the basic model for classical optics. Their simplicity brings the possibility for analytical developments which convey physical interpretations not attainable with more exact approaches. Moreover, two-level models have good quantitative accuracy in the description of laser-matter interactions near resonance at moderate laser intensities, where the rotating wave approximation is applied [1]. For the case of strong fields, where a large number of atomic or molecular transitions are simultaneously involved and ionization is present, the two-level model does not provide a complete description, although it can still be used to study the role of bound-state transitions in high-order harmonic generation [2]. Nevertheless, under particular conditions some of these complex systems are dominated by two-level transitions even for the strong driving case (for instance, the molecular Hydrogen ion at large internuclear distances [3]). Two-level transitions have also been associated to harmonic generation in molecules involving a rescattering center different from the electron's parent ion [4] and connected with charge-resonant states in odd-charge molecular ions [5]. Nowadays the recent trends in optical parametric chirped-pulse amplification (OP-CPA) techniques to produce high-power mid-infrared laser radiation [6] renew the interest of few-level systems in the off-resonant strong-coupling regime, since in this spectral region few atomic transitions can be reasonably isolated from the rest [7,8]. In addition, the forthcoming development of extreme intensity laser sources may permit us to directly address the excitation of dipolar two-level transitions in nuclei [9].

Two-level atoms interacting with intense laser light show a significant nonlinear behavior dominating the complex temporal dynamics. This dynamics is translated to the atom dipole evolution and, therefore, to the structure of the emitted field. The radiation spectrum under such circumstances shows

a plateau structure, in which harmonics with similar intensities extend to high frequencies [10]. This is a universal behavior, present in other models of light-matter interaction (also in classical anharmonic oscillators) and the signature of the failure of the perturbative regime. The physics beneath this structure is well understood for the case of atoms and molecules in strong electromagnetic ionizing fields [11]. In this case, the relevant process responsible for the plateau consists in the ionization of the electrons, their acceleration through the field-induced quiver motion, followed by the recollision with the parent ion with the release of the electron's kinetic energy into electromagnetic radiation. On the other hand, for a two-level system, the plateau emerges from transitions between adiabatic states as was pointed out in Refs. [12,13] (see also the discussion in the last section of this article).

The study of coherently driven two-level systems beyond the perturbative limit has a fundamental reference in Ref. [14], with special focus on the near-resonant conditions. In Ref. [15], a quantitative description of the harmonic spectra of strongly driven two-level systems was reported by means of a Floquet-based theory. This approach resulted in a closed iterative analytical formulation, based on a continued-fraction method, that provided for exact ratios between the harmonic intensities. Later on, this approach was used to study the harmonic enhancement connected with field-induced multiphoton resonances [16]. Other continued fraction approaches have also been used to derive approximated analytical expressions for the plateau extension [17]. The nonharmonic peaks also present in the radiative spectrum of the electric dipole have been studied for the case of large frequencies and/or very high amplitudes of the driving fields [18,19]. In these studies, the nonharmonic resonances are identified as satellite peaks around each harmonic, separated by the transition frequency between the quasienergy states. Two groups of peaks were identified (hyper-Raman lines of Stokes and anti-Stokes type) according to their relative position with respect to the harmonic peaks. Also, these authors derived analytical formulas for the quasienergies. In the present article we use the exact approach developed in Ref. [15] to address the complete description of the dipole spectrum in the general case. We will show that the apparent complexity of the spectra can be

*Present address: JILA, University of Colorado, Boulder, Colorado 80309-0440, USA.

reduced to two contributions, namely harmonic radiation and laser-induced fluorescence. This latter family accounts for the emergence of the mentioned satellite structure (Stokes and anti-Stokes lines) in the case of strong driving and/or in the limit of high driving frequencies. In particular, our approach gives a simple explanation of the asymmetry between the intensities of the Stokes and anti-Stokes satellite peaks. On the other hand, we obtain a polynomial equation whose solution gives the position of the Stark-shifted transition energy to, in principle, arbitrary accuracy. Restricting to the lowest degree of this equation, we derive an analytical formula for this later quantity. We test it against the exact numerical integration of the two-level Schrödinger equation and show the convergence to the result of Ref. [18] (in the limit of validity considered in this reference). We also derive approximated formulas for the extension of the harmonic plateau. Our formula for the cut-off energy agrees with that of Ref. [17] and converges to that in Ref. [19] in the limit of Rabi frequencies much greater than the transition frequency. On the other hand, our formula for the plateau's onset frequency converges to [17] in the low-frequency limit and gives better comparison with the exact results for higher driving frequencies. Finally, from the phase of the higher-order harmonics, we show their locking and demonstrate numerically the possibility of producing attosecond pulses.

II. THEORY

We begin with the standard formulation for a two-level system driven by a monochromatic field, out of the rotating wave approximation. The dynamics of the probability amplitudes are given by:

$$i \frac{d}{dt} a_1(t) = -\frac{1}{2} [\chi e^{-i\omega t} + \chi^* e^{i\omega t}] a_2(t), \quad (1)$$

$$i \frac{d}{dt} a_2(t) = \omega_0 a_2(t) - \frac{1}{2} [\chi e^{-i\omega t} + \chi^* e^{i\omega t}] a_1(t), \quad (2)$$

where labels 1 and 2 stand for the lower and upper levels, respectively; ω_0 is the atomic transition frequency; ω is the monochromatic field frequency; and $\chi = \mathcal{E}_0 \mu / \hbar$ is the Rabi frequency, where \mathcal{E}_0 is the electromagnetic amplitude and μ is the dipole matrix element. The electromagnetic amplitude is defined by a linearly polarized monochromatic field of the form $\mathbf{E}(t) = \mathbf{E}_0 \cos(\omega t + \phi)$, where \mathbf{E}_0 and ϕ are the amplitude and the phase of the field, respectively, with $\mathcal{E}_0 = |\mathbf{E}_0| e^{-i\phi}$, and the dipole matrix element is $\mu = \langle 1|e_z|2\rangle$, being a real quantity and assuming z the field polarization direction. We define the Bloch variables u and v as the real and imaginary parts of $a_1(t)a_2^*(t)$, respectively, and the population inversion as $w(t) = |a_2(t)|^2 - |a_1(t)|^2$. Then, from Eqs. (1) and (2) it can be derived:

$$\frac{d}{dt} u(t) = -\omega_0 v(t), \quad (3)$$

$$\frac{d}{dt} v(t) = \omega_0 u(t) + \frac{1}{2} [\chi e^{-i\omega t} + \chi^* e^{i\omega t}] w(t), \quad (4)$$

$$\frac{d}{dt} w(t) = -2[\chi e^{-i\omega t} + \chi^* e^{i\omega t}] v(t). \quad (5)$$

The atomic dipole is defined as $d(t) \equiv 2\mu u(t)$. Figure 1 shows the spectral content $|u(\omega)|^2$ computed numerically from

FIG. 1. Dipole spectrum, $|u(\omega)|^2$, of the driven two-level atom. (a) Spectrum at low field amplitude ($|\chi|/\omega_0 = 0.005$ and $\omega/\omega_0 = 0.1$); (b) spectrum at higher field amplitude ($|\chi|/\omega_0 = 1.5$ and $\omega/\omega_0 = 0.2$). (Inset) Detail of the dipole spectrum in (b) showing the structure of satellite peaks around the harmonics.

Eqs. (3)–(5). To be specific, in this article we have chosen the driving field phase as $\phi = -\pi/2$. To reduce the effect of the abrupt envelope, we have considered a sinus squared field turn-on of two cycles, followed by 16 cycles of constant amplitude. The dipole spectrum has been calculated through the Fourier transform of $u(t)$ in these later 16 cycles. For small field amplitudes, Fig. 1(a), the spectrum is dominated by two peaks, one located at the driving field frequency ω (Rayleigh scattering) and another at the transition frequency ω_0 (field-induced fluorescence). As the field amplitude increases, Fig. 1(b), the complexity of the dipole spectrum increases with the appearance of harmonic frequencies of the driving field surrounded by satellite peaks, see the inset of Fig. 1(b), whose position varies with the driving field intensity. In Refs. [18,19] these satellite structures are referred to as hyper-Raman lines. We should note that the relative intensity of the two satellite peaks around each harmonic varies with the driving field parameters, the satellite structure being asymmetric in the general case. Also, note that the harmonic structure shows the emergence of a plateau region with peaks of similar intensities. Mid-infrared radiation can provide a suitable scenario in order to match the parameters considered in Fig. 1(b). For example, the $2s$ - $3p$ transition in the Hydrogen atom is close to five photon resonance using a 3 - (μm) -wavelength laser. In this case, the current technology is almost ready; see, for example, Ref. [8].

Combining Eqs. (3) and (4) we obtain

$$\frac{d^2}{dt^2} u(t) + \omega_0^2 u(t) = -\frac{\omega_0}{2} [\chi e^{-i\omega t} + \chi^* e^{i\omega t}] w(t), \quad (6)$$

which describes the atomic dipole evolution. As discussed in Ref. [15], the dipole dynamics corresponds to the harmonic oscillator in the small coupling limit ($w(t) \simeq -1$) and, therefore, Eq. (6) provides a connection between the fundamental atomic models of classical and quantum optics. On the other

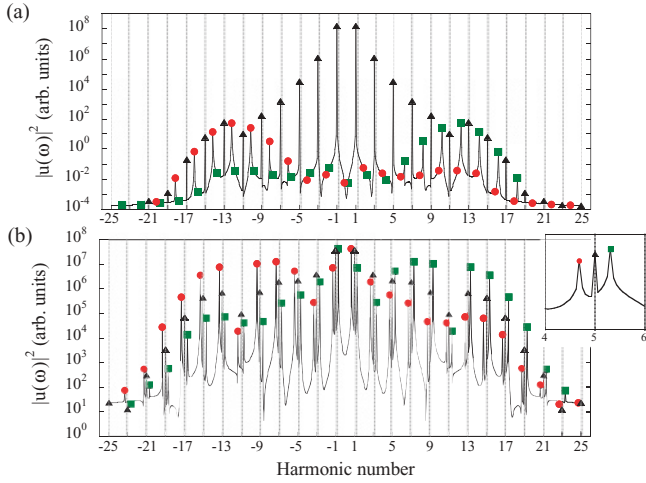

FIG. 2. (Color online) Dipole spectrum, $|u(\omega)|^2$, plotted for negative and positive frequencies in two different cases, (a) $\omega/\omega_0 = 0.1$, $|\chi|/\omega_0 = 0.5$, and (b) $\omega/\omega_0 = 0.2$, $|\chi|/\omega_0 = 1.5$. This latter one corresponds to the same case as in Fig. 1(b), including the inset. The two families composing the spectrum have been labeled with solid black triangles (harmonic family) and solid green boxes (fluorescence family). The complex conjugate of this later is labeled with solid red circles.

circles correspond to the complex conjugate of the latter. The harmonic family contains its own conjugate. The apparent complexity of the spectra at high field amplitudes, for instance, the case shown in Fig. 1(b), raises when the fluorescent family extends to negative frequencies, and its conjugate to positive. In this case each harmonic appears as surrounded by two satellite peaks, one belonging to the fluorescence family and the other to its complex conjugate. Figure 2(b) shows the same case as shown in Fig. 1(b), with the peaks labeled according to their correspondent family. As mentioned above, in general the intensity of the satellites around a particular harmonic is not the same, as the relative position of each satellite peak in the fluorescence family and its conjugate do not coincide.

IV. STARK SHIFT

The physical interpretation of α_0 in the fluorescence family can be found in the limit of low intensities $\chi \rightarrow 0$. As discussed before, in this limit the dipole evolution corresponds to the classical harmonic oscillator. This latter problem is described only by two spectral contributions, one peak at the laser frequency ω and other at the natural frequency ω_0 of the oscillator. As the field increases, the two-level system reveals its nonlinearity, and natural and field frequency are mixed. Clearly, the harmonic spectrum rises from the mixture of the field frequency with itself, while the fluorescence family comes out of the mixture of the natural and field frequencies. Therefore, the central frequency α_0 of the fluorescence family is to be interpreted as the effective transition frequency of the two-level atom, which is AC Stark shifted from ω_0 as the field increases.

Next we shall derive an approximated expression for the Stark shifted transition frequency. To do this, we evaluate the effective transition frequency α_0 by solving $\det(M) = 0$. For

an arbitrary large truncation of M , a limiting exact solution for this quantity can be found numerically. If we are interested, however, in closed analytical estimations we should consider the regime of moderate coupling, for which the fluorescence family may be composed of several peaks but with a clear maximum at the central frequency α_0 . This situation allows us to neglect the influence of the peaks at the sides of α_0 and to consider only the central term of matrix M (i.e., an 1×1 truncation). The effective transition given by $\det(M) = 0$ reduces to $\Theta(\alpha_0) = 0$, whose solutions are

$$\alpha_{0,\pm}^2 = \frac{1}{2} \left[\omega^2 + \omega_0^2 + 2|\chi|^2 \pm \sqrt{(\omega^2 + \omega_0^2 + 2|\chi|^2)^2 - 4\omega^2\omega_0^2} \right]. \quad (16)$$

The stark shifted transition frequency corresponds to $\alpha_{0,+}$ (which has the correct limit ω_0 when $|\chi|$ tends to 0), while $\alpha_{0,-}$ converges to the laser frequency in the limit $|\chi|$ tending to 0. Therefore, the two solutions in (16) represent the two possible spectral families, harmonics and fluorescence, which are restricted to single peaks as a result of the 1×1 truncation of M . In the limit of small field intensities, and for $\omega_0 \geq 2\omega$, Eq. (16) is reduced to a Stark shift of $|\chi|^2\omega_0/(\omega_0^2 - \omega^2)$, in correspondence with the form presented in Ref. [18].

Note that, even with the drastic truncation of M , the harmonic $\alpha_{0,-}$ is practically insensitive to the intensity field. In Fig. 3(a) we plot Eq. (16) for $\omega/\omega_0 = 0.1$ (taking only the positive frequencies), increasing the field from $|\chi|/\omega_0 = 0.01$ to $|\chi|/\omega_0 = 0.5$. The figure clearly shows that $\alpha_{0,-}$ remains

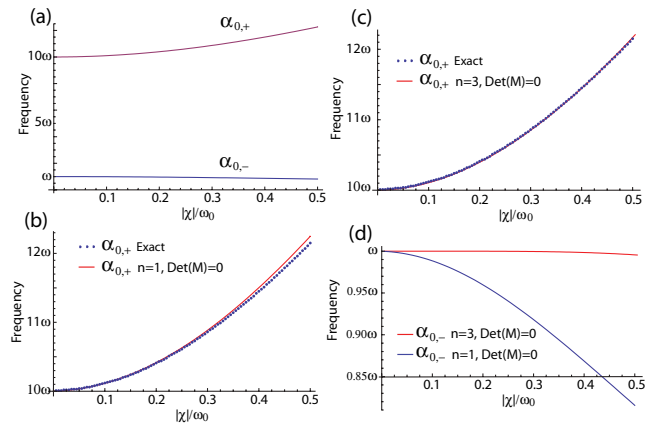

FIG. 3. (Color online) (a) Plot of formula (16) for $\omega/\omega_0 = 0.1$ versus the Rabi frequency, resulting from the truncation of M to 1×1 . $\alpha_{0,\pm}$ refer to the frequencies of the central peak in each of the two families composing the dipole spectrum. Since $\alpha_{0,-}$ corresponds to the harmonic family, it is practically insensitive to the intensity field. (b) Test of the analytical solution $\alpha_{0,+}$ against the exact numerical results from Eqs. (1) and (2) for $\omega/\omega_0 = 0.1$. The numerical data shows a good agreement with the analytical formula for the Stark shift although for large intensities small deviations appear. Parts (c) and (d) of this figure show the results for $\alpha_{0,\pm}$ resulting from the truncation of M to 3×3 . The results are obtained numerically from the equation $\det(M_{3 \times 3}) = 0$ and are compared with (c) the exact numerical result also shown in part (b) of this figure and (d) with the results for $\alpha_{0,-}$ from the 1×1 truncation shown in part (a) of this figure.

practically constant as the intensity field increases, at variance with $\alpha_{0,+}$, which clearly depends on the field intensity. The comparison of the analytical solution $\alpha_{0,+}$ given by Eq. (16) with the numerical results of the fluorescence peak computing Eqs. (1) and (2) give rise to a good match, see Fig. 3(b). As expected, the approximated formula obtained by (16) is practically exact at low field intensities but gradually deviates, at large intensities, from the exact numerically calculated solution.

As discussed before, a better accuracy can be found including the influence of the fluorescence peaks surrounding the central one at α . For instance, the nearest neighbors are included if we truncate M to a 3×3 matrix. In this case, $\det(M) = 0$ yields a polynomial of order 12 in α , that cannot be solved analytically. However, the numerical solution of the problem can be attained easily in this case, as well as for higher truncation orders. In Fig. 3(c) we plot the Stark shift of the fluorescence transition and the points obtained

by $\det(M_{3 \times 3}) = 0$. As expected, the accuracy of the results increases in this latter case compared with the order truncation $n = 1$. We depict in Fig. 3(d) α_0 for the harmonic family in the $n = 1$ and $n = 3$ truncation order. Note that the dependence of this quantity with the field strength is smaller in the latter case, as the frequency of the harmonic should be independent of the intensity in the exact case (see the following section).

V. THE HARMONIC FAMILY

In order to analyze the harmonic spectrum, we consider the matrix (15) evaluated in $\alpha_0 = \omega$. First, we demonstrate that in this case the condition $\det(M) = 0$ is independent of the resonance frequency (ω_0) or the laser intensity ($|\chi|$). Note from (14) that $\Phi_+(\alpha = \omega) = 0$ and $\Phi_-(\alpha = -\omega) = 0$. These two zeros in M provide a supplementary symmetry that allows us to reduce the complexity of the matrix to the following structure

$$M(\alpha) = \left(\begin{array}{cc|cc|c} A(-\omega)_{\frac{n-1}{2} \times \frac{n-1}{2}} & \Phi_+(-3\omega) & & & \\ 0 & \Theta(-\omega) & \Phi_+(-\omega) & & \\ & \Phi_-(\omega) & \Theta(\omega) & & 0 \\ & & & \Phi_-(3\omega) & A(\omega)_{\frac{n-1}{2} \times \frac{n-1}{2}} \end{array} \right), \quad (17)$$

where $A(\pm\omega)$ are $\frac{n-1}{2} \times \frac{n-1}{2}$ submatrices (n is the truncation of the matrix M), which depends on the laser frequency ω but also on the resonance frequency and the laser intensity. Now, starting from the new form (17) of the truncated matrix M , we can calculate its determinant as

$$\det[M] = \det[A(\omega)]\det[A(-\omega)] \times [\Theta(\omega)\Theta(-\omega) - \Phi_+(-\omega)\Phi_-(\omega)] = 0, \quad (18)$$

since $[\Theta(\omega)\Theta(-\omega) - \Phi_+(-\omega)\Phi_-(\omega)] = 0$, see Eqs. (13) and (14). Therefore the location of the harmonic family is independent of the laser intensity. Let us now study the different aspects of the harmonic spectrum.

A. Harmonic ratios and relative phases

Coming back to Eq. (12), and defining the ratio between neighboring harmonics as $Z(\alpha) = u(\alpha)/u(\alpha - 2\omega)$, we have the following relation

$$Z(\alpha) = -\frac{\Phi_-(\alpha)}{\Theta(\alpha) + \Phi_+(\alpha)Z(\alpha + 2\omega)}. \quad (19)$$

This recursive expansion is exact and, therefore, reproduces accurately the relative weights between the peaks of the harmonic and fluorescence spectral families [15]. While the ratios between the harmonics inside the plateau region form a complex sequence, it is not so in the regions outside the plateau, where the harmonics decrease monotonically with the frequency, and the relative ratio $Z(\alpha)$ is a small quantity. In such regions we may approximate

$$Z(\alpha) \simeq -\frac{\Phi_-(\alpha)}{\Theta(\alpha)}. \quad (20)$$

The spectral region with frequencies below the plateau is characterized by the conditions $\alpha > 2\omega$ and $\alpha < \omega_0$, yielding $\Theta(\alpha) > 0$ and $\Phi_- \propto \exp(-2i\phi)$. Consequently, $Z(\alpha) \propto -\exp(-2i\phi)$ and the relative phase between consecutive harmonics before the plateau is $\exp[-2i\phi + \pi]$. On the other hand, the spectral region above the plateau is characterized by α arbitrarily large, therefore, $\Theta(\alpha) < 0$ and $\Phi_- \propto \exp(-2i\phi)$. Consequently, the relative phase between consecutive harmonics after the plateau is $\exp(-2i\phi)$. Inside the plateau region, the phase distribution is in general more complex and can only be determined using the recurrent relation (19) analogously as it was done in Ref. [15] for the harmonic intensities. Figure 4 shows the harmonic spectrum and phases computed numerically from Eqs. (3) to (5) in the strong coupling case ($|\chi|/\omega_0 = 4$ and $\omega/\omega_0 = 0.2$). The plateau region is shaded in gray (for a detailed discussion of the plateau's limits see below). As stated before, the field phase has been taken as $\phi = -\pi/2$ and, therefore, the above discussion predicts a relative phase between consecutive harmonics of 2π before the plateau and π after the plateau, in accordance with the numerical results shown in Fig. 4. Note that the above phase relations hold also approximately in the extreme parts of the plateau. This is a relevant aspect, as it implies that the harmonics near the plateau's cutoff are approximately phase locked. This spontaneous locking is also found in harmonic generation with ionizing systems and implies the possibility of synthesis of attosecond pulses from the Fourier synthesis of the harmonics near the cutoff. This possibility is analyzed in Fig. 5 in which we present the time evolution of the dipole resulting from the inverse Fourier transform of the spectral components with frequencies above 34ω , for the case shown in Fig. 4. The black-filled curves show the squared envelope

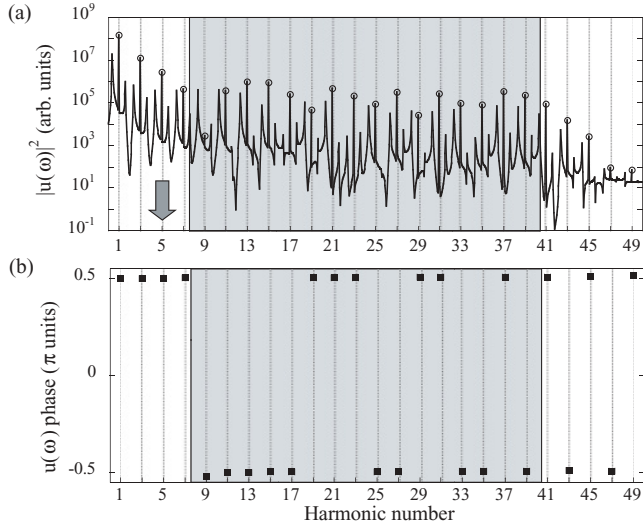

FIG. 4. (Color online) Dipole spectral intensities (a) and phases (b) for the strongly driven case with $|\chi|/\omega_0 = 4$ and $\omega/\omega_0 = 0.2$. The harmonic peak family is highlighted with open circles. The shadowed box encloses the harmonic plateau structure. The limits of this box have been defined using the expressions (22) and (24) for the plateau onset and cut-off frequencies. The arrow points to the plateau's onset frequency in the weak driving limit, equal to ω_0 .

of the dipole, resulting in a train of pulses with durations well below the optical period. The irregularity (no periodicity) of the squared envelope of the dipole in Fig. 5 is because of the resonant family contribution.

B. Plateau's onset and cutoff frequencies

We can have an approximated idea for the plateau's extension by finding its limiting frequencies. To do this we will simply consider as a reasonable estimation the fact that the neighboring harmonics in the plateau have similar intensities: $|u(\alpha - 2\omega)| \simeq |u(\alpha)| \simeq |u(\alpha + 2\omega)|$. The plateau onset can be obtained using this condition together with the relative phase for the lower frequency harmonics derived above:

FIG. 5. (Color online) (Black-filled curve) Detail of the inverse Fourier transform of the higher frequency part of the dipole spectrum shown in Fig. 4. Frequencies below 34ω are filtered out. Only the field envelope is represented. (Red line) Sketch of the amplitude of the driving field at the same time interval.

FIG. 6. (Color online) Frequencies for the plateau's onset (red line) and cutoff (green line) derived from Eqs. (22) and (24) for the case $\omega/\omega_0 = 0.1$. The visual estimation from the numerically computed spectra are plotted with black and blue points, we have added an error bar of $\pm 2\omega$ as an error estimation of the method.

$\exp(-2i\phi + \pi)$. For this case Eq. (12) yields

$$\Phi_-(\alpha)e^{+2i\phi} - \Theta(\alpha) + \Phi_+(\alpha)e^{-2i\phi} = 0, \quad (21)$$

which has a solution

$$\alpha^2 = \frac{1}{2}[\omega_0^2 + \omega^2 + \sqrt{(\omega_0^2 - \omega^2)^2 + 16\omega^2|\chi|^2}]. \quad (22)$$

In the limit $\omega \rightarrow 0$, the plateau's onset is approximately ω_0 which is the estimation in Ref. [17].

The value of the frequency at the plateau's cutoff can be inferred imposing the phase condition for the higher-frequency harmonics: $\exp(-2i\phi)$. We have then

$$\Phi_-(\alpha)e^{+2i\phi} + \Theta(\alpha) + \Phi_+(\alpha)e^{-2i\phi} = 0, \quad (23)$$

which has a solution

$$\alpha^2 = \omega_0^2 + 4|\chi|^2, \quad (24)$$

in coincidence with Ref. [17] and also converges to that in Ref. [19] in the limit of $\omega_0 \rightarrow 0$. For large field intensities, the plateau extends linearly with the field amplitude in contrast with the case of high-order harmonic generation in ionizing systems, where the cutoff is proportional to the intensity.

Figure 6 shows the results of Eqs. (22) and (24) for the case $\omega/\omega_0 = 0.1$ and different field amplitudes. Superimposed to this, we plot the values of the harmonic number for the plateau's onset and cutoff extracted from the numerical integration of Eqs. (1) and (2). For the latter case the plateau's onset remains practically constant and equal to ω_0 ; however, for larger photon frequencies, the departure between Eq. (22) and the low coupling limit ω_0 becomes more apparent. For instance, in the case plotted in Fig. 4 the plateau's onset frequency evaluated from Eq. (22) (corresponding to the lower limit of the shadowed box) is about 2ω above ω_0 (pointed out by an arrow).

VI. PHYSICAL INTERPRETATION: THE ADIABATIC REGIME

The above formulas have a clear physical interpretation if we consider the limit of small driving frequencies, $\omega \ll \omega_0$

FIG. 7. (Color online) Scheme of the instantaneous eigenenergies of the two level atom during one driving field period. In the adiabatic limit, the maximum (a) and minimum (b) level differences define the energies of the plateau onset and cutoff, respectively.

and $\omega \ll |\chi|$ [12,13]. In this case we can consider the instantaneous eigenstates of the time-dependent Hamiltonian as physically meaningful. The diagonalization of (1) and (2) gives the eigenenergies

$$\lambda_{\pm} = \frac{1}{2}(\omega_0 \pm \sqrt{\omega_0^2 + 4F^2(t)}), \quad (25)$$

with $F(t) = \text{Re}\{\chi \exp(-i\omega t)\}$, oscillating harmonically. Figure 7 shows a schematic plot of these two eigenenergies along a laser cycle. The instantaneous transition energy is given by $\lambda_+ - \lambda_- = \sqrt{\omega_0^2 + 4F^2(t)}$ which oscillates between ω_0 [at times when $F(t) = 0$] and $\sqrt{\omega_0^2 + 4|\chi|^2}$ [at the maximum amplitude of $F(t)$]. These two values coincide with the harmonic plateau onset and cutoff at the limit $\omega \rightarrow 0$ derived in the above section, see Eqs. (22) and (24). This suggests that the plateau structure of the two-level dipole spectrum is originated by the transitions between the field dressed states. This mechanism differs from the strong-field scenario, where the same structure is originated by the high-energy radiation emitted from the recollision between an ionized electron with the parent atom. A fundamental difference between these two cases also appears in the identification of the moment where the higher-frequency harmonics are emitted. In the two-level case, Eq. (25), these harmonics correspond to the maximum of F^2 and, therefore, to the maximum of the driving field, while

in real atoms the ionized electron recollides with the parent atom at times where the driving field is near zero.

VII. CONCLUSIONS

We present a formalism to fully describe the dipole spectrum of a two-level system excited by a nonresonant intense electromagnetic field. The derived formalism beyond the rotating wave approximation is general within the electric dipole approximation for monochromatic fields. This new approach allows to perform a fundamental decomposition of the complex dipole spectrum structure into two families: the harmonic frequencies of the driving field and the field-induced nonlinear fluorescence frequencies. Moreover, it provides analytical expressions for the nonresonant Stark shift for the fluorescence family and of the onset and cutoff limits for the harmonic family. Within this formalism, we predict the generation of pulses with lower duration than the period of the driving field by selectively filtering out the frequencies of the emitted radiation, in close analogy with the attosecond pulse generation in the case of ionizing electromagnetic fields [11].

It is important to note that the presented formalism is an optimal tool to treat the burgeoning new physical scenarios where the two-level system approximation is applied, such as harmonic generation in molecules or dipolar two-level transitions in nuclei. Therefore, our approach is suitable to theoretically address experiments in the field in the near future.
