Summary

Contractility of striated muscle can be modulated by various mutations in nebulin and titin present in human disease. Mijailovich et al. perform computational simulations coupled with experimental observations to provide insights into the mechanisms by which mutations in these proteins cause disease phenotypes.

Abstract

Various mutations in the structural proteins nebulin and titin that are present in human disease are known to affect the contractility of striated muscle. Loss of nebulin is associated with reduced actin filament length and impairment of myosin binding to actin, whereas titin is thought to regulate muscle passive elasticity and is likely involved in length-dependent activation. Here, we sought to assess the modulation of muscle function by these sarcomeric proteins by using the computational platform MUSICO (MUscle SIMulation COde) to quantitatively separate the effects of structural changes, kinetics of crossbridge cycling, and calcium sensitivity of the thin filaments. The simulations show that variation in thin filament length cannot by itself account for experimental observations of the contractility in nebulin-deficient muscle, but instead must be accompanied by a decreased myosin binding rate. Additionally, in order to match the observed calcium sensitivity, the rate of TnI detachment from actin needed to be increased. Simulations for cardiac muscle provided quantitative estimates of the effects of different titin-based passive elasticities on muscle force and activation in response to changes in sarcomere length and inter-filament lattice spacing. Predicted force-pCa relations showed a decrease in both active tension and sensitivity to calcium with a decrease in passive tension and sarcomere length. We conclude that this behavior is caused by partial redistribution of the muscle load between active muscle force and titin-dependent passive force, and also by redistribution of stretch along the thin filament, which together modulate the release of TnI from actin. These data help advance understanding of how nebulin and titin mutations affect muscle function.

Keywords: MUSICO platform, thin filament regulation, 3D explicit lattice, calcium sensitivity, mutation of sarcomeric proteins, skeletal muscle, cardiac muscle

INTRODUCTION

During muscle contraction, myosin binding to actin is primarily regulated by Ca^{2+} , via the thin filament-associated proteins tropomyosin (Tm) and troponin (Tn). There are many models of thin filament regulation, but the kinetics of interactions between the Tm-Tn complexes are, at present, best described by the 3-state McKillop and Geeves model (McKillop and Geeves, 1993) and the long range cooperative continuous flexible chain (CFC) model (Geeves et al., 2011; Mijailovich et al., 2012a) that includes structural constraints between Tm-Tn regulatory units (Fig.1). The interaction of Tn with actin is regulated by Ca^{2+} binding to Troponin C (TnC). TnC has two binding sites in skeletal muscle and one in cardiac muscle (Potter and Gergely, 1975; van Eerd and Takahashi, 1975; Leavis and Kraft, 1978; Leavis et al., 1978; Holroyde et al., 1980). Coupling these regulatory models with crossbridge models in the explicit 3D sarcomere lattice (Daniel et al., 1998; Chase et al., 2004; Mijailovich et al., 2016) can provide a general tool for studying the effects of mutations in regulatory and auxiliary structural proteins on muscle function.

The structural proteins nebulin and titin (Fig.1) are essential for proper physiological function of muscle. The degree of expression and the precise roles of these proteins vary between different types of muscle. Genetic mutations in these proteins are associated with many diseases (Pelin et al., 1999; Gerull et al., 2002; Wallgren-Pettersson et al., 2004; Lawlor et al., 2011; Taylor et al., 2011; Herman et al., 2012; Ceyhan-Birsoy et al., 2013; Begay et al., 2015; Oates et al., 2018; Ware and Cook, 2018). Several hypotheses have been proposed in order to explain the roles of nebulin and titin in muscle function and disease. For example, nebulin isoform size, associated with different types of skeletal muscle, has been proposed to regulate the length of thin filaments (Kruger et al., 1991; Labeit et al., 1991; Witt et al., 2006; Labeit et al., 2011). Thus, in muscle deficient in nebulin, thin filament length is reduced and active tension is lower due to a reduction in thick-thin filament overlap (Witt et al., 2006; Ottenheijm et al., 2012; Li et al., 2015). Additionally, nebulin enhances myosin binding (Bang et al., 2009; Chandra et al., 2009; Ottenheijm et al., 2010), similarly to tropomyosin (Maytum et al., 1999), and might play a role in regulating muscle contraction. In cardiac muscle, there are only low levels of nebulin present, marginalizing its effect on contraction (Kolb et al., 2016). Similar to nebulin deficient muscles, cardiac muscle shows variable lengths of thin filaments (Robinson and Winegrad, 1977, 1979; Burgoyne et al., 2008) and lower isometric tension at full activation. On the other hand, titin elasticity, modulated by various mutations and splice variants, can strongly affect cardiac muscle function (Granzier et al., 2009; Chung et al., 2013; Methawasin et al., 2014; Hinson et al., 2015; Methawasin et al., 2016), for example length-dependent activation of crossbridges (Wang and Fuchs, 1994; Metzger, 1995; Cazorla et al., 2001; Fukuda et al., 2003; Fukuda and Granzier, 2005; Ait-Mou et al., 2016).

The key contractile unit of striated muscle, denoted as the sarcomere (Fig. 1), integrates all the above discussed structural elements and depending on the activation level, defines changes in muscle tension and length. The muscle contractile tension per unit amount of actin-

myosin overlap is determined by the number of attached crossbridges and their state in the force-generating cycle. For a well-defined actomyosin cycle the kinetics of myosin binding and detachment determines the density of bound crossbridges. However, the number of attached crossbridges per unit length of thin/thick filament overlap is tightly regulated by the calcium concentration and the associated kinetics of the interactions of regulatory proteins with actin. Higher concentrations of calcium and higher degrees of filament overlap strongly correlate with contractile force.

The degree of filament overlap is determined by the sarcomere length and the lengths of myosin and actin filaments. The length of myosin filaments is well conserved at $\sim 1.6 \mu\text{m}$, but the length of actin filaments can vary from muscle type to muscle type. Mutations in nebulin or lack of nebulin will also produce large variations in actin filament length. For example, Witt et al. (Witt et al., 2006) observed a large variation of actin filament lengths in tibialis cranialis muscle, isolated from a knock-out (Neb-KO) mouse model, having a range from ~ 0.4 to $1.2 \mu\text{m}$, whereas in the wild type (wt) muscles the actin filament lengths are approximately constant at $\sim 1.2 \mu\text{m}$. This large variation in length in Neb-KO muscle can explain, at least in part, the reduced isometric force generation and the leftward shift in the descending limb of the force-sarcomere length relations of Neb-KO fibers (Witt et al., 2006). Similar behavior is observed in patients with nebulin-based nemaline myopathy (Neb-NM) (Ottenheijm et al., 2009). Additionally, force-pCa relations showed a lower sensitivity to calcium concentration in both Neb-KO and Neb-NM fibers (Chandra et al., 2009; Ottenheijm et al., 2010). However, it is unlikely that variable and, typically, shorter lengths of thin filaments in Neb-KO muscle can quantitatively explain all observations, and it may be necessary to consider other mechanisms such as reduced myosin cycling rates and reduced thin filament activation (Ottenheijm et al., 2012).

In cardiac muscle, nebulin is found only in miniscule amounts (Kazmierski et al., 2003) (Kolb et al., 2016). Similarly to the range of actin filament lengths in nebulin-deficient skeletal muscle and the different actin filament length in different skeletal muscle types (Ottenheijm et al., 2012), in cardiac muscle the observed range of thin filament lengths is in atrial muscle ~ 0.6 – $1.1 \mu\text{m}$ (Robinson and Winegrad, 1977) and in rat papillary muscle ~ 0.9 – $1.1 \mu\text{m}$ (Robinson and Winegrad, 1977, 1979; Burgoyne et al., 2008).

The elastic properties of the sarcomere can also be modulated by mutations in structural proteins. The elastic properties of heart muscle are important for both diastolic filling and energy storage. In cardiac muscle, titin plays important roles in the structure and elasticity of the sarcomere (Trombitas et al., 1998; Granzier et al., 2002; Granzier and Labeit, 2006; King et al., 2011) and titin may affect the Frank-Starling relation in early diastole (Helmes et al., 2003). Notably, titin mutations can compromise elasticity and modulate cardiac cell function (Anderson et al., 2013; LeWinter and Granzier, 2013, 2014; Hinson et al., 2015). The cellular basis of this behavior is strongly associated with the change in calcium sensitivity with sarcomere length, resulting in a leftward shift of the force-pCa relations with an increase in sarcomere length

(Wang and Fuchs, 1994; Metzger, 1995; Cazorla et al., 2001; Fukuda and Granzier, 2005). This increase in calcium sensitivity at longer sarcomere length, known as length dependent activation, has been primarily attributed to the effect of changes in radial and longitudinal titin-based forces (Cazorla et al., 2001; Fukuda and Granzier, 2005; Fukuda et al., 2005; Methawasin et al., 2014; Ait-Mou et al., 2016). Recent studies have provided evidence that changes in the stiffness of titin can indeed play an important role in modulating calcium regulation via altering the structure of the thick filament (Ait-Mou et al., 2016). Several theoretical studies address the role of the elasticity of sarcomeric filamentous proteins in muscle contraction: (1) In a parametric model, Campbell estimated the effect of titin's nonlinear elasticity on the heterogeneity of sarcomere lengths along muscle fibers in response to a lengthening protocol (Campbell, 2009), (2) in a spatially explicit 3D model of the sarcomere Fenwick et al. (Fenwick et al., 2017) estimated the effects of crossbridge and thin filament compliances on isometric tension and force-velocity relations, and (3) Powers et al. determined how titin elasticity modulates force-sarcomere length relations and ATP utilization rates (Powers et al., 2018). However, from all these studies it is difficult to quantitatively separate the role of each of the possible contributing mechanisms to functional behavior at the organ level, or whether there are other mechanisms that have not been evaluated. Here we focused on the work by Cazorla et al. (Cazorla et al., 2001), because this study contains the most complete data required for the simulations we present here. It includes multiple passive tension levels at the same sarcomere length (achieved by varying the history of pre-stretch prior to activation), it measured interfilament spacing at different sarcomere lengths (SL), and it reports the effect of lattice compression by dextran.

To quantitatively estimate the effect of nebulin deficiency on muscle function and the effect of titin passive elasticity and change in inter-filament lattice spacing on length-dependent activation we used the computational platform MUSICO (MUScle SIMulation COde). MUSICO takes into account the crossbridge cycling kinetics, the explicit 3D geometry of the myofilament lattice including variation in actin filament lengths and titin based passive elasticity, and thin filament regulation involving a continuous flexible chain for the troponin/tropomyosin system (Smith, 2001; Smith et al., 2003; Geeves et al., 2011; Mijailovich et al., 2012a). In the calculations shown below, we determined the isometric active force (per myosin filament) for the physiological range of intracellular calcium concentrations and all conditions of geometry and muscle type. Specifically, the simulations include the lattice spacings between the thick and thin filaments, constant or variable thin filament lengths, the passive stiffness of titin molecules and the observed slack lengths in skeletal and cardiac muscles. The role(s) of nebulin in decreasing isometric force and affecting its sensitivity to calcium are quantitatively tested by MUSICO simulations. The predictions differentiate the effects of changes in thin filament lengths, crossbridge kinetics and TnC sensitivity to calcium and match observed changes in nebulin deficient muscles relative to wild type muscles. Similarly, the MUSICO simulations distinguish the effects of mutation-induced changes in titin elasticity and inter-filament spacings at different sarcomere lengths, and the lattice compression by dextran. It is important to note that variable thin filament lengths are observed in skeletal muscles lacking nebulin due to mutations in the

NEB gene and in cardiac muscle where nebulin is normally not expressed. It is warranted, therefore, to evaluate how thin filament length variation affects the contractility of both muscle types. The passive elasticity derived from titin is more relevant in the physiological sarcomere length range of cardiac muscle than in skeletal muscle, due to the aforementioned shorter molecular spring region of cardiac muscle (Powers et al., 2018), thus, for simplicity we only thoroughly analyze the role of titin in cardiac muscle. In so doing, the MUSICO simulations provide an opportunity to quantitatively assess and separate the multiple effects associated with structural and kinetics changes caused by mutations in nebulin and titin that can be experimentally measured only in the aggregate.

Results show that only part of the tension deficit observed in nebulin-deficient muscle can be explained by the effect of shorter lengths of actin filaments but matching of the observed tension deficit also requires that nebulin enhances the rate of myosin binding to actin and alters the calcium sensitivity at different sarcomere lengths. Similarly, the decrease in active tension and calcium sensitivity seen with decreased titin-based passive tension in cardiac muscle can be attributed to a partial redistribution of the muscle load between active muscle force and titin-based passive force, and by redistribution of strain along the thin filament. The nonuniform strain per se may cause significant changes in TnI-actin bond forces, modulating the release of TnI from actin, and hence, the degree of activation of the thin filament.

MATERIALS AND METHODS

The MUSICO simulation platform (Mijailovich et al., 2016) has a modular organization allowing it to incorporate a spatially explicit 3-D sarcomere structure, any one of several actomyosin cycles ((Mijailovich et al., 2016); Mijailovich, S.M., et al. 2015. Biophysical Society 59th Annual Meeting. Abstr. 337a; Mijailovich, S.M., et al. 2017. Biophysical Society 61st Annual Meeting. Abstr. 115a) and various models of thin filament regulation by calcium (Mijailovich et al., 2012a; Mijailovich et al., 2012b). This flexible structure makes the MUSICO simulation platform well suited for investigating the effects of changes in sarcomeric proteins, their 3-D arrangement in the sarcomere, protein-protein interactions, thin filament regulation by Ca^{2+} and the roles of structural proteins such as nebulin and titin (Fig. 1). The basic sarcomere geometry minimally includes the fixed lengths of myosin and actin filaments, the specified slack length of a sarcomere, and the transverse inter-filament spacing (Mijailovich et al., 2016). Each actin filament includes tropomyosin-troponin (TmTn) units aligned along each of two actin monomer strands, forming two continuous regulatory chains (Mijailovich et al., 2012a). The MUSICO platform now incorporates a coupling of thin filament regulation (Geeves et al., 2011; Mijailovich et al., 2012a) to our published 3D explicit model of crossbridge kinetics (Mijailovich et al., 2016) and the implementation of new features that include variable lengths of thin filament and (nonlinear) elastic contributions of titin to sarcomere contraction. In this section we describe the broader concepts and put the detailed descriptions in the appendices. Appendix A describes the geometrical aspects of the 3D interactions between myosin heads with their binding sites on

actin. In Appendix B we describe the formulation of strain dependent rates in the actomyosin cycle. In Appendix C we describe the basic concepts of thin filament regulation by calcium (Mijailovich et al., 2012a; Mijailovich et al., 2012b) and in Appendix D the coupling between strain dependent crossbridge cycle and thin filament regulation by calcium.

3D myofibril lattice structure

The minimal contractile unit in vertebrate muscle can be considered as a myofibril. For a typical myofibril of 1.2 μm in diameter the estimated the number of myosin filaments from structural data (Millman, 1998; Irving et al., 2000) is about 500 to 650. A myofibril runs the entire length of the muscle fiber and consists of a large number of sarcomeres in series. In a half-sarcomere, each half myosin filament with ~ 150 myosin molecules faces six actin filaments; each actin filament has from 360 to 440 myosin binding sites, depending on the actin filament length, arranged in a double-stranded helix. The maximum overlap region is defined by the number of myosin crowns where 50 crowns interact with about 512 active actin sites. The actin filament length as well as the number of actin monomers may vary due to mutations or presence or absence of nebulin.

Actin-myosin interactions are determined by the discrete lattice structure of interdigitated actin and myosin filaments (Fig. 1). Each myosin filament is decorated with crowns of myosin dimers, spaced by ~ 14.3 nm along the filament where each crown consists of three myosin dimers with transverse orientations spaced by 120° , and successive crowns along the filament are rotated by $+40^\circ$ looking towards the Z-line (Fig.2). An important parameter is the average inter-filament spacing, $d_{1,0}$, which may be measured from the 1,0 equatorial reflection in small angle X-ray diffraction patterns (Higuchi et al., 1995; Millman, 1998).

The actin monomers in a thin filament form a double-stranded helix structure associated with the regulatory proteins tropomyosin and troponin with binding sites separated by ~ 5.47 nm on each strand, with a half-period of ~ 35.55 nm in the relaxed state (Huxley et al., 1994; Wakabayashi et al., 1994; Bordas et al., 1999; Prodanovic et al., 2016). The difference in periodicities between actin binding sites (~ 35.55 nm) and myosin crowns (42.9 nm) creates a range of longitudinal spacings between myosin heads and actin binding sites, and this range of spacings is strongly modulated by the extensibility of myofilaments. In the 3-D sarcomere lattice, the actin binding domains on the myosin heads and the binding sites on actin require both longitudinal position matching and angular matching in the azimuthal plane (Fig.3). A myosin head and the closest actin site form the most probable pair of these molecules that can create a crossbridge interconnecting actin and myosin filaments (Mijailovich et al., 2016).

Mutations in, or lack of, nebulin, as observed in nemaline myopathy, are correlated with a large variation in thin filament lengths and are also associated with a reduced myosin binding rate to actin. Large variations in actin filament lengths are also observed in cardiac muscle due to low expression levels of nebulin. The passive elasticity of muscle due to titin can be compromised by mutations strongly modulating muscle contractility and regulation. To quantitatively assess the

effects of changes in structural proteins titin and nebulin on muscle contractility, we implemented in MUSICO both the variable actin filament lengths due to mutations in nebulin and titin as a nonlinear spring connecting the Z disc with the tip of myosin filament (Fig. 1).

Crossbridge Rate Kinetics

Matching myosin heads with binding sites on actin. In the three-dimensional sarcomere lattice, the relative distance between a myosin head and the adjacent binding site on actin is defined by four factors (Mijailovich et al, 2016): (i) the axial displacements along myosin and actin filaments, (ii) the transverse distance between myosin and actin filaments, $d_{M-A} = \frac{2}{3}d_{1,0}$, where $d_{1,0}$ is the average inter-filament lattice spacing derived from the 1,0 X-ray reflection, (iii) the angle α defining the relative position of myosin to actin filament, and (iv) the angle β defining how much a myosin head needs to turn along the actin perimeter of actin in order to reach an actin monomer in the correct orientation. These spatial distances and angles are essential information for formulating the strain dependence of the state transition rates, reflecting the discrete geometric relationships between myosin heads and actin binding sites (Fig.3). The definition of the myosin binding step in relation to the 3-D sarcomere lattice is described in Appendix A.

Strain dependent rates in the actomyosin cycle. The modular structure of the computational platform MUSICO can incorporate many different actomyosin cycles. To quantitatively assess the effect of titin and nebulin, without loss of generality, we considered a minimal three state model that includes a swinging lever arm step or power stroke (Huxley and Simmons, 1971). For simplicity we use here a 3 state scheme (Mijailovich et al., 2016), similar to that proposed by Duke (Duke, 1999) and Daniel et al. (Daniel et al., 1998), that includes one detached myosin state, $M \cdot ADP \cdot Pi$, and two attached myosin states: weakly bound, $A \cdot M \cdot ADP \cdot Pi$, and a strongly bound to actin after Pi release, $A \cdot M \cdot ADP$ state (Fig. A1).

The state transition rate constants between actomyosin states in crossbridge models are derived from the functions for the free energy of the crossbridge states in terms of the axial strain component x . In the 3-D sarcomere lattice, however, the strain dependent rate of myosin binding to actin is modulated, in addition to the axial strain x (Fig. 3A), by the spatial position of the actin filaments and the azimuthal departure of a myosin-binding site on actin filament from the plane passing through actin longitudinal axes (Fig. 3C). This effect is implemented in MUSICO via weight factors C_α and C_β , for the azimuthal departures and, in addition, includes the normalization factor f_{sk} , that takes into account the number of actin sites that a crossbridge can reach and bind (for further details see Appendix A and (Mijailovich et al., 2016)).

Calcium regulation of myosin binding to actin filaments

The contractility of striated muscle is regulated by the calcium-dependent azimuthal movements of tropomyosin-troponin complexes over the surface of the actin filament. In the steric blocking

model, the affinity of myosin for regulated F-actin is controlled by tropomyosin (Tm), where Tm molecules are aligned along each strand of the actin double-stranded helix. An assumption common in most regulatory models is that each tropomyosin molecule moves between three discrete orientations modulating actin affinities for myosin (McKillop and Geeves, 1993; Pirani et al., 2005; Poole et al., 2006).

A closer look at the tropomyosin units shows structural evidence that neighboring tropomyosins overlap and that one end of TnT is bound to a specific site on Tm whereas its N-terminus overlaps the adjacent Tm forming linked Tm–Tm regions. Thus, on each strand of F-actin, the interconnected neighboring TmTn units form the appearance of a continuous flexible chain (CFC) (Lorenz et al., 1993; Vibert et al., 1997) rather than a set of the independent TmTn units. The implementation of a CFC in sliding filament models provides structural, rather than ad hoc, insight in the observed cooperativity effects in models of thin filament regulation (Mijailovich et al., 2012a).

For modeling thin filament regulation as a CFC, we follow the approach of Smith et al. (Smith, 2001; Smith and Geeves, 2003; Smith et al., 2003; Geeves et al., 2011) and we have developed a Monte Carlo algorithm to quantify spatially explicit myosin binding to regulated F-actin in solution (Geeves et al., 2011; Mijailovich et al., 2012a). The algorithm consists of three main steps: (1) calculation of the state transitions between actin–TmTn states as a function of calcium concentration, (2) calculation of mean CFC angular positions and their azimuthal angular fluctuations along the actin filament and (3) calculation of state transitions between actin-myosin states. These processes are interrelated and regulated by the calcium concentration. The CFC position and its fluctuations modulate the original state transition rates of TnI or myosin binding to actin, whereas the spatial position of pinning sites, at which the TnI and myosin are bound to actin, determines the mean CFC angular position and the thermally induced azimuthal fluctuations (Geeves et al., 2011; Mijailovich et al., 2012a). General definitions, calculations of CFC angular position and its variance, and the coupling between the calcium regulated position of the CFC and myosin cycle states are described in Appendix C.

Monte Carlo simulations of rate dependent stochastic processes

In the stochastic model, we employed the standard Metropolis algorithm where a kinetic transition in a time step Δt occurs when a random number in $(0, 1)$ lies in the range $(0, k\Delta t)$, where k is the first-order transition rate constant. This algorithm generates a Markov process if $k\Delta t \ll 1$, so that at most one transition occurs per Monte Carlo time step in a single subsystem, here considered as two CFCs on one actin filament for TnI transitions or one myosin filament and its associated actin filaments for crossbridge kinetics. This approach prevents interference between multiple transitions within a single subsystem and the interference between the systems is negligibly small. Thus, Δt must be much smaller than the inverse of the fastest rate constant of the system, k_{max} , and in practice $k_{max}\Delta t < 0.001$ was required to achieve satisfactory statistics.

The coupling between thin filament regulatory processes and the actomyosin cycle requires two sets of Monte Carlo random number drawings and the overall numerical procedure within each time step includes: (1) the first set of drawings defining transitions of TnI-actin states; (2) calculation of chain configuration with updated TnI-actin states and myosin bound states from the previous time step; (3) the second set of random number drawings defining the changes on actomyosin states regulated by the CFC; and (4) calculation of the mechanical equilibrium with external forces and constraints. The last step includes an iterative procedure to account for nonlinear elasticities included in the mechanical system, for example the nonlinear elasticity of titin.

For each TnI or crossbridge, we use one Monte Carlo random number drawing to define whether the TnI or crossbridge remains in its current state or it will change its state into one of the other possible states within the current time step Δt . For each TnI or crossbridge the probability, in the range from 0 to 1, is divided into probability bins, P_{ij} , in a specified order, including the set of probability bins associated with a TnI or crossbridge changing state and a bin associated with the probability of remaining in the current state. Depending in which bin the drawn random number falls, the fate of a particular TnI or crossbridge is defined and set for the following time step.

The calculation of the transition probabilities from the transition rates between TnI-actin states and between actomyosin states in the 3D sarcomere lattice are as described in (Mijailovich et al., 2012a) and (Mijailovich et al., 2016), respectively. Here we briefly describe the modulation of TnI-actin and myosin-actin transitions by accounting for the current configuration of myosin bound states and position of CFC at a prescribed concentration of calcium.

In a half sarcomere each myosin half-filament interacts with six actin filaments, but because of symmetry, each half of a myosin filament effectively interacts with two actin filaments. The interactions between myosin heads (crossbridges) and myosin binding sites on actin in the 3-D sarcomere lattice are as described in (Mijailovich et al., 2016). Furthermore, each actin filament can be viewed as a double-stranded helix where each strand is associated with one CFC. We consider here that one CFC subsystem consists of one CFC and one actin strand. Because each TmTn unit covers 7 actin monomers, the number of TnI-actin binding sites per strand is equal to one seventh of the number of actin monomers per strand (Mijailovich et al., 2012a).

The coupling between crossbridge cycling and calcium regulation of the thin filament is described in Appendix D.

Model parameters

Sarcomere Geometry. The 3D sarcomere lattice in vertebrate striated muscle, is composed of myosin filaments each surrounded with six actin filaments and each actin filament with three

myosin filaments (Figs. 1 and 3B). Each half myosin filament is associated with six titin molecules. Actin filaments can vary in length depending on species, muscle type and presence or absence of nebulin in skeletal muscle. The actin filaments have a monomer spacing of 2.735 nm and the half period of one strand is 35.55 nm under relaxed conditions (Huxley et al., 1994; Wakabayashi et al., 1994; Prodanovic et al., 2016). The length of a myosin filament is $\sim 1.58 \mu\text{m}$, having 50 crowns, i.e. 150 myosin molecules per half-thick filament, with a crown spacing of 14.3 nm (Luther et al., 2008). This number of crowns and spacing provides maximum overlap with thin filament of $\sim 0.7 \mu\text{m}$. The actin radius is $r_a = 3.5 \text{ nm}$ and myosin radius is $r_m = 7.8 \text{ nm}$ (Fig.3) (Mijailovich et al., 2016). The lattice inter-filament spacing depends on sarcomere length, the specificities of the muscle type and experimental conditions. The values of the spacing $d_{1,0}$ are specified for each set of simulations.

Variability of actin filament lengths in skeletal muscle. It has been hypothesized that nebulin, a filamentous protein extending along the entire length of the actin filament, maintains constant length of thin filaments, but in disease, e.g. human nemaline myopathy, mutations in, or lack of, nebulin can result in much shorter randomly distributed thin filament lengths. In order to measure thin filament lengths Witt and colleagues (Witt et al, 2006) labeled skinned muscle fibers by streptavidin-coated gold beads and showed a uniform thin filament length distribution in wild type muscle, $\sim 1.2 \mu\text{m}$ measured from the Z-disk (Figure 4A), whereas in Neb-KO sarcomeres, they observed shorter filaments ranging in length from ~ 0.4 to $1.2 \mu\text{m}$ (Figure 4B). We define a complementary cumulative probability function of filament lengths, $\widehat{\Phi}_c(L_a) = \Phi_c(L_a)/a$, from the function $\Phi_c(L_a)$ used for fitting of the histograms in Figs. 4A and B (red lines) and normalization frequency, a . The distribution of actin filament lengths is the derivative of the cumulative probability function, $\widehat{\Phi}(L_a) = 1 - \widehat{\Phi}_c$, defined as $d\widehat{\Phi}/dL_a$ (Figs. 4 C and D). The inverse function of $\widehat{\Phi}(L_a)$ defines the actin filament length as a function of cumulative probability, $L_a(\widehat{\Phi}) = L_a^o - b \ln[(\widehat{\Phi})/(1 - \widehat{\Phi})]$. The variable lengths of thin filaments are assigned in our spatially explicit MUSICO sarcomere geometry by substituting sequentially drawn random numbers, $Rnd\#$ in expression $L_a(\widehat{\Phi} = Rnd\#)$ where $Rnd\#$ is in range from 0 to 1 (Fig. 4D).

Variability of lengths of actin filaments in cardiac muscle. The length of actin filaments in rat cardiac atrial trabeculae muscle also varies in range from ~ 0.6 to $1.1 \mu\text{m}$ (Robinson and Winegrad, 1977). Using the best fit distribution of actin lengths from Fig. 5A we obtained the cumulative probability function $\widehat{\Phi} = 1/(1 + e^{-(L_a - L_a^o)/b})^c$, where L_a is the thin filament length (Fig. 5B). The inverse function of $\widehat{\Phi}(L_a)$ defines the spatially random distribution the filament lengths, $L_a(\widehat{\Phi}) = L_a^o - b \ln[(1 - \widehat{\Phi}^{1/c})/\widehat{\Phi}^{1/c}]$, for the assigned values for $\widehat{\Phi}$ from sequentially drawn random numbers, $Rnd\#$.

Inter-filament lattice spacing. In skeletal muscle, lattice volume is approximately constant under ordinary physiological conditions. Thus, the inter-filament lattice spaces can be calculated at

any length from lattice volume data (Kurg et al., 1982; Millman, 1998), by the relation $d_{1,0} = \sqrt{\zeta_{sarc}/[(2/\sqrt{3}) SL]}$ where for mouse EDL muscle $\zeta_{sarc} = 4.03 \times 10^6 \text{ nm}^3$ and sarcomere length, SL , is in range from 2 to 4 μm . The skeletal muscle Force-pCa simulations are performed at sarcomere lengths of 2.5 μm and 2.0 μm at which inter-filament lattice spacing $d_{1,0}$ is 37.36 and 41.77 nm, respectively. However, lattice volumes in cardiac muscle are not constant (Yagi et al., 2004) and need to be independently measured.

The inter-filament spacings of skinned cardiac trabeculae muscle were obtained from experimental observations (Irving et al., 2000; Cazorla et al., 2001) at sarcomere lengths of 2.3 and 2.0 μm , having $d_{1,0}$ values of ~ 40.9 nm and ~ 42.9 nm respectively. The spacings in trypsin treated muscles were larger having values of ~ 43.7 and ~ 47.3 nm at sarcomere lengths (SL) 2.3 and 1.9 μm respectively, whereas they were much smaller after compression with 2.5% dextran having values of ~ 35.0 and ~ 35.6 nm at SL 2.3 and 2.0 μm , respectively (see also Table 1).

Myofilament Elasticity. Actin and myosin filaments are extensible with filament moduli (elastic modulus times cross-section area) derived from X-ray diffraction or direct measurement: for actin, $K_a = 0.65 \times 10^5 \text{ pN}$; and for myosin $K_m = 1.32 \times 10^5 \text{ pN}$ (Huxley et al., 1994; Kojima et al., 1994). We used here the modulus, AE, rather than stiffness, AE/L, because the reported stiffness values depend on the filament length, L, and cross-section area A is not well defined for myosin and actin filaments. The presence or lack of nebulin can strongly affect the elasticity of the thin filament (Kiss et al., 2018), but a fourfold decrease in thin filament stiffness only mildly affects isometric contractile force in the steady state, i.e. $< 3\%$, thus only a single value of K_a is used in all simulations (see Fig. S2 in Supplemental Material). Similarly, the change in calcium sensitivity is small ($\Delta p\text{Ca} < 0.025$).

The elasticity of titin in the physiological range is much more important in cardiac muscle than in skeletal muscle, due to the shorter molecular spring of cardiac titin (Powers et al., 2018). For simplicity, we assumed that all passive tension transmitted to a myosin filament is contributed by titin. After recalculation of passive force per half myosin filament to force per titin molecule at sarcomere lengths of 2.3 and 2.0 μm we found an excellent agreement with the observations of Helmes et al. (Fig. 5C) (Helmes et al., 1999). Because all calculations are done at isometric sarcomere length, the compounded stiffness of six titin molecules per half myosin filament is set to reach the passive force at the prescribed length and linearly changes around that point due to small deformations of the extensible myofilaments. At a slack length of 1.9 μm the passive force and titin stiffness are assumed to be ~ 0 (Granzier and Irving, 1995).

Crossbridge Model Parameters. For simplicity, we used a three-state cycle that includes a detached state, a weakly bound and a strongly bound state. Following the approach of Duke (Duke, 1999) the state transition rate constants are: wt equilibrium constant for binding at SL= 2.5 μm is $K_{bind} = k_{bind}/k_{unbind} = e^{-\Delta G_{bind}/k_B T} \cong 20$, where $\Delta G_{bind} = -3 k_B T$ for skeletal and

for cardiac muscle values for the rate constants at appropriate SL and passive tensions are shown in Table 1; forward rate constant at zero crossbridge strain for skeletal muscle at SL= 2.5 μm k_{bind} is 40 s^{-1} in wt and 16.8 s^{-1} in Neb-KO; at SL= 2.0 μm k_{bind} is 25 s^{-1} in wt and 7.5 s^{-1} in Neb-KO; for cardiac muscle k_{bind} is given in Table 1; for the power stroke, the equilibrium constant is defined by $\Delta G_{stroke} = -15 k_B T$ for skeletal (wt) and $= -10.3 k_B T$ for cardiac, whereas the power stroke $d = 10.5 \text{ nm}$ is the same for both types of muscle; and for ADP release/detachment, $k_{ADP}^o = 150 \text{ s}^{-1}$ and the second power stroke $\delta = 1.0 \text{ nm}$ are taken to be the same in all simulations. The tensions for nebulin mutants in skeletal muscle and under various conditions in cardiac muscle are achieved by adjusting k_{bind} and ΔG_{bind} , but keeping k_{-bind} at a constant value of 2 s^{-1} . These binding rates strongly depend on inter-filament spacing and their values are assigned for each simulation. Because of the exponential forms in the expressions for the state transition rates can become very large and can generate numerical problems – they are capped to $k_{23}^{cap} = 1000 \text{ s}^{-1}$, $k_{32}^{cap} = 100 \text{ s}^{-1}$ and $k_{31}^{cap} = 10^4 \text{ s}^{-1}$. These values are chosen as optimal values to satisfy Monte Carlo statistics for time steps of the order of 1 μs . When the cap value is reached, the reverse rates are changed to decay exponentially to satisfy the equilibrium constant, $K_{ij}(x)$. In all simulations, crossbridge stiffness is taken to be $\kappa = 1.25 \text{ pN/nm}$ (as used by (Duke, 1999)) and the value for $k_B T = 4 \text{ pN}\cdot\text{nm}$ at 15°C ($T = 288 \text{ }^\circ\text{K}$).

CFC model parameters. For the CFC model we used the same parameters reported in (Mijailovich et al., 2012a): a tropomyosin pinning angle, $\phi_- = -25^\circ$; myosin imposed Tm angular displacement, $\phi_+ = 10^\circ$; The tropomyosin (Tm) persistence length estimated in multiple experiments ranges between 45 nm to 170 nm (Phillips and Chacko, 1996; Li et al., 2010a; Sousa et al., 2010; Loong et al., 2012). If we take into account a curved shape of tropomyosin, that allows helical wrapping around without any strain, this could result in less flexible tropomyosin having longer persistence length up to 450 nm (Li et al., 2010b), thus we adopted value of $L_{pTm} = 150 \text{ nm}$ (Wolgemuth and Sun, 2006; Mijailovich et al., 2012a) as a reasonable compromise value. Inclusion of troponin stiffens the Tm chains via TnT interaction with Tm, thus the tropomyosin–troponin chain, TmTn, could have increased bending stiffness and longer persistence length, as for example $L_{pTmTn} = 250 \text{ nm}$ used in (Mijailovich et al., 2012a). For other parameters, the angular Tm bending stiffness per unit length $\kappa_{CFC} = 2.0 \times 10^4 \text{ pN nm}^4$; the persistence length of Tm–Tn confined chain $1/\xi = (4\kappa_{CFC}/\alpha_{cp})^{1/4} = 22.2 \text{ nm}$ as in (Smith et al., 2003; Mijailovich et al., 2012a); the angular standard deviation of the free chain $\sigma_o = 29.7^\circ$; the strength of the chain confining potential $\alpha = 0.341 \text{ pN}$. For cardiac muscle the interaction of the free CFC chain with actin can be weaker and the stiffness of Tm-Tn chain stronger, so for cardiac muscle we used $1/\xi = 25 \text{ nm}$, that corresponds to a slightly wider $\sigma_o = 35.7^\circ$. If κ_{CFC} is kept constant, the strength of the chain confining potential is weaker having a value for α_{cp} of 0.205 pN.

The level of thin filament activation is related to the calcium concentration, $[Ca^{2+}]$, and was derived from the approach of Mijailovich et al. (Mijailovich et al., 2012a) where the level of activation is defined by the TnI detachment rate from actin, $k_B = k_{-I}$, whereas the TnI reattachment rate $k_{-B} = k_I$ is held constant at 100 s^{-1} . The detachment rate k_{-I} is in large part associated with the binding of calcium to TnC, but the strength of the tropomyosin interaction with the actin surface, the elasticity of CFC and the cooperative effects of interactions between myosin binding and tropomyosin chain could all play a role. In order to uncouple the enhancement of the activation level by the cooperativity induced by bound myosins to actin from calcium concentration induced dissociation of TnI from actin, we constructed for each simulation case the relationship between the equilibrium constant $K_B = k_B/k_{-B}$ and the calcium concentration (see Tables S1 and S2 in supplemental material).

In the model of muscle activation calcium binding is coupled with a change of TnI affinity to actin, and this interaction is defined by $K_B = 1/K_I$. The full description of calcium binding kinetics to TnC and transitions within tropomyosin components that include the interaction of TnI with actin is essential for modeling muscle responses to calcium transients (e.g. twitch contractions). For simplicity, however, we did not go into the details of these transitions and we kept only essential information necessary for steady state conditions. Because both simulations ($F-K_B$) and observations ($T-[Ca^{2+}]$) follow a Hill curve, $\log K_B$ and $pCa = -\log([Ca^{2+}])$ are approximately linearly related with the slope equal to the ratios of the Hill coefficients, n_H/η_H . The $\log K_B$ - pCa relationships show a slight shift between the cases and reflect the differences in calcium sensitivity (see Tables S1 and S2) observed under different experimental conditions.

Procedure for estimation of model parameters. The MUSICO platform is formulated on three principal pillars: the 3D explicit (multi)sarcomere geometry, a strain dependent crossbridge cycle and calcium-dependent thin filament regulation. This model provides the precision necessary to quantify the effects of kinetics and the structural changes, associated with mutations in contractile and regulatory proteins, to muscle function, but require a large number of model parameters to properly define muscle fiber structure, crossbridge kinetics and thin filament regulation by calcium. We contend that conventional fitting of the data is not ideal because the published experimental data show large variations and fitting many free parameters can result in unreasonable estimates. Thus we used established structural data and best estimates deduced from experimentally established kinetic data, for as many parameters as possible. In this study we consider only steady state isometric tension, in which case the number of variable parameters is reduced to 2-3 depending on the particular sets of data that model prediction have to match. Specifically, we adjusted only three parameters: (1) k_{bind} because change of interfilament spacing at different sarcomere lengths and possible myosin activation by stretching thick filament via titin at longer sarcomere lengths likely will modulate the myosin binding rate rather than rates of other steps on the cycle; (2) $K_B = 1/K_I$ that defines interaction of TnI to actin associated with Ca^{2+} binding on TnC or release of Ca^{2+} from TnC, and (3) confined persistence

length, $1/\xi$, that includes elasticity of continuous flexible chain (CFC) and tropomyosin interaction to actin, defines the cooperativity factor related to the Hill coefficient in force-pCa relations.

A sensitivity analysis is typically needed when fitted parameters have a large range of possible values (Mijailovich et al., 2010; Mijailovich et al., 2012a; Ujfalusi et al., 2018), but in this study we adjusted only three parameters (k_{bind} , $K_B = 1/K_I$ and $1/\xi$) and they were sufficient to match all experimental data. It is important to note that we adjusted these parameters using data from different experiments: k_{bind} to achieve isometric tension at full activation where $K_B = 1/K_I$ are irrelevant, and $K_B = 1/K_I$ to achieve observed calcium sensitivity (pCa_{50}), and confined persistence length to achieve Hill coefficient n_H in force-pCa relations, where k_{bind} is set from the previous fit. Because the adjusted parameters k_{bind} and K_B are decoupled, a classical sensitivity analysis seems unnecessary. Also, K_B strongly affects pCa_{50} and the persistence length, $1/\xi$, is primarily associated with the Hill coefficient n_H having only weak coupling, thus each parameter can be adjusted with minimal changes in the others.

Conversion between observed tension and isometric force per myosin filament. Due to the stochastic process of myosin interacting with actin, the forces in the myofilaments fluctuate in time and each filament experiences somewhat different force. For comparison with observed isometric tensions we include in all plots both the tension in kPa and the average force per myosin filament, F , in pN. The scales are related by a factor that takes into account how many myosin filaments there are per unit of the fiber cross-sectional area (Linari et al., 1998; Mijailovich et al., 2016). **Because the total number of thick filaments in a myofibril or muscle fiber does not change with experimental conditions, for the estimation of the number of thick filaments per unit of cross section area, we used the lattice spacing, $d_{1,0}$, at slack length, i.e. at the same length where the muscle cross-sectional area that is used in the tension calculations is measured.**

In fibers from mouse skinned skeletal muscle the lattice spacing, at slack sarcomere length of $2.25 \mu\text{m}$ is $d_{1,0} = 39.38$ (Kurg et al., 1982; Millman, 1998) and the corresponding number of thick filaments per μm^2 myofibrillar area is ~ 562 . In most species and skeletal muscles, the myofibrils occupy from 80 to 85% of the fiber volume (Eisenberg, 1983). Assuming the fraction of cross section occupied by myofibrils as 0.83 (Moblely and Eisenberg, 1975), the number of thick filaments per μm^2 in cross-section of skinned muscle cell is ~ 466 . The scaling factor provides a relationship between isometric tension, T_o , and average force per myosin filament, F_o , where, for example in skeletal muscle, $T_o = 125 \text{ kPa}$ corresponds to $F_o \approx 268 \text{ pN}$ per myosin filament.

The lattice spacing, in skinned rat cardiac trabeculae cells at slack sarcomere length ($1.9 \mu\text{m}$), is $d_{1,0} = 43.5 \text{ nm}$ (Irving et al., 2000) and the number of thick filaments per μm^2 myofibril is ~ 458 . Taking in account the fraction of the cross section area in cardiac cell occupied by

myofibrils as 68% (Cazorla et al., 2000) this reduces the number of myosin filaments over the muscle cell cross-section to ~ 311 per μm^2 . In this case, the scaling factor provides that $T_o = 40$ kPa corresponds to $F_o = 128.5$ pN/myosin filament or 64.25 pN/actin filament.

Stochastic process, model size and myofibril edge effects. Due to stochastic transitions in the crossbridge cycle the force per myosin filament can vary between the filaments by up to $\pm 15\%$ at any instant of time, and also by about the same amount in the same filament over time. In contrast, the variation in average force per myosin filament is small, for example if the number of myosin filaments that matches the number of the filaments in an average myofibril the fluctuations in isometric force are minimal ($< 0.1\%$) and reflect observed tension variations.

In the parameter exploration phase we limited the stochastic simulations to a half sarcomere with 200 myosin and 400 actin filaments that is about $1/3$ of the number of filaments in a cross section of a typical myofibril. This number of filaments is sufficient for stable simulations and statistical averaging without requiring running the simulation multiple times. In the final simulations we increased the number myosin filaments per half sarcomere to 500.

A myofibril shows incomplete hexagonal lattice at the periphery. By keeping the ratio of the number of half myosin filament to the number of thin filaments 1:2, the error in calculations in an incomplete lattice are only associated with the effect of thick and thin filament extensibility. In steady state, the effect of filament extensibility is small and is related to matching-mismatching of crossbridges with myosin binding sites on actin filaments resulting in minor change in number of bound crossbridges.

The interaction of myofibrils or muscle fibers with other components of muscle such as collagen and other components of muscle cells aligned parallel to the fibers are not taken in account because in the current simulations we only considered active force and tension under isometric steady state conditions.

The MUSICO software environment and simulation details

The MUSICO software has been developed as C++ object-oriented application that includes LAPACK linear algebra package and deal.II finite element library. Typical run times for these simulations depend on the number of actin and myosin filaments. For the simulation of 200 myosin filaments over 1 s with a time step of $1 \mu\text{s}$ is ~ 10 h on the AEG IS04-KG grid site, consisting of 6 nodes, each equipped with 2 AMD Opteron 6276 16-core processors and 96 GB RAM, totaling 192 processors.

Online supplemental material

The supplemental text describes the three state actomyosin cycle (Fig. S1), the formulation of strain dependent state transition rates; relationship between thin filament regulation state transition rates and calcium sensitivity of isometric force in wt and nebulin deficient skeletal

muscles (Table S1); the effects of passive tension on calcium sensitivity in cardiac muscle (Table S2); the prospective decrease in isometric force and muscle stiffness (Fig. S2) and in calcium sensitivity (Fig. S3) due to the increase in actin filament compliance that appears in nebulin deficient actin filaments (Kiss et al., 2018); normalized force-pCa relation in wt vs. nebulin deficient muscles (Fig. S4) and at high and low passive tension (Fig. S5).

RESULTS

The contractility of muscle modulated by nebulin

Using MUSICO we evaluated whether the force deficit in nebulin-based nemaline myopathy can be explained by (i) shorter and variable thin filament lengths, (ii) altered crossbridge cycling kinetics and (iii) reduced myofilament calcium sensitivity. We quantitatively estimated the effect of nebulin deficiency on muscle function in mice employing MUSICO simulations where we compared the active force (per myosin filament) in normal (wt) and nebulin deficient (Neb-KO) muscles. Predicted force-length relationships of wt muscle, with normal sarcomere geometry including uniform distribution of the length of actin filament filaments ($\sim 1.2 \mu\text{m}$) and for Neb-KO muscle with shorter and variable length of actin filaments are shown in Fig. 6A. These predictions are compared to observations shown as green filled circles for wt and red filled triangles for Neb-KO (Ottenheijm et al., 2009). The predicted force-length relation for wt (pink line with triangle symbols) closely follows the observations (green filled circles). Ottenheijm et al. did not measure tension of either wt or Neb-KO at sarcomere lengths $< 2.2 \mu\text{m}$ because at these lengths thin filaments overlap with those from the adjacent half sarcomere and the striation pattern is compromised, making sarcomere length measurement unreliable. In the MUSICO simulations we took into account the decrease of tension at sarcomere lengths where thin filaments overlap each other, partially preventing myosin binding. In wt fibers, at sarcomere lengths $< 2.25 \mu\text{m}$, the decrease in tension or force per myosin filament is caused by thin-thin filament overlap where thin filament passing the M-line partially blocks the interaction of thick filaments, reducing the effective myosin binding rate. The resulting tension at a SL of $2.0 \mu\text{m}$ is $\sim 12.5\%$ less than the plateau tension.

The nebulin deficient sarcomere with variable lengths of the thin filaments, showed a left-ward shift of the force-length relation (gray line with symbols filled squares), but the shift is insufficient to reach the experimentally determined values in Neb-KO fibers (red filled triangles). Thin filaments also overlap for $\text{SL} < 2.6 \mu\text{m}$ in Neb-KO fibers because the longest actin filaments can reach lengths up to $1.4 \mu\text{m}$. However, because of the small number of thin filaments involved in this process, the decrease in tension at $2.0 \mu\text{m}$ is only about $\sim 5\%$ compared to the tension with no thin-thin filament overlap. Interestingly, the increase of the average overlap between myosin filament and shorter thin filaments increases the corresponding tension by a much larger amount than the decrease caused by thin-thin filament overlap, thus the tension continues to increase with further decreases in sarcomere length. If only the variable thin

filament lengths of Neb-KO are taken into account, the predicted tension with the same actomyosin kinetics (gray line with symbols filled squares) slightly exceeds wt tension at $SL \sim 2.0 \mu\text{m}$. This MUSICO prediction is similar to the estimates of Chandra et al. (Chandra et al., 2009). To obtain large decreases in the magnitude of force and a much larger vertical shift of the force-length relation requires decreasing the myosin binding rate, k_{bind} , by more than twofold, (blue line with cyan filled triangles). This large decrease in k_{bind} can be, in part, attributed to loss of enhancement of the binding rate by nebulin. Collectively these data demonstrate that both reduced thin filament length in nebulin deficient muscle and reduced binding rates are necessary to explain the observations in fully activated muscles (Fig. 6A).

The effect of nebulin deficiency on calcium sensitivity is revealed by the force-pCa curves shown in Fig. 6B. Again, the predicted force-pCa curve for wt (pink line with triangle symbols) closely follows the observations (green filled circles), whereas the Neb-KO sarcomere showed a drop of about 25% at full activation (gray line with filled square symbols) and negligible change in sensitivity to $[\text{Ca}^{2+}]$ (see Fig. S4). This decrease is less than half of the decrease observed in Neb-KO muscles (red triangles) (Witt et al., 2006). Decreasing the myosin binding rate, k_{bind} , by about 2.4 times, with no change of kinetics of calcium binding to TnC and associated TnI affinity to actin, enabled matching the simulation to the observed force at full activation (blue dotted line with hollow blue triangles), but showed lower calcium sensitivity by $\Delta\text{pCa} \cong 0.116$ comparing to the observations (Witt et al., 2006). A large part of this loss of calcium sensitivity ($\Delta\text{pCa} \cong 0.090$) can be attributed to the reduced cooperativity between the CFC chain and a reduced number of bound myosins (blue arrow in Fig. 6B and S4A). To simulate the observations (red filled triangles) it was necessary to increase the detachment rate of TnI from the thin filament, k_{-I} , denoted by the equilibrium constant $K_B = 1/K_I$. Because all simulations are done under isometric conditions and at steady state, the observed three to fourfold decrease in thin filament stiffness in Neb-KO muscles (Kiss et al., 2018) results in only a small effect on the isometric tension (or force per myosin filament), i.e. a decrease of up to 3% (Fig. S2 in Supplemental Material). Similarly, the net change in sensitivity for the range in thin filament compliances is also small (Figs. S3A and B): $\Delta\text{pCa}_{50} \sim 0.038$ when thin filament stiffness changed from 65 pNnm^{-1} reported by Kojima et al. (Kojima et al., 1994) and 34 pNnm^{-1} estimated in wt soleus muscle thin filaments from small-angle X-ray diffraction studies (Kiss et al., 2018); the net effect of the decrease in thin filament stiffness between wt and Neb-KO deficient thin filaments (by a factor of 3) on the calcium sensitivity is even smaller, $\Delta\text{pCa} < 0.025$.

Follow-up mechanical studies performed at a sarcomere length of $2.0 \mu\text{m}$ (Chandra et al., 2009) confirmed that nebulin significantly enhances tension generation (Fig. 6C) by a relative value similar to that reported earlier (Witt et al., 2006) (Figs. 6 A and B), but the isometric tensions in fully activated of both wt and Neb-KO muscles were significantly lower. This reduction in tension can be only partially explained by the tension reduction due to the thin-thin filament overlap and likely is associated with altered binding kinetics, presumably caused by the

differences in experimental conditions. For example, a change of sarcomere length from 2.3 to 2.0 μm increases lattice interfilament spacing (Kurg et al., 1982; Millman, 1998), and it is likely associated with a reduced myosin binding rate or, alternatively, with other mechanisms associated with length-dependent activation. Chandra et al. showed that nebulin decreases calcium sensitivity, unlike the study by Witt et al. that found no difference. In order to quantitatively explore the origins of these differences we performed MUSICO simulations at a sarcomere length of 2.0 μm and adjusted the kinetics to match observations of Chandra et al. (Fig. 6C).

The MUSICO predicted tensions in wt muscle fibers, taking into account only the variability of thin filament lengths at full activation, showed similar tension values as in wt fibers (Fig. 6C). These similar tensions parallel MUSICO predictions for the force-length relation at $SL=2.0 \mu\text{m}$ in Fig. 6A where a significant decrease in wt tension due to the thin-thin filament double overlap is compensated by an increase in Neb-KO tension due to the increase of overall overlap between variable length thin filaments and thick filaments. This effect is reflected in an almost identical tension-pCa relation for wt and Neb-KO if the only differences considered are in the thin filament length distributions (Fig. 6C, pink line with triangle symbols vs. gray line with filled squares).

Because at a sarcomere length of 2.0 μm there is almost no effect of thin filament length variability, to achieve the observed drop in tension in Neb-KO requires a decrease in myosin binding rate, k_{bind} , by about 3.3 times in order to match the observed tension that is $\sim 45\%$ of the tension at full activation (Chandra et al. 2009). However, if there is no change in the kinetics of calcium binding to TnC and associated TnI affinity to actin, the observed force at full activation is matched by the above decreased k_{bind} (blue dotted line with hollow blue triangles), but this results in higher calcium sensitivity by $\Delta pCa \cong 0.075$ relative to the observations (red filled triangles). The loss of calcium sensitivity is due to reduced cooperativity between CFC chain and a lower number of bound myosins of $\Delta pCa \cong 0.083$ but only covers about a half of the observed loss of sensitivity (See also Fig. S4B). This is opposite to that shown in Fig. 6B, indicating that in order to explain the observations it is necessary to decrease the calcium sensitivity of Neb-KO by, for example, a decrease in TnI detachment the rate from the actin filament, k_{-I} . In this case, the Hill coefficient, n_H , of ~ 3.55 for Neb-KO is slightly lower than of ~ 3.9 for wt indicating a moderate loss of cooperative interactions between actin filaments, myosin, tropomyosin, troponin and calcium. This behavior could be affected by the use of reconstituted fiber bundles with fast skeletal muscle recombinant Tn in Chandra et al. study. This major structural change could in part contribute to the decreased sensitivity of Neb-KO to calcium and loss of cooperativity.

The contractility of muscle modulated by titin

Using MUSICO, we quantitatively determined the effect of titin passive elasticity and change in inter-filament lattice spacing on myofilament length-dependent activation. The geometrical model for all cardiac muscles includes the observed variation in actin filament lengths and nonlinear (passive) elasticity of titin. We compared the calcium sensitivity of active force (per myosin filament) at various levels of passive force by changing sarcomere length (2.3 vs. 2.0 μm), using a large prestretch to 2.5 μm and after holding, releasing to 2.3 μm or 2.0 μm and then activating, denoted here as the mechanical protocol. Alternatively, the passive tension was reduced by trypsin treatment. We simulated the effect of lattice spacing induced changes in the force-pCa relation. All MUSICO parameters affected by the variation in protocols are shown in Table 1.

Fig. 7 shows that reduction in titin-based passive tension, by either mechanical prestretch and release (A) or lowering titin passive tension by trypsin (B), reduces the magnitude of the isometric force in fully activated muscle fibers ($\text{pCa} = 4.5$) and also decreases sensitivity to calcium. The change in isometric force at full activation induced by reducing passive tension by decreasing sarcomere length from 2.3 to 2.0 μm is larger than the mechanical reduction of passive tension at 2.3 μm . An excellent fit can be achieved by reducing the rate of myosin binding to actin, k_{bind} , and this change is correlated with the reduction in passive tension (see Table 1). The decrease in sensitivity is caused by a reduced rate of calcium binding to TnC and a reduced affinity of TnI to actin by passive forces, i.e. an increase of TnI detachment rate from actin, k_{-I} . Compression of the myofilament lattice by dextran strongly increases myosin binding rates and the force at full activation is more than 10% higher (C).

The input data and the predicted isometric forces in fully activated muscle are summarized in Table 1. The observed decrease in the isometric active force at a fixed sarcomere length can be achieved by decreasing the binding rate, k_{bind} . Changing sarcomere length from 2.3 to 2.0 μm causes a decrease of isometric active force due to a decrease in passive force and an increase in inter-filament lattice spacing. In this case, decreases in k_{bind} are due to an increase in inter-filament lattice spacing, i.e. radial strains. The opposite effect is shown when inter-filament spacing is decreased by lattice compression by dextran. In this case the observed increase in active tension is achieved by an increase in k_{bind} . For simplicity, in all simulations shown in Fig.7 we fixed k_{-bind} to 7.41 s^{-1} and only changed k_{bind} .

Effect of titin-based passive tension and inter-filament spacing on calcium sensitivity. The change in sensitivity, ΔpCa_{50} (from the control at $\text{SL} = 2.0 \mu\text{m}$), with passive tension is correlated with the increase in active force, but the change $|\Delta\text{Log}(K_{B50})|$ is much smaller in relative terms indicating that additional mechanisms contribute to the disproportionate increase in ΔpCa_{50} (Table S2). The low passive tensions (LPT) induced by trypsin treatment showed only minor differences compared to LPT (mechanical protocol) at $\text{SL} = 2.3 \mu\text{m}$ and the changes in ΔpCa_{50}

and $|\Delta\text{Log}(K_{B50})|$ were in the same proportion suggesting that changes in binding rates is sufficient to explain changes in sensitivities relative to the control at $SL = 2.0 \mu\text{m}$.

After compression by dextran, the change in force, ΔpCa_{50} and magnitude of $|\Delta\text{Log}(K_{B50})|$ from control at $SL = 2.0 \mu\text{m}$ are well correlated with passive tension, but they have different changes in the magnitude of the intercepts at zero passive tension. Importantly, ΔpCa_{50} increases faster than $|\Delta\text{Log}(K_{B50})|$ and has a lower relative intercept at zero passive tension, indicating that several different mechanisms affect these changes, but to a much lesser degree than predicted from the mechanical protocols (see Fig. S5). Comparison of the LPT (control) with LPT after compression with Dextran at $SL = 2.0 \mu\text{m}$ shows large shifts in ΔpCa_{50} of 0.258 compared to the much smaller change in $|\Delta\text{Log}(K_{B50})|$, indicating that large decreases in inter-filament lattice spacing by dextran produce large changes in sensitivity.

DISCUSSION

The MUSICO simulations, now including the continuous flexible chain (CFC) model (Geeves et al., 2011; Mijailovich et al., 2012a), predict force-pCa relationships. This makes it possible to test hypotheses related to changes in calcium sensitivity under various experimental conditions including compromised contractility due to mutations in key sarcomere proteins. The inclusion of titin and nebulin in MUSICO provides an opportunity to quantitatively separate effects that cannot be measured directly, allowing validation of hypotheses concerning the roles of these proteins and potentially explaining the functional effects of mutations in titin and nebulin. This modeling approach takes into account known geometrical factors, for example, the thin filament length variability in nebulin-deficient skeletal muscles or in cardiac muscles, changes in titin elasticity, altered inter-filament lattice spacing induced by changes in sarcomere length or lattice compression by dextran. Each MUSICO simulation includes the specific conditions associated with each experiment examined, including calcium concentration and the passive force changes that occur with altered sarcomere length.

Role of nebulin in contractility of skeletal muscle

It has been hypothesized that the principal role of nebulin is to regulate the length of thin filaments (Kruger et al., 1991; Labeit et al., 1991; Witt et al., 2006). Witt et al. observed the lengths of thin filament lengths in fast skeletal muscle of normal (wt) and in nebulin-free mice (also denoted as Neb-KO) (Witt et al., 2006). They measured the effect of this deletion on force-length relations in fully activated muscles and force-pCa relations in partially activated skinned muscles. This study shows similar behavior to that observed in the quadriceps muscles of nemaline myopathy patients (Ottenheijm et al., 2009; Ottenheijm et al., 2012), but from the data presented it was difficult to quantitatively separate the effects of the variability of thin filament lengths observed in Neb-KO, changes in force-pCa relations, and other functional roles of nebulin (Chandra et al., 2009; Ottenheijm et al., 2010).

Observations from multiple experimental studies in humans (Ottenheijm et al., 2008; Ottenheijm et al., 2012) and murine muscles (Witt et al., 2006; Chandra et al., 2009; Ottenheijm et al., 2012; Li et al., 2015) suggest three principal factors in nebulin deficient muscles: (i) changes in thin filament lengths strongly modulate the overlap between thin and thick filaments and therefore the generation of tension (Witt et al., 2006; Ottenheijm et al., 2012); (ii) changes in crossbridge cycling kinetics (Bang et al., 2009; Chandra et al., 2009; Ottenheijm et al., 2010; Ottenheijm et al., 2012) that also affect generation in muscle tension; (iii) changes in muscle regulation reflected in altered sensitivity to calcium concentration $[Ca^{2+}]$ (Chandra et al., 2009; Ottenheijm et al., 2012). The murine studies in wt and nebulin knock-outs reveal the symptoms observed in nemaline myopathy such as muscle weakness (Ottenheijm et al., 2012), but cannot, on their own, reveal the quantitative distinctions between the effect of sarcomere structural changes, compromised binding kinetics and modulation of thin filament regulation by calcium. The MUSICO platform includes the changes in sarcomere geometry between wt and nebulin-deficient muscles, estimates the changes in cycling kinetics in fully activated muscle required to match the observations and quantify the changes in thin filament regulation kinetics to match observed force-pCa relations. Thus MUSICO simulations enable us to quantitatively separate the contributions of the above changes to force and calcium sensitivity that can be only experimentally observed in the aggregate.

Effect of variability of thin filament lengths and crossbridge cycling kinetics. Nebulin deficient muscle lacks the characteristic plateau in the force-length relationship in both murine nebulin knockouts and humans with nemaline myopathies (Ottenheijm et al., 2009; Ottenheijm et al., 2012). The MUSICO predictions for wt muscles showed a plateau at optimal thick–thin filament overlap and a descending limb at sarcomere lengths exceeding $\sim 2.58 \mu\text{m}$ (Fig. 6A), reflecting the approximately constant thin filament length (Fig. 4 A and C) and the length of the bare zone in the thick filament. At shorter sarcomere lengths ($< 2.2 \mu\text{m}$), tension is significantly reduced due to impaired myosin binding in regions where thin filaments with opposite orientations overlap. The effective myosin binding rate in this region based on simulation is reduced by $\sim 65\%$ causing a reduction in tension at sarcomere length of $2.0 \mu\text{m}$ of about 12.5% from the tension at the plateau. In contrast, the MUSICO simulations including only observed shorter and nonuniformly distributed filament lengths in Neb-KO (as in Fig. 4 B and D) predicted a continuous increase in isometric tension with a decrease in sarcomere lengths (Fig. 6A). Moreover, because the thin-thin filament overlap interference showed only a modest decrease in force, the tension even exceeds the isometric tension at $SL = 2 \mu\text{m}$. Thus, the simulations including only the nonuniform distribution in length of thin filaments in Neb-KO were not sufficient to explain the observed reductions in the force-length relation, relative to wt muscle. These simulations showed only about a 20% drop in isometric force at full thick-thin filament overlap and a leftward shift in the descending limb of force-sarcomere length relation of about a half of that observed. Therefore, other mechanisms likely operate as well (red triangles in Fig. 6A). For example, decreasing crossbridge cycling rates via k_{bind} by about 2.4 times provides good agreement with the

observation (blue line with cyan filled triangles vs. red triangles in Fig.6A). This decrease of k_{bind} in Neb-KO muscles likely reflects loss of the enhancement of myosin binding to actin in presence of nebulin.

There could be other possible mechanisms, however, to explain the observations. An alternative hypothesis is that the drop in tension in nebulin deficient muscles is caused by an increase in compliance in nebulin deficient muscle with no change in crossbridge cycling rates (Kawai et al., 2018). However, MUSICO simulations showed that only about a 3% drop in the isometric tension (Fig. S2 in supplemental material) that can be attributed to the increase in thin filament compliance observed by Kiss et al, (Kiss et al., 2018). On the other hand, nebulin deficiency could also cause a reduced force per attached crossbridge (Kawai et al., 2018), a possibility that requires future study.

Myofilament calcium sensitivity. Force-pCa relations were used to identify differences in the calcium sensitivity of force production. In most of the studies a decrease in calcium sensitivity in nebulin-deficient muscle fibers was reported (Chandra et al., 2009; Ottenheijm et al., 2010; Ottenheijm et al., 2012). But other studies reported no difference in calcium sensitivity between wt and Neb KO (Witt et al., 2006; Bang et al., 2009), thus bringing some uncertainty in the observations from the former studies. The differences in sensitivity were attributed to the differences in experimental procedures or, alternatively, to the difference in sarcomere lengths used in these the studies (Ottenheijm et al., 2012).

The MUSICO simulations enable a quantitative separation of the effects of variable sarcomere lengths, the change in crossbridge cycling kinetics, and thin filament regulation. The simulations reveal that although the maximum isometric forces at full activation match the predicted force for wt and, after decreasing k_{bind} by about 2.4 times, for Neb-KO, as shown in Fig. 6A, the predicted force pCa relation for Neb-KO is shifted rightward comparing compared to Witt et al. (blue dotted line with open triangles in Fig. 6B and Fig. S4A). The shift, i.e. loss of calcium sensitivity is caused by reduced cooperativity by lower number of bound myosins interacting with CFC chain. The predicted lower sensitivity needs to be compensated by an increase in activation level via an increase of k_{-1} in order to match the observations. These studies were performed at a sarcomere length of 2.5 μm where in wt sarcomeres, thick-thin filament overlap is optimal and there is no force reduction due to thin-thin filament overlap. In studies performed at shorter sarcomere lengths (Chandra et al., 2009), however, thin-thin filament interference at a sarcomere length of 2.0 μm , and probably other effects, decreased the isometric force at full activation in both wt and Neb-KO. In order to match the tension in Neb-KO k_{bind} should be decreased by about 3.3 fold. In this case, the loss of calcium sensitivity caused by reduced cooperativity has a similar magnitude ($\Delta\text{pCa}_{50} \cong 0.083$ at SL= 2.0 μm vs. 0.090 at SL= 2.5 μm as shown in Figs. 6C and 6B, respectively). However, the decrease in sensitivity at SL =2.0 μm is not sufficient to match the observation, and the simulation predicted higher sensitivity (blue dotted line in Fig.6 C) than observed by Chandra et al. (red triangles).

Thus to fit the observations, in the first case, at $SL=2.5\ \mu\text{m}$, it is necessary to increase sensitivity by increasing TnI detachment from the thin filament (K_B arrow to the left in Fig. 6B and S4A) and in the second case, at $SL= 2.0\ \mu\text{m}$, the decrease in sensitivity requires a decrease in TnI detachment from the thin filament (shown as K_B arrow to the right in Fig 6C and S4B).

In a recent publication, Kiss et al. observed a decrease in thin filament stiffness in Neb-KO of 2.5 to 3 times compared to wt (Kiss et al., 2018). Our simulations show only small changes in sensitivity with a $\Delta p\text{Ca}$ of ~ 0.038 for the experimentally observed changes in thin filament stiffness of 3 fold assuming that the thin filament length in wt and neb-KO are uniform (see Fig. S3 in Supplemental Material). The lengths of thin filaments in Neb-KO however, are known to be nonuniform and shorter than in wt, thus the effect of 3-fold decrease in thin filament stiffness on calcium sensitivity is even smaller, $\Delta p\text{Ca}<0.025$. Because this change of sensitivity is more than an order of magnitude smaller than observed, it is neglected in our analysis. This change in sensitivity is much smaller than the change in sensitivity due to altered thin filament stiffness reported by Chase et al. (Chase et al., 2004). The large change in sensitivity estimated by Chase et al. is likely a consequence of the large range in thin filament stiffness that were simulated, up to 100 fold, that far exceeds the stiffness changes observed by Kiss et al. It seems then, that the changes in calcium sensitivity in nebulin deficient muscles are primarily due to changes in crossbridge cycling kinetics and changes in the detachment rates of TnI.

Role of passive tension in contractility of cardiac muscle

In cardiac muscle, the role of passive tension is important for understanding the sarcomere length dependence of calcium activation, which is the underlying basis of the Frank Starling mechanism (Kentish et al., 1986). Titin is identified as one of the key contributors to myocyte passive force and length dependent calcium sensitivity (Granzier and Irving, 1995; Cazorla et al., 2001). It was hypothesized that the observed increase in calcium sensitivity could be triggered by an increase in affinity of troponin C for calcium at larger sarcomere lengths and cooperative effects associated with increase in the number of strongly binding crossbridges (Cazorla et al., 2001). MUSICO simulations can estimate quantitative differences in the magnitude of isometric force and calcium sensitivity at different levels of titin passive forces, changes in the inter-filament lattice spacing and modulation in cycling rates in crossbridge cycle allowing these factors to be evaluated separately.

Effect of crossbridge binding rates and inter-filament lattice spacing on isometric force in fully activated cardiac muscle. Cazorla et al. reported isometric tensions at full activation and force- $p\text{Ca}$ relations at high and low passive tension. This was achieved by either changing sarcomere length, by a mechanical protocol, by degradation of titin by trypsin, or changing lattice inter-filament spacing with dextran (Cazorla et al., 2001). Because the changes in sarcomere length (SL) and treatment by trypsin change the lattice spacings, and the decrease of SL increases the effective thin-thick filament overlap due to variable thin filament lengths in cardiac muscle, it is

difficult to extract the net effect of these multiple changes from the observations that provide aggregate data. Thus, let us first start with a comparative analysis at each SL and then examine the effect of changes in sarcomere length.

At SL=2.3 μm mechanical reduction of the passive tension decreases the active force by about 8.1% from the level at high passive tension (Table 1). In this case, there is no change in inter-filament lattice spacing, but a decrease of k_{bind} by about 15.2% is required to match the observations (Cazorla et al., 2001). In contrast, at SL=2.0 μm , the tension in titin is small so the mechanical change from high passive tension (HPT) to low passive tension (LPT) at this sarcomere length shows negligible change in active force and no change in either k_{bind} or lattice spacing. This comparison suggests that the decrease of k_{bind} at SL=2.3 μm can be attributed solely to the change from high to low passive tension.

Reducing passive tension by trypsin at SL=2.3 μm decreases the active force by a much smaller amount (3.5%), compared to HPT, and the decrease in k_{bind} is also small (~4.3%) suggesting that the same decrease in passive tension has a much greater effect on active force when achieved by the mechanical maneuver than by the trypsin protocol. Comparing the increase in active tension from mechanical (protocol) LPT to trypsin LPT also at SL=2.3 μm shows an increase in active force of 5%, in k_{bind} of 12.9%, and an increase in lattice spacing of about 6.8%. It seems that degradation of titin not only reduces passive tension but also enhances k_{bind} at LPT and the magnitude of the isometric force. The enhancement of the isometric force and k_{bind} by degradation of titin might be attributed to some other mechanism than increase in lattice spacing because it is widely anticipated that both k_{bind} , and the force, decrease with an increase in spacing.

Compression of the sarcomere lattice by dextran at SL=2.3 μm showed a spacing decrease of ~14.5%, an increase in active force by 6.8% and k_{bind} by ~29.1% at high passive tension (HPT) with a larger increase in active force of ~10.7% and k_{bind} of ~37.6% at LPT induced by the mechanical protocol (Table 1). At short sarcomere lengths (SL=2.0 μm), addition of dextran at LPT after mechanical manipulation decreases inter-filament spacing by 16.9%, but the enhancement of force is much smaller, an increase of 6.1%, accompanied by relatively small increases in the binding rate of only 6.7%.

If we now return to the change in force at decreasing sarcomere length, we can anticipate that a decrease in sarcomere length increases the degree of thin-thick filament overlap, but myosin binding rates decrease due in part to an increase in lattice inter-filament spacing. In order to dissect the contribution of the degree of overlap vs. the density of bound crossbridges to the developed tension we quantified the magnitude of each contribution separately.

The nonuniform distribution of actin filaments lengths (see Fig. 5A) results in a distribution of thick-thin filament overlap lengths and an increase in isometric active force at shorter sarcomere lengths. At full activation and the same kinetic state transition rates, the force

at SL= 2.3 μm is only about 66% of the force that could be generated if the thin filament lengths were uniform and 1.1 μm long. At shorter sarcomere lengths the force will increase to ~83% at SL= 2.0 μm and to ~87% at SL= 1.9 μm of the maximum force (Fig. 8). Note that if all thin filaments are 1.1 μm long, the active force does not change in the above sarcomere length range because all the thick and thin filaments fully overlap. On the other hand, thin-thin filament overlap appears at sarcomere lengths of 2.0 and 1.9 μm , but because only a small number of thin filaments with nonuniformly distributed lengths experience this overlap, the decrease of force is small (< 1%) and has a negligible effect on the isometric forces.

Overall, due to the effective increase of thick-thin filament overlap with decreasing sarcomere length, the magnitude of active force is expected to increase unless it is counterbalanced by decreases in k_{bind} in order to meet the observations of Cazorla et al. (Cazorla et al., 2001). As we described above, the decrease in k_{bind} can only be in part attributed to increases in inter-filament spacing (Table 1) and other mechanisms likely affect k_{bind} as well.

The decrease in tension with a decrease in sarcomere length from SL of 2.3 to 2.0 μm can be predicted by decreasing the binding rate k_{bind} by 42.8% for changing from HPT to LPT by decreasing the sarcomere length only and by 32.6% at LPT after the mechanical protocol (Table 1). In both cases, the increase in lattice inter-filament spacing is ~ 4.6% and is weakly associated with large decreases in k_{bind} . Because the effective overlap increases with a decrease in SL, and a decrease in k_{bind} affects the active force per unit of overlap, the calculated decrease of active force is proportional to difference of the products of k_{bind} and the degree of overlap at SLs 2.3 and 2.0 μm . Thus, in order to extract the net effect of the decrease of k_{bind} on the active force, the force should be normalized to the full overlap length that can be achieved with 1.1 μm long thin filaments at all three sarcomere lengths as shown in Fig. 8. Due to the distribution of thin filament lengths, the effective thick-thin filament overlap at sarcomere lengths 2.3 and 2.0 μm is 66 and 83% of the full overlap, respectively (Fig. 8). Thus, after normalization of the net active force decrease with the decrease in length is 10.5% for change from HPT to LPT by decreasing of SL only, and only 2.6% at LPT after mechanical protocol. These data suggest that passive tension has a much stronger effect on the change of normalized force than does the inter-filament lattice spacing.

In trypsinized preparations, the passive tension is low showing minor differences with change of length. But, in this case, lattice spacing increases by 8.4% and k_{bind} decreases by 67.7% for a change of length from 2.3 and 1.9 μm . These much larger changes in k_{bind} and in lattice spacing than in the absence of trypsin are associated with a much larger reduction in normalized net active force by 66.7%. Because the change in passive tension is small, the change in normalized active force can be almost entirely attributed to the decrease in k_{bind} that is likely strongly associated with the large increase in lattice spacing.

In contrast, in the sarcomere lattice compressed by dextran, the increase in lattice spacing with a decrease in sarcomere length from SL of 2.3 to 2.0 μm is much smaller ($\sim 1.7\%$) than in the trypsin case and it is likely only weakly associated with the large decrease in binding rate k_{bind} by 47.7 % at LPT (mechanical protocol) and by 55.0% for change from HPT to LPT by decreasing sarcomere length only (Table 1). The net active force, after normalization, decreases by 26.2 % at LPT (mechanical protocol) and by 29.6% for change from HPT to LPT by decreasing SL only. This change parallels the decrease in k_{bind} .

Effect of titin-based passive tension on myofilament calcium sensitivity. MUSICO predictions show similar values for the Hill coefficient, n_H , and ΔpCa as observed (Cazorla et al., 2001) and confirms an increase of calcium sensitivity with increases in passive tension (Table S2). The same trend is also obtained from the calculated K_B -pCa relations suggesting that the kinetics of binding and detachment of TnI from actin are synchronized, in part, with calcium binding to TnC. Typically, a decrease in the rate of calcium dissociation from TnC, $k_{-I} = k_B$ i.e. an increase in the equilibrium rate, K_B is associated with a leftward shift of pCa curves, i.e. toward higher sensitivity, and can be expressed in terms of ΔpCa_{50} . However, changes of Hill coefficient, n_H , in the force-pCa relation and associated change in η_H in the K_B -pCa relations indicate that the cooperative interactions between myosin binding and tropomyosin chain have a strong effect on calcium sensitivity. There are likely other contributions to myofilament calcium sensitivity. Ait-Mou et al. (Ait-Mou et al., 2016) proposed a model where myofilament length dependent activation involves, at least in part, transduction of titin-based passive tension into changes in the ordering of the myosin heads and that some communicating structure transmits strain to the thick filaments leading to an alteration in the structure of troponin and, presumably, the degree of activation of the thick filament. In several papers from the Lombardi group, as summarized in a recent review by Malcolm Irving (Irving, 2017) a model is proposed whereby a thick filament strain dependent conversion of heads from an ordered state, perhaps the so-called super-relaxed (SRX) state proposed by Cooke (McNamara et al., 2015) to a disordered state is associated from going from a myosin filament “off” state to an “on” state. Reconditi et al. (Reconditi et al., 2017) have also proposed a “feed-forward mechanism” based on this concept that could possibly be used to explain myofilament length dependent activation. A recent paper (Ma et al., 2018) suggests, however, that thick filament-based regulation is likely to be more complex than the previous studies would suggest. For simplicity, in this paper we include an increase of effective myosin binding rate to actin at longer sarcomere lengths, where this increase in rate could be attributed to decreases in interfilament spacing, or any other mechanism associated with thick filament activation.

Towards resolving the underlying mechanisms of nemaline myopathy and myofilament length dependent activation

Various mutations in nebulin and titin present in human disease strongly affect the contractile function in skeletal and cardiac muscles. Several hypotheses have been proposed in order to explain these observations but clear mechanisms of the dynamic action of these proteins in the 3-D sarcomere lattice are still lacking. As shown here, MUSICO simulations can provide valuable insight into separating the effects of nonuniform length distributions of thin filaments, modulation of binding rates by the presence of nebulin, changes in inter-filament lattice spacing, and the modulation of calcium sensitivity associated with thin filament calcium regulation.

The flexibility of the MUSICO platform and simulations of plausible mechanisms have provided good fits to the data, but many questions regarding the underlying mechanisms remain. For example, what could be the possible roles of nebulin in skeletal muscle or titin-based passive tension in cardiac muscle regarding modulation of calcium sensitivity? Is it enhancing Ca^{2+} binding to TnC, or reducing TnI affinity to actin, or could the force that a myosin molecule generates be enhanced? What are the molecular details of the mechanisms by which passive force alters calcium sensitivity and inter-filament spacings? Are there additional mechanisms for modulation of calcium binding to TnC, or TnI to actin? Does titin contribute to activating thick filaments and/or does it alter TnI-actin interactions?

Resolving the mechanisms in quantitative terms for the effects of variable thin filament lengths, passive tension, titin elasticity, and inter-filament lattice spacing is complex and requires a thorough analysis with consistent sets of data that go beyond maximum isometric tension and force-pCa relations. In order to fit multiple experiments by the same set of parameters we primarily used relatively well established parameters. However, a few parameters that are less well established, for example myosin and TnI binding rates to actin, were adjusted to provide agreement with the experimental data. It is important to note that the chosen sets of parameters, although providing excellent agreement between MUSICO simulations and the observations (Figs. 6 and 7), may not be unique. Nevertheless, the parameters we used in simulations are within the range of values reported in the literature, including our own observations, and use of a different set of values is not expected to alter overall outcomes from those presented here.

In order to establish more consistent, and constrained, parameter sets more experiments under similar if not identical conditions are required. For example, the history of force development, isotonic shortening and fast transients need to be included in determining model parameters. Overall good fits are not sufficient to quantitatively explain the involved mechanisms if they are not constrained with a sufficient number of experimental observations obtained under the same conditions. For another example, the analysis of calcium sensitivity is usually based on the normalized force-pCa data, but this analysis may, in some cases, be misleading because the number of strongly bound crossbridges modulates position and states of regulatory proteins and therefore generated force. Thus, not taking into account absolute active tension levels can skew cooperativity effects leading to interpretations that deviate from the underlying mechanisms.

The strong coupling between modeling and experiments in the present study, however, enabled quantitative separation of the contributions from structural changes in nebulin deficient muscles, changes in myosin binding kinetics and modulation of thin filament calcium regulation. This takes a significant step toward understanding the underlying mechanisms leading to muscle weakness in nemaline myopathy. Similarly, we quantified the effects of titin-based passive tension, length dependence of calcium activation and inter-filament lattice spacing on cardiac muscle's ability to generate tension and alter calcium sensitivity. These are key steps toward understanding contractile performance at larger filling volumes of the heart. These findings suggest that the Frank-Starling mechanism of the heart may, in part, be due to an effect of titin-based passive force on the length dependence of maximal active tension and calcium sensitivity.

CONCLUSIONS

This study supports the notion that both nebulin and titin play important roles in muscle contraction. The effect of variable thin filament lengths in nebulin deficient muscle accounts for about half of the decrease in isometric force and the leftward shift of the descending force-length limb observed in fully activated muscle. The match is further improved by 2.4 and 3.3 fold decreases in k_{bind} at sarcomere lengths of 2.5 μm and 2.0 μm , respectively. Thus, the changes in binding kinetics could be attributed to an enhancement of binding rates by the presence of nebulin, but the increase in calcium sensitivity at longer sarcomere length ($\sim 2.5 \mu\text{m}$) and the decrease in sensitivity at shorter sarcomere lengths ($\sim 2.0 \mu\text{m}$), could be achieved by increasing or decreasing the sensitivity of TnI detachment from actin, respectively.

In cardiac muscle, isometric active force decreases when titin-based passive tension is reduced at both long and short sarcomere lengths. Increases in inter-filament lattice spacing decrease myosin binding rates at shortened muscle length, and overall tension decreases despite a significant increase in thick-thin filament overlap due to the nonuniform distribution of thin filament lengths. Sensitivity to calcium is decreased by both a decrease in passive tension and an increase in inter-filament lattice spacing. Similar effects are observed in lattices compressed by 2.5% dextran, although isometric force is significantly higher due to the overall reduction in inter-filament lattice spacing. In this case, the changes in binding kinetics could be attributed only in part to enhancement of binding rates by reduced inter-filament spacing at longer sarcomere lengths ($\sim 2.3 \mu\text{m}$) or by compression by dextran. The latter effect could be linked to higher calcium sensitivity at higher passive tension at longer sarcomere lengths. These overall effects can be attributed to myofilament length-dependent activation (Lakatta and Jewell, 1977; Kentish et al., 1986; Cazorla et al., 2001; de Tombe et al., 2010; Ait-Mou et al., 2016), but unveiling the detailed underlying mechanisms requires further investigation.

In summary, the MUSICO simulation platform is a multiscale model of the sarcomere that is able to reveal inter-dependencies that cannot be resolved experimentally. To realize its full potential to unveil fundamental underlying mechanisms leading to diseases such as nemaline

myopathies in skeletal muscle and the subcellular basis of the Frank-Starling mechanism, more comprehensive data sets that tightly constrain the parameters are required. In this process, MUSICO, in itself, can provide a valuable hypothesis-generating tool to provide guidance on what experimental measurements would be needed to optimally constrain fitting the model to data. In so doing, MUSICO iteratively becomes an increasingly more effective tool for revealing fundamental contractile mechanisms in health and disease.

Appendix A

Geometrical aspects of interactions between myosin heads with binding sites on actin

Defining the myosin binding step in the 3-D sarcomere lattice is complicated because myosin heads can interact with only one myosin binding site on actin out of several reachable adjacent sites (Fig. 3A). The distance between a myosin head and the binding site on actin, $\mathbf{x}_m^l(t)$, that determines the net crossbridge force is calculated from the instantaneous spatial positions of each myosin molecule. Here the subscript m denotes the myosin head and l the associated binding site on actin reachable by head m . The vector $\mathbf{x}_m^l(t)$ is defined by four parameters: the axial strain x_m^l , the radial spacing between centers of actin and myosin filament d_m^l and the relative angles α_m^l and β_m^l (Fig. 3). Note that for each myosin molecule m there would be l_{max} binding sites on actin in the neighborhood of m . l_{max} associated sites on actin can be located on one or two actin filaments, depending on the angle α_m^l , thus d_m^l can include multiple d_{M-A}^l , one for each associated actin filament (for details see (Mijailovich et al., 2016)).

In almost all sliding filament models, the strain dependent rate constants between actomyosin states, denoted as (k_{ij}) , exclusively depend on the strain component x , i.e. axial change of distance between a myosin head and the binding site on actin due to bond stretch Fig. 3A, while all other components are ignored. In the stochastic 3D sarcomere model used here, we adopt the same approach, but, however, for possible binding of each myosin on multiple actin sites we calculate strain dependent rate constants $k(x_m^l)$, where x_m^l is a crossbridge strain of l_{max} reachable actin sites. These constants are further modulated by weight factors that take into

account the lattice spacing between the filaments, $d_m^l = d_{M-A}$ (Fig. 3B) and the azimuthal angles α and β (Fig. 3C). The resulting l_{max} binding rate constants per myosin molecule are then used for construction of binding probabilities for the stochastic process as explained below. In order to match the overall binding flux in probabilistic sliding filament models, the binding rate distribution is scaled down by the factor f_{sk} , that takes into account the average number of sites on actin reachable by each crossbridge for the prescribed strain dependent binding rate function (Mijailovich et al., 2016).

Appendix B

Strain dependent rates in the actomyosin cycle

The three state actomyosin cycle is defined by six state transition rates (Fig.A1) of which three are strain dependent. **The strain dependence shown below is strictly defined in terms of strain in axial direction, x , whereas the effects of azimuthal movements are incorporated into the rate constants via the azimuthal weight factors.**

For myosin binding to actin, the strain dependent rate in quadratic form is derived from a Langevin type of equation balancing thermal fluctuations of the detached myosin molecule, elastic restoring, inertial, and viscous drag forces (Kramers, 1940; Papoulis, 1991; Hunt et al., 1994; Daniel et al., 1998). At zero strain ($x = 0$) binding rate is defined by overall rate k_{bind}

$$k_{12}(x) = k_{bind} e^{-\kappa x^2/2k_B T} \quad (A1)$$

as a function of the elasticity of the crossbridges, κ , and the crossbridge (axial) displacement from its unstrained position, denoted as x . The reverse reaction occurs at a constant rate $k_{21} = k_{bind} e^{\Delta G_{bind}/k_B T}$, where $\Delta G_{bind} < 0$ is reduction in free energy due to myosin binding, where k_B is the Boltzmann constant, T is absolute temperature in °K.

The transitions between the two attached states $A \cdot M \cdot ADP \cdot P_i$ and $A \cdot M \cdot ADP$ are rapid, and this transition includes P_i release accompanied by a large (negative) change in chemical free energy ΔG_{stroke} and the displacement of lever arm carrying out the power stroke, d .

$$K_{23}(x) \equiv k_{23}(x)/k_{32}(x) = e^{-[\Delta G_{stroke} + \kappa d^2(\frac{x}{d} + \frac{1}{2})]/k_B T} \quad (A2)$$

For the strain dependent ADP release (i.e., $A \cdot M \cdot ADP \rightarrow A \cdot M$), the forward rate is defined as function of the rate of ADP release when the elastic element is relaxed, k_{ADP}^0 and the displacement that the lever arm must move to open the nucleotide pocket, δ .

$$k_{31}(x) = k_{ADP}^0 e^{-[\kappa \delta d(\frac{x}{d} + 1 + \frac{\delta}{2d})]/k_B T} \quad (A3)$$

The full expressions for the above strain dependent rate functions are given in the Supplemental Material.

Appendix C

Thin filament regulation by calcium

Structurally, the Tm molecule is a coiled coil of about 40 nm in length (Censullo and Cheung, 1994), covers seven monomers on the same strand of the actin double-stranded helix, and is associated with one troponin (Tn) forming a TmTn unit (Fig.1). The troponin complex consists of three subcomponents: troponin C, troponin I and troponin T, denoted as TnC, TnI, and TnT, respectively (White et al., 1987). In the absence of calcium the N-terminal region of TnC is closed and the C-terminal of adjacent TnI is bound to actin, prohibiting Tm movement, i.e., holding Tm in the “blocked” state. Thus, in relaxed muscle, TnI holds Tm in an azimuthal position ϕ_- that sterically blocks myosin-S1 binding sites on F-actin (Mijailovich et al., 2012a).

In the presence of Ca^{2+} , binding of one or two Ca^{2+} ions to TnC generates a conformational change in TnI, lowering the affinity of TnI to F-actin. The release of the TnI C-terminus from F-actin allows the unconstrained Tm chain to move toward the “closed” state, i.e., the azimuthal position ϕ_o , favoring myosin binding to F-actin and, therefore, muscle contraction (Vibert et al., 1997; Smith and Geeves, 2003). The closed state permits weak myosin binding as observed at low Ca^{2+} , but the strong myosin binding requires further movement of Tm chain to azimuthal position ϕ_+ denoted as the “open” state.

There is structural evidence that neighboring tropomyosins overlap and that one end of TnT is bound to a specific site on Tm whereas its N-terminus overlaps the adjacent Tm forming linked Tm–Tm regions. The interconnected neighboring TmTn units, therefore, form the appearance of a continuous flexible chain (CFC) (Lorenz et al., 1993; Vibert et al., 1997). There are two CFCs on each actin filament following the filament double-stranded helix structure.

CFC angular position and its variance. The tropomyosin-actin spatial interactions are modeled as the interactions of loosely-confined quasi-continuous semiflexible chain (CFC) with the actin surface in the presence of troponin. Each CFC spans one strand along the whole length of actin filament, having two CFCs per F-actin. The governing equation of the CFC interacting with F-actin is defined by the expression for the energy of a distorted chain with angular displacement $\phi(s)$ at position s (Smith, 2001). For simplicity the CFC is assumed to be elastically homogeneous, with bending stiffness, κ_{TmTn} , and an angular confinement potential well, with single minimum, α_{cp} (Smith et al., 2003).

The angular displacements of the TmTn chain are dynamic having a range of values caused by the energy of thermal fluctuations. The functional of thermally-excited chain configurations is defined via the Feynman path integral (Feynman and Hibbs, 1965; Smith, 2001) over the complete set of confined worm-like configurations displacement $\{\phi(s)\}$. For the current configuration of bound TnIs and myosins at defined positions, s , along F-actin, the path of minimum energy represents the mean chain angle $\bar{\phi}(s)$ and the standard deviation $\sigma_{\phi}(s)$ of

chain angles arising from thermal excitation (for details see (Smith, 2001; Smith et al., 2003; Geeves et al., 2011; Mijailovich et al., 2012a)).

If there are no constraints, the mean configuration of the CFC is in the closed state sitting on the bottom of the confined potential at the angle $\bar{\phi}_o \approx 0$, and the standard deviation of fluctuating angle, σ_ϕ , has a value of about, $\sigma_o = (k_B T / 8 \kappa_{CFC} \xi^3)^{1/2}$ where $\kappa_{CFC} = \kappa_{TmTn} R^2$, where R is the radius at which tropomyosin sits on the actin filament and $1/\xi = (4 \kappa_{CFC} / \alpha_{cp})^{1/4}$ is the confined persistence length of the CFC (Smith et al., 2003). When the CFC is constrained, the chain is pinned at the positions where TnIs are bound to actin at an angle $\phi_- = 0$, forming a local blocked state, whereas the chain is assumed to be conditionally constrained at positions where myosins are strongly bound to actin, preventing the CFC from reaching angles $\phi < \phi_+$, forming a local open state. At positions where myosins are weakly bound, the chain is conditionally constrained preventing the CFC from reaching angles $\phi < \phi_o$. The pinning and the conditional constraints guarantee that the blocked, open and closed states correspond to the three orientations seen in cryo-EM images (Pirani et al., 2005; Poole et al., 2006).

The configuration of a whole CFC, constrained at the positions of bound molecules of myosin and TnI along actin filament and their respective angular displacements ϕ_- , ϕ_o and ϕ_+ , is obtained as a piecewise semi-analytic solution constructed, along each strand of F-actin, by merging the analytic expressions for the functions $\bar{\phi}(s)$ and σ_ϕ of neighboring TmTn units (Smith, 2001; Mijailovich et al., 2012a). The compatibility conditions require matching of angular displacements, slope and curvature at common pinning points between neighboring chain segments, where each segment is defined by the functions $\bar{\phi}(s)$ and $\sigma_\phi(s)$ over the length of the arc satisfying the boundary angular displacements and slopes (Smith, 2001; Mijailovich et al., 2012a). The standard deviation at a pinning site $\sigma_\phi(s_p)$ is zero, and deviation $\sigma_\phi(s)$ increases for myosin binding sites further away from the pinning sites, and at distances beyond the confined persistence length, $1/\xi$, the standard deviation $\sigma_\phi(s)$ approaches σ_o .

Chain-regulated kinetics. The coupling between the calcium regulated position of the CFC and a three state myosin cycle involves (i) modulation of myosin binding and the transition between weakly and strongly bound myosin states by the current position of the CFC to the actin site; and (ii) restriction of TnI rebinding to actin by nearby bound myosins. The biochemical Tn-A states include a bound state of TnI to actin that maintains TmTn the position inhibiting myosin-S1 binding, and the other state where TnI is not bound to actin allowing the TmTn chain to move azimuthally along the actin surface. The CFC chain on the actin surface is not static, but dynamically moves azimuthally, except at locations where TnI is bound to actin, and permits myosin binding for a fraction of time when a binding site on actin is available. Because these azimuthal fluctuations are much faster than myosin binding, the fraction of time that an actin site is available for weak myosin binding is proportional to the probability that the local position of

CFC is at $\phi \geq \phi_o$, and the transition from weak to strong binding, when $\phi \geq \phi_+$. These probabilities are calculated from the local mean angular position of the chain, $\bar{\phi}_i$, and its standard deviation, $\sigma_\phi = \sigma_i$, where i denotes actin site at the discrete position, s_i , along an actin filament strand (Mijailovich et al., 2012a). Conversely, bound myosins reduce the mobility of the CFC and modulate TnI rebinding to actin. In this case the fraction of time that a TnI can reach its actin site is proportional to the probability that the local position of CFC is at $\phi \leq \phi_-$.

Appendix D

The coupling between crossbridge cycling and thin filament regulation by calcium

Modulation of TnI-actin transitions by bound myosins. TnI and actin have two states and the transition between these states is defined by the equilibrium state transition constant $K_B = 1/K_I = k_{-I}/k_I$ where k_I is binding rate of TnI to actin. In the absence of calcium, most TnIs are bound to actin, but in the presence of calcium, calcium binds TnC and in a calcium concentration manner, increases K_B (Mijailovich et al., 2012a) or decreases K_I (Geeves et al., 2011). For simplicity we assume that k_{-I} is only dependent on $[Ca^{2+}]$, whereas the binding rate of TnI to actin is a weighted function of the rate of TnI binding to actin from the unweighted closed state rate, k_I^o (Mijailovich et al., 2012a). The transition probability of attachment of TnI to actin is $P_I = C_I^{CFC} k_I^o \Delta t$ where C_I^{CFC} is a weight factor, and the transition probability for the detachment of TnI from actin is simply $P_{-I} = k_{-I} \Delta t$. The first Monte Carlo drawing is performed over all CFCs, i.e. two times the number of all actin filaments. If any change of TnI state is drawn, the TnI state is updated for calculation of the CFC configuration in the current time step.

Modulation of myosin-actin transitions by the CFC. The probabilities of changing state in the three state model are constructed so that each state can transition to two neighboring states. The transition states from the detached state M.ADP.Pi includes two attachment probabilities P_{12} and P_{13} associated with axial strain dependent rates, including binding to multiple binding sites on actin. For the crossbridges in the detached state, the attachment probability is shared between all reachable actin states defined as $P_{12} = \left(\sum_{l=0}^{l_{max}} P_{12}(\mathbf{x}_m^l) \right)$, where $P_{12}(\mathbf{x}_m^l) = k_{12}^*(x_m^l) \cdot C_\alpha(\alpha_m^l) \cdot C_\beta(\beta_m^l) \cdot C_{M-wb}^{CFC}(\phi_m^l, \sigma_m^l) \Delta t$ and $k_{12}^* = k_{12}/f_{sk}$. Because P_{att} is the sum of the probabilities of attaching myosin heads to each of reachable sites $l = 1$ to l_{max} , the equivalent axial strain dependent binding rate k_{12}^* is set to provide the same flux as the probabilistic binding rate k_{12} . The scaling factor, f_{sk} , decreases the magnitude of k_{12} at each x by an average number of reachable binding sites to myosin heads (Mijailovich et al., 2016). The weight factors C_α and C_β are associated with the azimuthal position of actin filaments in the sarcomere lattice relative to the myosin head, angle α and azimuthal angle of actin site β (see (Mijailovich et al., 2016)). The weight factors are $C_{M-wb}^{CFC}(\phi_m^l, \sigma_m^l)$ are proportional to the fraction of time step, Δt , when these transitions are possible, i.e., to the weighted probabilities that the CFC is at positions

$\phi_m^l \geq \phi_o$, that modulates weak myosin binding, denoted as subscript $M - wb$ (Mijailovich et al., 2012a). The binding rate k_{13} is very slow and we assume the probability $P_{13} \cong 0$.

The transitions from the weakly to the strongly attached states (2 and 3) are defined by the probabilities $P_{21} = k_{21}(x)\Delta t$ and $P_{23} = C_{M-sb}^{CFC} k_{23}(x)\Delta t$ for the pre-stroke state 2 (A·M·ADP·P_i), and $P_{32} = k_{32}(x)\Delta t$ and $P_{31} = k_{31}(x)\Delta t$ for the post stroke state 3 (A·M·ADP). Calculation of these probabilities is almost identical as reported in (Mijailovich et al., 2016), except P_{23} includes the weight factor C_{M-sb}^{CFC} that modulates weak to strong myosin binding, denoted as subscript $M - wb$. The factor C_{M-sb}^{CFC} is proportional to the fraction of time step, Δt , when the isomerization possible, i.e. $\phi \geq \phi_+$ (Mijailovich et al., 2012a).

Abbreviations of the protocols reported by (Cazorla et al., 2001): Low passive tension, LPT; High passive tension, HPT; Mechanical protocol (Mech); Skinned muscle preparations in which the titin had been degraded by 0.25 mg/mL trypsin for 25 minutes at 25°C (Trypsin); Reduced filament spacing by osmotic compression with 2.5% dextran in skinned muscle preparation (Dextran). In all simulations is used $k_{-bind} = 7.41 \text{ s}^{-1}$. Number of bound crossbridges per a half myosin filament, denoted as # XB. Total number of crossbridges per a half myosin filament is 150.

Figure Legends:

Figure 1. The three-dimensional structural organization of sarcomeres includes thick (or myosin) filaments with interdigitated thin filaments composed of actin and regulatory proteins and the ancillary proteins nebulin and titin. Thin filaments are crosslinked within the Z-disc by protein networks at both ends of a sarcomere, whereas myosin filaments are crosslinked in the M-line situated in the middle of the filaments and in the central region of the sarcomere. Nebulin (pink line) spans most of the length of thin filament with its C terminus in the Z-disc and its N-terminus near the thin filament pointed end. Enlarged portion of actin filament shows capping protein tropomodulin (Tmod), tropomyosins (Tms) and components of the troponin complex: TnC with two or one calcium binding sites as expressed in skeletal and cardiac muscles respectively, TnI interacting with actin to anchor associated tropomyosin to actin filaments in the absence of bound calcium, and TnT supporting head to tail interactions between two neighboring tropomyosin molecules to form a continuous flexible chain (CFC). Each tropomyosin molecule covers seven actin monomers and is associated with one troponin complex, also repeating every seventh actin monomer. Two CFC's span the length of thin filaments coextensive with the two strands of actin monomers. Titin molecules (red lines) span half the sarcomere, mostly along myosin filaments, connecting the Z-discs (N-terminus) to the central M-band (C-terminus). Six titin molecules are bound to each half of thick filament (Granzier and Irving, 1995; Liversage et al., 2001; Tskhovrebova and Trinick, 2010) most likely interacting with six thin filaments near and within Z-line region, although some other arrangements of branching the titin molecules from tips of myosin filaments toward Z-disc are possible (Liversage et al., 2001; Tskhovrebova and Trinick, 2010). The figure is inspired by illustration in (Lee et al., 2013). The thin filament sketch is adapted from the fragment figure of (Gordon et al., 2000) and the thick filament from (Anderson and Granzier, 2012).

Figure 2. Three-dimensional view of myosin (thick) filaments in vertebrate striated muscle. (A) Myosin filaments extend from the central M-band toward Z-discs with crossbridges arranged in a three-stranded helical arrays with helical pitches of 3×42.9 nm, i.e. three myosin molecules (crowns) are located at 14.3 nm intervals. Inspired by 3D lattice figure from (Williams et al., 2013). (B) The crowns, consisting of three myosin molecules, are shifted for 40° azimuthally axially for 14.3 nm and repeating every fourth crown displaced axially for 42.9 nm. Further away myosin molecules are shown in lighter colors. Inspired by projection of myosin filament in the lattice cross-section from figure in (Squire, 1997).

Figure 3. The relative distance between a myosin head and the adjacent binding site on actin in the three-dimensional sarcomere lattice. (A) Myosin molecules form a triple helix along the myosin filament where the myosin heads are arranged in layers and at each layer form a "crown" with three myosin molecules. The crowns $\mathcal{L}_c = 1, 2,$ and 3 are axially separated by 14.3 nm and rotated by 40° , forming different angular arrangements with actin filaments, but only those that might interact with the actin filament are shown. On the other side, the actin monomers are

helically arranged in a double-strand helical structure and favorable myosin-binding sites on actin filament associated with nearby myosin heads are shown in dark gray. In the axial direction, each myosin pair of heads, denoted as a crossbridge and multiple binding sites on surrounding actin filaments form a large number of arrangements defined by the change in relative axial distances, x , between the unstrained position of the crossbridge and the nearest actin-binding site. (B) The hexagonal sarcomere lattice with 2:1 actin to myosin filament ratio shows in the azimuthal plane that up to three myosins can attach to each actin filament. The lattice size is defined by the distance of the 1,0 reflection from the center of the X-ray pattern, denoted as $d_{1,0}$, and calculated distance between axes of myosin and actin filaments, d_{A-M} . (C) The spatial arrangement of a crown \mathcal{L}_c interacting with six surrounding actin filaments is shown. The heads in crowns $\mathcal{L}_c = 1, 2$ and 3 have different azimuthal spatial arrangement relative to binding sites on the actin filaments displayed by separation by distance d_{A-M} and azimuthal angles α and β . The figures are adapted from (Mijailovich et al., 2016).

Figure 4. Nebulin specifies thin filament length distributions in skeletal muscle. The distance between silver grains and the edge the nearest Z-disk from mouse tibialis cranialis muscle, observed by Witt et al. (Witt et al., 2006), show uniform distribution of grains in wild-type, up to a distance of 1.2 μm (A), in contrast, to the grain distribution in Neb-KO muscle fibers where the distribution gradually decreases from ~ 0.4 to ~ 1.2 μm (B). The red lines are best fits of the histograms in A and B by a functions $\Phi_c(L_z)$ relating observed frequency of silver grains at distance from Z-line, L_z . After normalization of $\Phi_c(L_z)$ with maximum frequency a and setting thin filament length as $L_a = L_z$ the cumulative probability function of filament lengths $\widehat{\Phi}$ (red lines) and thin filament length distributions $d\widehat{\Phi}/dL_a$ (green lines) are formulated and displayed for wt (C) and Neb-KO muscle fibers (D). Spatially distributed actin filaments of variable lengths across a sarcomere, necessary for MUSICO simulations, can be obtained from sequentially drawn random numbers, $Rnd\#$, in range from 0 to 1 (D).

Figure 5. Distribution of actin (thin) filament lengths in rat atrial trabeculae and description of titin's nonlinear elasticity. (A) The best fit of the thin filament length distribution (green line) observed in rat atrial trabeculae (grey bars) (Robinson and Winegrad, 1977). (B) The cumulative probability density function $\widehat{\Phi}$ (red line) is derived from the best fit (green line) and used for generation of spatially distributed lengths of thin filaments in sarcomere lattice by sequentially drawing random numbers, $0 \leq Rnd\# \leq 1$. Derived sarcomere geometry mimics the distributed thin filament lengths observed in the atrial trabeculae and it is used in the MUSICO simulations. (C) The nonlinear elasticity of a titin molecule as a function of sarcomere length observed in cardiac muscle by (Helmes et al., 1999) (black filled symbols with bars). The force per a titin molecule estimated from high passive tension (Cazorla et al., 2001) at two sarcomere lengths (red filled triangle) matches the force-length data reported Helmes et al. In contrast the force at low passive tension (mechanical) underestimates the observed values at all three sarcomere lengths (cyan filled blue triangles). Sarcomere lattice compression with 4% dextran

did not affect titin forces showing that forces at high passive tension (open green squares) coincides with observation of Helmes et al. and that at low passive tension (open green diamonds) underestimate forces of Helmes et al., but have similar values with forces estimated from Casorla et al. at low passive tension (mechanical).

Figure 6. The effect of nebulin on force-length and force-pCa relations. (A) The MUSICO predicted force-SL relation (pink triangles and line) agrees well with observations in wt muscle (green circles with bars). Including in calculations only the variation of thin filament lengths in Neb-KO (grey squares and line) shows about 18 % decrease in force at full overlap (wt at SL= 2.5 μm) and shifts to the left by about 0.4 μm . In order to achieve the observed large drop in active tension (red triangles with bars) it was necessary to decrease the affinity of myosin to regulated thin filament (i.e. k_{bind}) by about 2.4-fold, in order to bring predictions (cyan filled blue triangles and line) close to observations in Neb-KO. (B) Predicted force-pCa relation at 2.5 μm for wt (pink triangles and line) agrees well with observations (green filled circles with bars) (Witt et al., 2006), and at fully activated muscle with the nebulin deficient sarcomere geometry and the same change in binding affinity as used in A, were sufficient to simulate magnitude of force at high calcium concentrations (blue open triangle and blue dotted line), but the predictions showed lower calcium sensitivity for $\Delta\text{pCa}_{50} = 0.0898$ (horizontal blue arrow). An increase in sensitivity was achieved by decreasing calcium off rate from TnC, i.e. an increase in TnI detachment rate from thin filament, and the predicted force-pCa relations (cyan filled triangles and blue line) then agreed well with observations (red triangles with bars). (C) Predicted force-pCa relation at 2.0 μm for wt (pink triangles and line) agree well with data of Chandra et al. (green filled circles with bars) but because of different experimental conditions (Chandra et al., 2009) it was necessary to decrease k_{bind} to 25 s^{-1} in order to reach observed tension at full activation. Here also at full activation nebulin deficient muscle binding affinity (i.e. k_{bind}) has to be decreased, in this case 3.3-fold, in order that predicted force matches observed tension levels (blue open triangle and blue dotted line vs. red triangles with bars). In this case the predictions also showed lower sensitivity for $\Delta\text{pCa}_{50} = 0.0827$ (blue horizontal arrow), but this decrease was not sufficient to match Neb-KO observations. Thus in order to match the observations of Chandra et al. the additional decrease in sensitivity was achieved by increasing calcium off rate from TnC used in the wt, i.e. a decrease of k_{-1} , and the predicted force-pCa relations (cyan filled triangles and blue line) then agreed well with observations (red triangles with bars). For simplicity, in all simulations we fixed $k_{-bind} \approx 2$ and only changed k_{bind} .

Figure 7. Effect of titin (passive) force on activation. Observed force-pCa relations (symbols with bars) are compared with MUSICO predictions (symbols only) at SL 2.0 and 2.3 μm , and at high and low tension. High passive tensions are achieved by stretching myocytes from SL 2.0 to 2.3 μm and then activating. Low tension is achieved by stretching myocytes to SL 2.5 μm , holding, releasing to SL of 2.3 μm and then activating (mechanical protocol) (A); low tension was also achieved by trypsin treatment of the cells at SL 2.3 μm (B); the effect of osmotic

compression (2.5% dextran) (C). For reference thin gray lines in panels B and C show force-pCa relations at 2.3 μm SL at high passive tension and at 2.0 μm SL from panel A.

Figure 8. Effect of sarcomere length on isometric force in fully activated cardiac muscle. Changes of multiple factors are shown at sarcomere lengths (SLs) 2.3, 2.0, 1.9 μm . Thin-thick overlap increases with the decrease of SL. The overlap is displayed as a fraction of thick-thin overlap at full overlap, where average thin filament length (dashed lines) display the magnitude of the average overlap. The binding rate, k_{bind} , decreases with the decrease of SL. The thick-thin filament overlap defines the region where crossbridges can bind to thin filaments and reflects the number of bound crossbridges per half myosin filament and, therefore, developed isometric force and tension. The titin-based passive tension is high at SL= 2.3 μm , low at SL= 2.0 μm and approximately zero at SL=1.9 μm . The inter-filament spacing increases with the decrease in SL. The values shown in bar graphs are: at SL = 2.3 μm as green bars, at 2.0 μm as orange bars, and at 1.9 μm as red bars. k_{bind} and active tensions are shown as % the values at SL=2.3 μm . The thin-thin filament overlap is small and only a small number of thin filaments interfere, thus its contribution to decrease in active force or tension is negligible.

Figure A1. The three-state model of the actomyosin cycle. The model consists of a detached state 1 (or M.ADP.Pi), weakly bound state 2 (or A.M.ADP.Pi) and strongly bound post power stroke state 3 (or A.M.ADP). The transition between the detached state 1 involves binding of crossbridges to available actin sites, forming weakly bound state 2, whereas transition from state 2 involves the phosphate released from the attached myosin head followed by lever arm displacement d to create a strongly bound state 3. Because the actomyosin cycle and the corresponding structural states of myosin head consist of at least six biochemical states, the reduction to the minimal three-state model requires grouping of transitions between A.M, A.M.ATP, M.ATP, and M.ADP.Pi states to a single transition where forward rate is dominated by the rate of ADP release and backward rate, i.e. reverse attachment from M.ATP to A.M.ATP, is by far slowest and can be neglected. The compounded state transition includes ADP release associated with lever arm displacement δ in order to open the nucleotide pocket, ATP binding, dissociation of myosin from actin, and ATP hydrolysis step.
