Version January 10, 2019 submitted to Remote Sens.

Abstract: This study reports on the combination of data from a ground penetrating radar (GPR) and a gamma ray detector for nonintrusive depth estimation of buried radioactive sources. The use of the GPR was to enable the estimation of the material density required for the calculation of the depth of the source from the radiation data. Four different models for bulk density estimation were analysed using three materials namely: sand, gravel and soil. The results showed that the GPR was able to estimate the bulk density of the three materials with an average error of 4.5%. The density estimates were then used together with gamma ray measurements to successfully estimate the depth of a 658 kBq caesium-137 radioactive source buried in each of the three materials investigated. However, a linear correction factor needs to be applied to the depth estimates due to the deviation of the estimated depth from the measured depth as the depth increases. This new application of GPR will further extend the possible fields of application of this ubiquitous geophysical tool.

Keywords: Ground penetrating radar; Radiation detection; Bulk density; Nuclear decommissioning; Nuclear wastes; Nonintrusive depth estimation

1. Introduction

Knowledge of the depth of penetration of radioactive contaminants is critical in characterising and decommissioning porous materials such as soil and concrete. This is because it determines the expected volume of wastes and subsequent choice of retrieval and disposal strategy [1]. This can have significant impact on the decommissioning cost because these materials are usually present in large volumes in contaminated sites [2]. Sources of contamination of this porous materials especially soil include fall out from nuclear weapons testing; nuclear accidents e.g. the Chernobyl and Fukushima accidents; and poor disposal of nuclear wastes [3–5]. In addition, the presence of these contaminants in the soil constitute a major public hazard due to their long half-life and chemical behaviour. For instance caesium-137 (Cs-137), which is one of the most predominant anthropogenic radioactive contaminants, is highly soluble and easily taken up by plants as a substitute for potassium thereby contaminating the food chain [6]. Therefore, there is a need to continuously monitor the depth of penetration of these contaminants in suspected sites.

However, traditional methods of depth estimation such as core sampling and logging are slow and have limited spatial sampling extent because of their intrusive nature. Furthermore, the nonintrusive methods reported in [5,7–14] are either based on regression models whose parameters typically have no physical significance or are limited to specific radioactive sources. Also, other nonintrusive methods reported in [15,16] use specialised shielding and collimator arrangements while those that employ machine learning [17–19] require significant amount of data to train the algorithms.

Therefore, a new nonintrusive depth estimation method based on an approximate three-dimensional (3D) attenuation model was recently developed [20]. The method is simple to setup and can be used to estimate the depth of any gamma emitting radioactive source. However, the method requires the density of the material in which the radioactive source is buried to be known before it can be used. This is usually not possible in practice without having recourse to intrusive density measurement methods [21]. Furthermore, the use of predefined or historical density values can result in misleading depth estimates because these values do not account for the changes undergone by the material over time due to environmental factors. Hence the need for an in situ density estimation technique that is nonintrusive. Ground penetrating radar (GPR) has been extensively used for the nonintrusive estimation of the soil moisture content of materials such as concrete and soil [22–25]. Therefore, it can potentially be used as a complementary sensor to provide this density information to the depth estimation process.

Consequently, this study reports on the combined use of a ground penetrating radar (GPR) and a gamma ray detector to estimate the depth of a buried radioactive source. Four different models for the estimation of bulk density from GPR were investigated using three different materials. The results from the best model were then used together with the data from the gamma ray detector to estimate the depth of a Cs-137 radioactive source buried in each of the materials. The rest of this article is divided into four sections. The next section describes the theoretical framework of the research while Section three presents the material and methods adopted for the research. The results and discussions are presented in Sections four and five respectively and the conclusion is presented Section six.

2. Theoretical framework

2.1. Approximate 3D linear attenuation model

Given a radioactive source S buried inside a material at depth z as shown in Figure 1, the ratio of the intensity $I_{(x,y,z)}$ measured at any position (x, y) on the surface of the material to that measured from a reference position (i.e. $(x, y) = (0, 0)$) on the same surface is given by [20]:

$$\log_e(J_{(x,y,z)}) \approx -\frac{\mu_m \rho_b}{2z} (x^2 + y^2) + \log_e(K_{(x,y,0)}) \quad (1)$$

where $J_{(x,y,z)} = \frac{I_{(x,y,z)}}{I_{(0,0,z)}}$, μ_m = mass attenuation coefficient, ρ_b = bulk density and $K_{(x,y,0)} = \frac{I_{(x,y,0)}}{I_{(0,0,0)}}$. Equation (1) is referred to as the approximate 3D attenuation model and can be used to estimate the depth of a buried gamma radiation source by fitting it to the data of intensities at a given gamma ray energy measured from discrete positions on the surface of the material volume. Both μ_m and ρ are properties of the material in which the source is buried. However, while μ_m is known to be relatively constant for different materials for a given photon energy, ρ_b must be estimated for the material under investigation before the attenuation model can be applied. Therefore, the use of GPR for nonintrusive estimation of ρ_b is the main aim of this study.

Figure 1. Radioactive point source S buried in a material volume

63 2.2. Principles of GPR

64 GPR is a geophysical technique for nonintrusive investigation of a wide variety of structures and
 65 materials e.g. soil, concrete etc. It does this by exploiting the response of these materials to propagating
 66 electromagnetic waves as illustrated in Figure (2). Electromagnetic waves from the transmitting
 67 antenna propagates into the surrounding medium at a velocity which is dependent mainly on the
 68 permittivity of the medium. The permittivity is a measure of the resistance offered by a material to
 69 the electric field induced by the waves. Furthermore, the measured permittivity of mixtures such as
 70 soil and concrete is referred to as the effective or bulk permittivity ϵ_b . This is because the measured
 71 permittivity of these materials is a combination of the permittivities of their constituents. In addition,
 72 the permittivity of a material is typically given as a relative quantity i.e. the ratio of the material's
 73 permittivity to that of free space. Therefore, all use of permittivity in this study refers to its relative
 74 value unless otherwise stated.

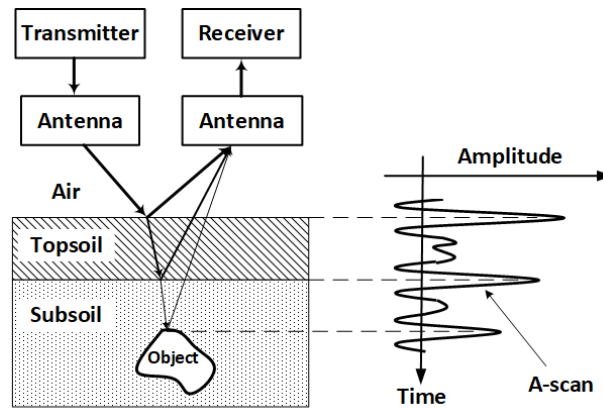

Figure 2. Principles of GPR. Reflected waves from boundaries a recorded by the receiver and displayed as a time varying signal called an A-scan

When the propagating waves encounter a boundary or interface, i.e. a layer with a different permittivity, part of the waves is reflected while the remaining is transmitted through the second layer. The proportion of the reflected wave is determined by the layer's reflection coefficient R which is given by:

$$R = \frac{\sqrt{\epsilon_{b,0}} - \sqrt{\epsilon_{b,1}}}{\sqrt{\epsilon_{b,0}} + \sqrt{\epsilon_{b,1}}} \quad (2)$$

75 where the $\epsilon_{b,0}$ and $\epsilon_{b,1}$ are the bulk permittivities of the first and second layers respectively. However,
 76 it should be noted that total reflection of the waves can occur if the second layer is a highly conductive
 77 material such as metal. The reflected waves are captured by the receiving antenna after which it is
 78 digitised by the receiver and displayed as a time varying signal commonly referred to as an A-scan

(Figure 2). Interfaces encountered by the propagating waves are indicated by pulses in the A-scan while the time of arrival of each pulse is an indication of the distance of the interface from the antennas.

2.3. Bulk density estimation using GPR

The estimation of the bulk density of a material using GPR consists of two steps namely: estimation of the material's permittivity, and estimation of the bulk density from the permittivity using permittivity mixing formulas. These steps are further discussed in the following subsections.

2.3.1. Estimation of the material's permittivity

If the medium of propagation is considered to be made up of layers with different permittivities, then the relative amplitude of the reflected pulse from the n th layer is given by [26]:

$$\frac{A_n}{A_{inc}} = \frac{\sqrt{\epsilon_{b,n}} - \sqrt{\epsilon_{b,n+1}}}{\sqrt{\epsilon_{b,n}} + \sqrt{\epsilon_{b,n+1}}} \left[\prod_{i=0}^{n-1} (1 - R_i^2) \right] e^{-\eta_0 \sum_{i=0}^n \frac{\sigma_i d_i}{\sqrt{\epsilon_{b,i}}}}, \quad (3)$$

where A_n is the amplitude of the reflected pulse from the n th layer, η_0 is the free space impedance, σ_i is the layer conductivity, d_i is the layer thickness, and A_{inc} is the amplitude of the incident pulse from the GPR system. The value of A_{inc} is usually obtained by measuring the reflection amplitude due to a flat metal surface placed at a fixed distance from the GPR system. This is because the metal surface is considered to be perfect electrical conductor with a reflection coefficient of -1. Therefore, the reflected pulse from the metal surface is the same as the inverse of the incident pulse from the GPR system.

For a two layer medium where the first layer is made up of air which has a permittivity of 1, the permittivity of the second layer can be obtained from Equation (3) by substituting $n = 0$ i.e.:

$$\epsilon_{b,1} = \left(\frac{1 + [A_0/A_{inc}]}{1 - [A_0/A_{inc}]} \right)^2 \quad (4)$$

where A_0 is the reflection amplitude from the interface between the first and second layer. This formula is widely used as the surface reflection method for the estimation of the permittivity and other properties of soils [27,28] and asphalt pavements [29–31]. Finally, Equation (3) can be used with a medium with any number of layers by iteratively applying it to all significant pulses in the A-scan to obtain the vertical variation of the medium's permittivity with depth.

2.3.2. Permittivity mixing formulas

Porous media such as soil and concrete can be considered as a mixture of several materials in different phases. For example, soil is typically modelled as a mixture of solid particles, water and air where the solid particles acts as a background material into which water and air are added as inclusions [32]. Permittivity mixing formulas express the bulk permittivity of these porous media as function of the permittivities of their constituents and the internal structure of the mixture. A number of permittivity mixing formulas have been proposed in the literature and these can be broadly divided into two categories.

The first category of formulas are those derived from the relationship between the induced electric field and the flux density. Since these category of formulas are derived from the physical laws of electromagnetism, they incorporate the microstructural properties of the mixture albeit with some simplifications. The general expression for this category of formulas is given by [33]:

$$\frac{\epsilon_b - \epsilon_0}{\epsilon_b + 2\epsilon_0 + v(\epsilon_b - \epsilon_0)} = \sum_{i=1}^n f_i \frac{\epsilon_i - \epsilon_0}{\epsilon_i + 2\epsilon_0 + v(\epsilon_b - \epsilon_0)} \quad (5)$$

where ϵ_0 is the permittivity of the background material, ϵ_i is the permittivity of other constituents of the mixture, f_i is the volume fraction of each constituent and v is a positive constant which indicates

the effect of the polarisation induced in the medium as a result of the propagating electric field. Furthermore, it was proved in [33] that most of the mixing formulas proposed under this category can be obtained from Equation (5) by substituting appropriate values for v . The second category of mixing formulas are the exponential or power law formulas which have the general form:

$$\epsilon_b^\alpha = \sum_{i=1}^n f_i \epsilon_i^\alpha \quad (6)$$

105 where α is a geometric parameter whose value is obtained by fitting the model to experimental data.
106 The common reported values for α are 0.5 [34–36] and 0.65 [37,38]. Furthermore, Equation (6) with
107 $\alpha = 0.5$ is also referred to as the complex refractive index model (CRIM).

108 In estimating the density of asphalt pavements using GPR, Leng *et al* [30] used three permittivity
109 mixing formulas namely: Rayleigh [39], Bottcher [40] and CRIM. Therefore, these three models were
110 also adopted for this study. Both the Rayleigh and Bottcher formulas can be derived from Equation
111 (5) using $v = 0$ and $v = 2$ respectively while the CRIM is obtained from Equation (6) with $\alpha = 0.5$ as
112 mentioned in the previous paragraph. In addition, Equation (6) with $\alpha = 0.65$ was also included in
113 this study and will henceforth be referred to as the Dobson mixing formula.

114 In summary, for a porous medium consisting of solid particles, air and water, the Rayleigh,
115 Bottcher, CRIM and Dobson mixing formulas for the bulk permittivity are given by:

$$\frac{\epsilon_b - \epsilon_s}{\epsilon_b + 2\epsilon_s} = (\phi - \theta) \frac{\epsilon_a - \epsilon_s}{\epsilon_a + 2\epsilon_s} + \theta \frac{\epsilon_w - \epsilon_s}{\epsilon_w + 2\epsilon_s}, \quad (7)$$

$$\frac{\epsilon_b - \epsilon_s}{3\epsilon_b} = (\phi - \theta) \frac{\epsilon_a - \epsilon_s}{\epsilon_a + 2\epsilon_b} + \theta \frac{\epsilon_w - \epsilon_s}{\epsilon_w + 2\epsilon_b}, \quad (8)$$

$$\epsilon_b^{0.5} = (1 - \phi)\epsilon_s^{0.5} + (\phi - \theta)\epsilon_a^{0.5} + \theta\epsilon_w^{0.5}, \quad (9)$$

$$\epsilon_b^{0.65} = (1 - \phi)\epsilon_s^{0.65} + (\phi - \theta)\epsilon_a^{0.65} + \theta\epsilon_w^{0.65}, \quad (10)$$

116 respectively where $\epsilon_s, \epsilon_w, \epsilon_a$ are the permittivities of solid particles, water and air respectively, θ is the
117 water content of the medium and ϕ is the porosity of the medium which is related to the bulk density
118 by:

$$\phi = 1 - \frac{\rho_b - \theta}{\rho_s} \quad (11)$$

119 where ρ_s is the specific density of the solid particles. It should be noted that the volume fractions f of
120 the air, water and solid particle depend on the porosity and water content of the medium consequently,
121 they were replaced in Equations (7-10) with their respective expressions from [35].

122 3. Materials and methods

123 The three materials investigated in this study are shown in Table 1. The bulk densities of each
124 of the material was measured using three different subsamples and the average value recorded. The
125 elemental composition of the sand and soil samples were obtained using Scanning Electron Microscopy
126 while that of the gravel sample was obtained from [41]. Furthermore, the mass attenuation coefficients
127 of all the elements in the three sample were obtained from tables published by the National Institute
128 of Standards [42]. These were then used together with the elemental compositions to calculate the
129 mass attenuation coefficients of the three materials at 662 keV which is the gamma ray energy at the
130 photo peak of the Cs-137 radioisotope used in this study. It can be observed from Table 1 that the mass
131 attenuation coefficient is relatively constant for all three materials therefore, an average value of 0.0775
132 was used in this study. The solid permittivity of soil and sand were obtained from [37] while that of
133 gravel was obtained from [43]. In addition, a specific density of 2.65 g cm⁻³ [44] was adopted for all

134 three materials. Finally, both the sand and gravel were dry samples while the water content of the soil
 135 was measured using the oven drying method.

Table 1. Properties of the materials used in the study

	Sand	10 mm Gravel	Soil
Bulk density (ρ_b) (g cm ⁻³)	1.52	1.54	1.26
Mass attenuation coefficient (μ_m) at 662 keV	0.0776	0.0775	0.0773
Solid permittivity (ϵ_s)	4.7	6.5	4.7
Specific density (ρ_s) (g cm ⁻³)	2.65	2.65	2.65
Water content (θ) (%)	0.0	0.0	6.0

136 3.1. Gamma ray data acquisition and processing

137 The experiment setup for the acquisition of the gamma ray intensity data is as shown in Figure
 138 3. The material volume is represented by a box in which the different materials were placed. The
 139 dimension of the box is 40 cm × 50 cm × 40 cm (length × width × height) and it was constructed with
 140 acrylic sheets with a thickness of 0.8 cm. Acrylic sheet was used because it is relatively transparent
 141 to gamma rays. The front of the box was divided into 4 × 4 cm² grids in order to identify each
 142 measurement position. The gamma ray detector used in the experiment was the CZT/500(s) detector
 143 from Ritec (Riga, Latvia). This is a cadmium zinc telluride detector which has a sensing volume of 0.5
 144 cm³ and is sealed in a casing with a diameter of 2.2 cm. Furthermore, the detector was placed inside a
 145 hollow cylindrical tungsten shield opened at both ends in order to eliminate background radiation
 146 from the laboratory environment.

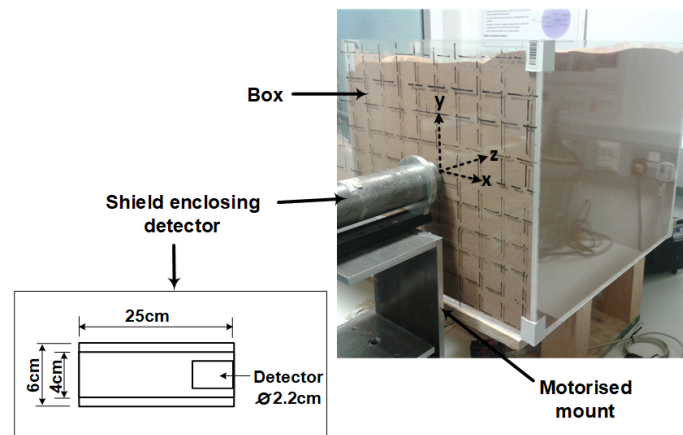

Figure 3. Setup for the gamma ray measurements. The Cs-137 point source was placed at varying position along the z-axis using a pipe that protruded behind the box while the intensity was measured at the desired positions on the surface of the box

147 During the experiment, the box was filled with one of the materials and a 658 kBq Cs-137
 148 radioactive point source was buried at varying depths from 2 cm to 22 cm at 4 cm intervals along the
 149 z-axis starting from the origin. This procedure was repeated for each of the materials. At each depth,
 150 the pulses from the detector were acquired using an oscilloscope (sampling rate = 500 kSa/s) from
 151 the desired number of grids. An acquisition time of 25 minutes per grid was used throughout the
 152 experiment. The acquired pulses were then stored and processed in a personal computer using the
 153 pulse height analysis algorithm described in [45] to generate the spectrum of the source at each grid.
 154 Therefore, a total of n spectra was acquired per depth where n is the number of grids. In addition, the
 155 background spectra for each of the three materials were also measured and subtracted from each of the
 156 generated spectrum. Finally, the photo peak function described in [46] was used to extract the number
 157 of gamma ray photons (i.e. intensity) at 662 keV from each of the generated spectrum.

158 3.2. GPR data acquisition and processing

159 As mentioned in Subsection 2.3, the first step in bulk density estimation using GPR is the
 160 estimation of the bulk permittivity using Equation (4). This will require the measurement of the
 161 amplitudes of the reflected pulses from each of the material and that from a metallic surface. The
 162 setup for the acquisition of the reflected pulses is shown in Figure 4. The orientation of the setup was
 163 kept the same with that of the gamma ray data acquisition to ensure consistency between the data
 164 from both experiments. The GPR system used is the MALA CX12 from GuidelineGeo (Sundbyberg,
 165 Sweden) with a central frequency of 1.2 GHz. In addition, a sampling frequency of 37 GHz and time
 166 window of 8.4 ns was used for throughout the experiment.

Figure 4. Setup for the GPR reflected pulse measurements. The antenna was placed 15 cm from the surface of the box

167 During the experiment, the GPR antenna was centrally positioned fifteen centimeters (15 cm)
 168 away from the front of the box while the reflected pulse was measured. This was repeated each time
 169 the box was filled with a different material. Furthermore, since the bulk permittivity was assumed to
 170 be uniform throughout the material volume, all the pulses were measured from this fixed position.
 171 In addition, the reflected pulse when the box was empty was also measured and subtracted from the
 172 reflected pulses measured when the box was filled with each of the material. This procedure removed
 173 the contributions of both the direct wave and box to the measured reflected pulses from the materials.
 174 Finally, the reflected pulse from a flat metal sheet was also measured in order to complete the data
 175 required to estimate the bulk permittivities of the materials.

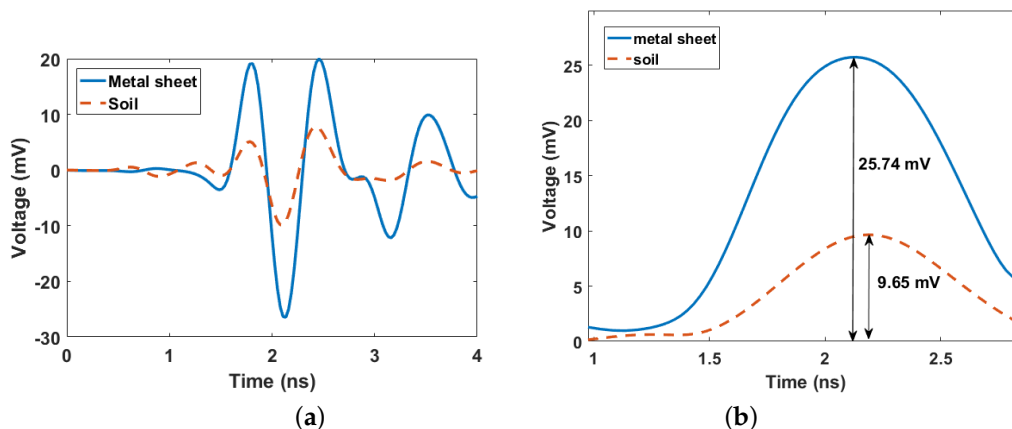

Figure 5. (a) Measured reflected pulses from the air-soil and air-metal interfaces without time-offset correction. Both pulses can be seen to arrive between 1.4-2.6 ns; (b) Envelope of the Hilbert transform of both pulses

176 After acquisition, the pulses were filtered using a finite impulse response bandpass filter with
 177 lower and upper frequencies of 0.5 GHz and 2.5 GHz respectively to remove unwanted frequency
 178 components. The filtered pulses from both the soil and metal sheet are shown in Figure 5a. The
 179 amplitude values of the pulses were obtained from the peak of the envelope of the Hilbert transform
 180 of the pulses. This is also shown in Figure 5b for the pulses from the soil and the metal sheet. Having
 181 obtained the required amplitude values, the bulk permittivities of the three materials were then
 182 estimated using Equation (4) and are shown in Table 2. The bulk permittivities of both the sand and
 183 gravel are consistent with the values reported in [43,47] while that of the soil is higher than both
 184 materials because of the water content. Also, note that the bulk permittivity of the gravel is higher than
 185 that of the sand despite both materials having approximately the same measured bulk densities. This
 186 difference is due to the solid permittivity of gravel which is higher than that of sand. Finally, using the
 187 estimated bulk permittivities, the bulk densities of each of the materials were then estimated using the
 188 four permittivity mixing formulas i.e. Equations (7 - 11) where the permittivities of water and air were
 189 taken to be 80.1 and 1 respectively. These results are presented and discussed in the next section.

Table 2. Estimated bulk permittivity for the three materials using Equation (4).

	Sand	Gravel	Soil
Bulk permittivity (ϵ_b)	2.93	3.57	4.84

190 4. Results

191 4.1. Bulk density estimation

192 The error in the estimated bulk densities for the four mixing formulas are shown in Figure 6. It
 193 can be observed that all the formulas yielded reasonably good estimates for both sand and gravel
 194 with an average error of 5% and 3.75% respectively. However, the Rayleigh and Dobson formulas
 195 had the best performance for sand with an error of 3% and 2% respectively. Conversely, the Bottcher
 196 and CRIM formulas had the best performance for the gravel with an error of 3% and -1% (negative
 197 errors means that the bulk density was under estimated). However, the significant difference in the
 198 performance of the formulas can be observed in the result for soil where all the formulas except the
 199 Dobson formula performed very poorly. The overestimation of the bulk density of soil by over 70%
 200 by both the Rayleigh and Bottcher formulas can be attributed to the fact that both formulas assume
 201 that the mixture is homogeneous [33] which is relatively true for both the sand and gravel samples.
 202 Conversely, soil is typically a complex mixture of sand, clay, silt, water, organic matter and other
 203 inorganic minerals consequently, the assumption of homogeneity is not valid.

Figure 6. Error in the estimated bulk densities of the three materials under investigation

204 The very good performance of the Dobson formula for soil compared to the poor performance of
 205 the CRIM formula is likely due to the inclusion of the effect of bound water by Dobson *et al* [37] in their
 206 estimation of the value of α in Equation (6). This is because at low water content (as is with the case of
 207 the soil used in this study), the water in the soil exists predominantly as bound water [37], i.e. as a
 208 thin film around the solid soil particles. Due to their restricted molecular motion, these bound water
 209 have a lower permittivity compared to free water in the pore of the soil matrix [35]. Therefore, the
 210 assumption that all the water in the soil behaves as free water (see [36]) which is the basis for arriving
 211 at a value of 0.5 for α is not correct. However, this assumption can be valid at high water content where
 212 the behaviour of free water dominates. This was further confirmed by [32] who observed that an α
 213 value of 0.5 seems to be appropriate for fully water-saturated porous media. Finally, since the Dobson
 214 formula had the least average error of 4.5% for all materials, its bulk density estimates were used in
 215 the subsequent sections to calculate the depth of the buried Cs-137 source.

216 4.2. Depth estimation of the buried Cs-137 radioisotope

217 The measured gamma ray intensities when the source was buried at 14 cm in the three materials
 218 are shown in the top row of Figure 7 as normalised raster images. The intensities were measured
 219 from a total of 7×7 grids covering a total scan area of $28 \times 28 \text{ cm}^2$. Furthermore, each pixel value of
 220 the image represents the number of gamma ray photons at 662 keV recorded by the detector at that
 221 position. The fitting of the attenuation model (i.e. Equation (1)) to the data from each of raster images
 222 using the density estimates from the Dobson mixing formula are shown in the corresponding bottom
 223 row of Figure 7. A good model fit can be observed for all three materials as indicated by the high
 224 adjusted r-squared values.

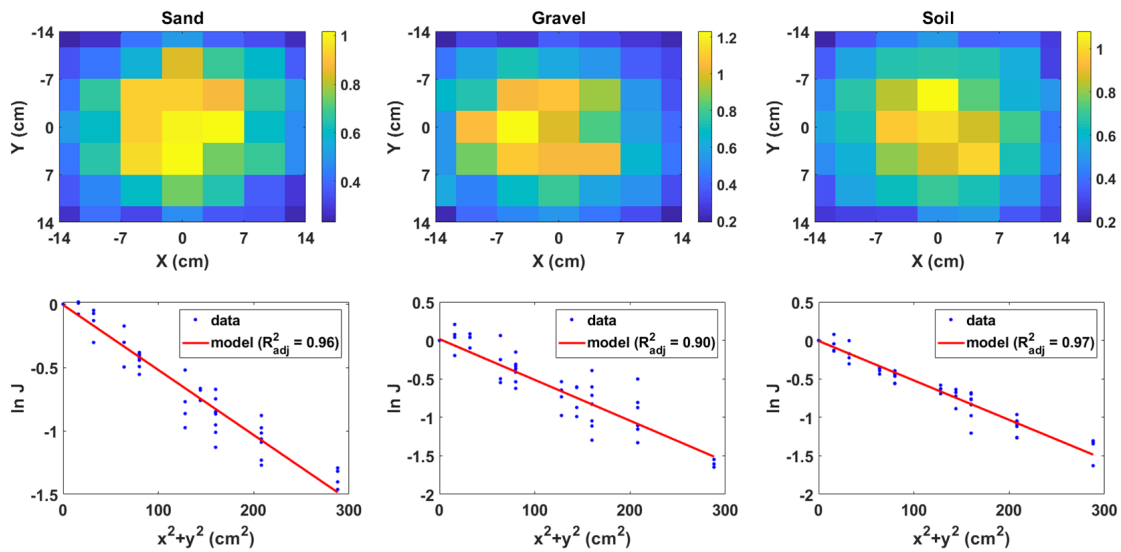

Figure 7. Normalised raster images of the Cs-137 source buried at a depth of 14 cm for each of the material (top row). Corresponding fit of the attenuation model for each of the depth images (bottom row).

225 The estimated depths of the buried Cs-137 radioisotope from the fitted attenuation model are
 226 shown in Figure 8 for all three materials. A consistent linear deviation of the estimated depth from the
 227 measured depth as the depth increases can be observed in all three materials. This deviation can be
 228 attributed to the fact that the attenuation model does not account for the inverse square reduction in
 229 the gamma ray intensity as the depth increases. However, a linear correlation between the estimated
 230 and measured depths can be visually observed in the figure for all three materials. This means that the
 231 measured depth can be predicted from the estimated depth by fitting a linear polynomial to the scatter
 232 graph. The fitted linear polynomials for the three materials are given in Table 3. The high adjusted
 233 r-squared values is indicative of the good linear correlation between the estimated and measured
 234 depths. Finally, it was shown in [45] that the parameters of these linear polynomials (i.e. the gradient
 235 and intercept) can be obtained using simulation tools such as MCNPX [48] and then used to correct
 236 estimated depths measured from field data.

Figure 8. Estimated depths of the buried Cs-137 source for the three materials.

Table 3. Linear polynomials fitted to the scatter graph of Figure 8 where z_{est} is the estimated depth and z_{mea} is the measured depth. This can be used as calibration equations to correct for the deviation of the estimated depth from the measured depth.

Material	$y = ax + b \pm error$	R_{adj}^2
Sand	$z_{est} = 0.64z_{mea} + 2.2 \pm 1.1$	0.99
Gravel	$z_{est} = 0.63z_{mea} + 1.9 \pm 1.2$	0.99
Soil	$z_{est} = 0.59z_{mea} + 1.5 \pm 1.9$	0.95

237 5. Discussions

238 The results presented in the previous section has proven the potential of GPR as a tool for
 239 estimating the material bulk density required for nonintrusive estimation of the depth of buried
 240 radioactive sources. This in situ density estimation will improve the accuracy in determining the
 241 depth of penetration of radioactive contaminants in materials such as soil and concrete compared to
 242 the use of historical density values. Furthermore, the nonintrusive nature of GPR will ensure that
 243 the contaminated material subsurface is not disturbed thereby preventing further spreading of the
 244 contamination.

245 However, one of the potential challenges in applying this depth estimation technique in the field
 246 is the time required to move a single gamma detector across the scan area. This can be eliminated by
 247 using a square array of gamma detectors since each detector and its shielding covers only a relatively
 248 small area of $4 \times 4 \text{ cm}^2$. The detector array can then be mounted on a trolley to scan the ground surface
 249 of the contaminated area. It should also be noted that the 25 minutes per grid measurement time taken
 250 to measure the gamma rays is due to the fact that each signal from the detector was first digitised by an
 251 oscilloscope and then transferred to a computer for processing. This time will be substantially reduced
 252 by using commercial multichannel analysers. These are dedicated high-speed electronics that process
 253 the output from a gamma detector and generate the spectrum of the radioactive source in real-time.

254 Another difficulty that maybe encountered in the field is the fact that Equation (4) depends only
 255 on the change in permittivity at the air-material interface. Consequently, it is unable to estimate the
 256 vertical variation in the bulk permittivity inside the material which can occur when investigating at
 257 greater depths e.g. up to 1 m. This difficulty can be resolved by iteratively applying Equation (3) to
 258 every significant pulse identified in the measured A-scan. This will yield the vertical variation of the
 259 permittivity inside the material from which the variation in density can be obtained using the Dobson
 260 mixing formula.

261 6. Conclusion

262 The use of GPR as a complementary sensor to provide in situ material density data required for
 263 the nonintrusive estimation of the depth of buried radioactive sources from radiation data have been
 264 demonstrated using three different materials. The results showed that the Dobson permittivity mixing
 265 formula provided the best bulk density estimates across the range of materials investigated. Therefore,
 266 its results were used with the radiation data to estimated the depth of a buried Cs-137 source using
 267 an approximate 3D attenuation model. In addition, different geometries for the measurement of the
 268 radiation data were analysed and it was found that measuring along a diagonal pattern can significantly
 269 reduce the measurement time and amount of data required to estimate the depth. However, a linear
 270 correction factor needs to be applied to the depth estimates to account for deviation of the estimated
 271 depth from the measured depth as the depth increases. This limitation will be further investigated in
 272 order to make the attenuation model more robust.

273 Finally, the benefits of combining GPR and radiation detectors are not limited to material density
 274 estimation. It also opens the possibility of nonintrusive three dimensional reconstruction of the
 275 contaminated subsurface by fusing GPR and radiation images. This will enhance visual monitoring of

276 these type of contaminated environments and provide guidance for autonomous decommissioning
277 systems.

278 **Author Contributions:** conceptualization, Ikechukwu Ukaegbu and Kelum Gamage; methodology, Ikechukwu
279 Ukaegbu; validation, Ikechukwu Ukaegbu; formal analysis, Ikechukwu Ukaegbu.; investigation, Ikechukwu
280 Ukaegbu and Michael Aspinall; writing—original draft preparation, Ikechukwu Ukaegbu; writing—review
281 and editing, Ikechukwu Ukaegbu, Kelum Gamage and Michael Aspinall; visualization, Ikechukwu Ukaegbu;
282 supervision, Kelum Gamage and Michael Aspinall; funding acquisition, Kelum Gamage

283 **Funding:** This research was funded by the Engineering and Physical Sciences Research Council, U.K.
284 (EP/N509231/1) and the Nuclear Decommissioning Authority, U.K. The APC was funded by Lancaster University

285 **Acknowledgments:** The authors would like to thank Dr. Douglas Offin (National Nuclear Laboratory, UK) for
286 industrial supervision of the project and Dr. Richard Wilbraham (Engineering department, Lancaster University,
287 UK) for assistance with the scanning electron microscopy measurements.

288 **Conflicts of Interest:** The authors declare no conflict of interest.
