Applied and Environmental Microbiology

24 ABSTRACT

25	Leptospira interrogans is the etiological agent of leptospirosis, a globally distributed
26	zoonotic disease. Human infection usually occurs through skin exposure with water and soil
27	contaminated with the urine of chronically infected animals. In this study, we aimed to
28	quantitatively characterize the survival of Leptospira interrogans serovar Copenhageni in
29	environmental matrices. We constructed laboratory microcosms to simulate natural conditions
30	and determined the persistence of DNA markers in soil, mud, spring water and sewage using a
31	qPCR and a PMA-qPCR assay. We found that L. interrogans does not survive at high
32	concentrations in the tested matrices. No net growth was detected in any of the experimental
33	conditions and in all cases the concentration of the DNA markers targeted decreased from the
34	beginning of the experiment following an exponential decay with a decreasing decay rate over
35	time. After 12 and 21 days of incubation the spiked concentration of 10 ⁶ L. interrogans cells/mL
36	or g decreased to approximately 100 cells/mL or g in soil and spring water microcosms,
37	respectively. Furthermore, culturable L. interrogans persisted at concentrations under the limit of
38	detection by PMA-qPCR or qPCR for at least 16 days in soil and 28 days in spring water.
39	Altogether our findings suggest that the environment is not a multiplication reservoir, but a
40	temporary carrier of the L. interrogans Copenhageni, although the observed prolonged
41	persistence at low concentrations may still enable the transmission of the disease.
42	
43	IMPORTANCE

44 Leptospirosis is a zoonotic disease caused by spirochetes of the genus *Leptospira* that

primarily affects impoverished populations worldwide. Although leptospirosis is transmitted by
contact with water and soil, little is known about the ability of the pathogen to survive in the

environment. In this study, we quantitatively characterized the survival of *L. interrogans* in environmental microcosms and found that although it cannot multiply in water, soil or sewage, it survives for extended time (days to weeks depending on the matrix). The survival parameters obtained here may help to better understand the distribution of pathogenic *Leptospira* in the environment and improve the predictions of human infection risks in endemic areas.

52

53 INTRODUCTION

Leptospirosis is a globally distributed life-threatening zoonotic disease that affects 54 55 humans and other mammals. The current estimates put the number of cases over 1,000,000 annually with almost 60,000 deaths making leptospirosis one of the most prevalent zoonotic 56 diseases worldwide (1). Leptospirosis is caused by motile spirochetes from the genus Leptospira. 57 58 Pathogenic leptospires colonize the kidneys of animal hosts and are chronically excreted with the 59 urine. Humans and other animals get infected through abrasions or cuts in the skin or mucous 60 membranes by contact with water or soil previously contaminated with infected urine (2). 61 Leptospirosis outbreaks are reported seasonally in endemic areas following rainfall events which lead to an increased human exposure to flood water, mud and run-off (3-7). Therefore, the 62 environment plays a central role in the spillover infections to humans and the circulation of the 63 64 bacteria within the animal reservoir. 65 Currently, there is a very limited knowledge about the persistence of pathogenic leptospires in environmental matrices and the factors affecting their fate (8). Persistence ranging 66 from few hours to several months have been reported for different species and serovars in 67 68 aquatic matrices such as tap, river, sea and distilled water (9–13). Similarly, in soil the reported

69 survival ranges span from few hours to 193 days (14–18). A number of factors have been

3

70	identified as affecting the persistence including pH, salinity, soil moisture, temperature and the
71	presence of accompanying microorganisms (9, 10, 19–23). However, these studies were based on
72	the isolation of leptospires by culture techniques or direct animal inoculation. These approaches
73	are time-consuming, insensitive and prone to errors such as the overgrowth by the autochthonous
74	microbiota. Furthermore, their results were qualitative and left a knowledge gap regarding the
75	quantitative survival dynamics of pathogenic leptospires in environmental matrices.
76	The ability of pathogenic leptospires to survive or even multiply in environmental
77	matrices is particularly critical to determine the extent to which they serve as a reservoir of the
78	disease. In this study, we aimed to quantify the survival of pathogenic leptospires in spring
79	water, sewage and soil under controlled laboratory conditions using qPCR. For this purpose, we
80	selected two species: Leptospira interrogans serovar Copenhageni, a highly virulent serovar that
81	has been associated with large seasonal outbreaks in urban slums in Brazil (5, 24); and
82	Leptospira biflexa serovar Patoc, a saprophytic species. We constructed laboratory microcosms
83	to simulate natural conditions and spiked them with known concentrations of leptospires. DNA
84	was extracted from each microcosm over a period of 28 days and quantified by qPCR and/or
85	PMA-qPCR. Finally, we developed a statistical model to describe the fate of Leptospira DNA
86	markers in the microcosms.
87	

88 RESULTS

89 Decay model

We developed a statistical model based on Weibull distributions to model the survival of *Leptospira* DNA markers in the microcosms. Starting with a full model including the covariates
species (*L. interrogans* and *L. biflexa*), medium (spring water, soil, mud and sewage), treatment

93	(sterile and non-sterile), and quantification method (qPCR and PMA-qPCR)), the final model
94	included species, medium, and quantification method (Table S1). Treatment (sterile/non-sterile
95	microcosm) did not contribute significantly to the model fit ($p = 0.19$), and was therefore not
96	selected as a covariate in the final model. The modeled shape of the decay curves was lower than
97	1 ($k = 0.715 \pm 0.03$), which indicated that the death hazard was not constant during the
98	experimental time, but instead decreased gradually after spiking. The modeled initial marker
99	concentration (μ_0) was 5.673±0.041 log ₁₀ units, which reflected the loss of DNA due to the
100	extraction procedure (see Supplementary Methods). Modeled decay parameters (ϕ and α) for
101	Leptospira DNA markers in each of the experimental condition are presented in Table 1. All
102	comparisons between markers below were based on this model.
103	

104 Differential persistence of *Leptospira* DNA markers in spring water and soil

105 The concentration of markers for both L. interrogans and L. biflexa decreased in all the 106 microcosms after spiking (Fig. 1). No differences were observed between decay rates of L. 107 *interrogans* and *L. biflexa* markers in spring water or soil. In spring water, *Leptospira* markers presented an almost flat decay curve ($\phi = 51.5$ and 42.2 for *L. interrogans* and *L. biflexa*, 108 109 respectively) in which the DNA concentration had decreased by approximately 0.5 log10 units at 110 the end of the experimental time. By contrast, the decay in soil microcosms was significantly 111 faster ($\phi = 16.3$ and 13.4, for L. interrogans and L. biflexa, respectively) with a rapid decrease during the first 8 days followed by stabilization at concentrations around 2.50×10^2 GE/g, 112 113 marginally over the limit of detection. Leptospires cultured in EMJH media did not show any 114 time lag before entering the exponential phase confirming that they were in good physiological

Applied and Environmental

Microbiology

115 conditions at the beginning of the experiments. Taken together these results indicate that there

116 was no net growth of *Leptospira* in spring water or soil.

117

118 Effect of moisture and soil characteristics on persistence

119 To evaluate the effect of soil moisture on the persistence of *L. interrogans* and *L. biflexa* 120 markers, we compared their decay in two soils with different physicochemical characteristics 121 adjusted to different moistures. We observed that the increase in moisture from field capacity to 122 muddy conditions did not have any effect on the persistence of L. interrogans or L. biflexa in 123 Brazilian and US soils as the decay parameters ϕ and α were not statistically different (Fig. 2; 124 Table 1). The decay rates (ϕ) in Brazilian soil and mud were significantly smaller for L. 125 interrogans and L. biflexa in comparison to the ones in US soil. Conversely, the proportion of 126 persistent markers (α) was significantly higher for both species in US soil and mud than in 127 Brazilian soil and mud, except for *L. interrogans* in Brazilian soil that showed no difference (Fig 128 2; Table 1). These observations indicated that moisture and intrinsic physicochemical 129 characteristics of the soil such as pH, organic content, and texture affected the persistence of 130 Leptospira.

131

132 Persistence of *Leptospira* DNA markers in sewage

In sewage microcosms, *Leptospira* markers presented a rapid decay ($\phi = 2.23$ and 1.83 for *L. interrogans* and *L. biflexa*, respectively), significantly faster than the decays observed in other media (Fig 2E and 2F; Table 1). In addition, we observed that *L. interrogans* markers could only be consistently quantified above the limit of detection for eight days (Fig. 2E) as opposed to *L. biflexa*, which was detected until the end of the experiment (Fig. 2F). This result is consistent

138 with the estimated decay parameter (α) that indicated that a larger proportion of L. biflexa 139 markers than L. interrogans persisted beyond the experimental time (Table 1). Thus, the 140 experimental data suggest that L. biflexa survives better than L. interrogans in sewage.

141

142 Persistence of L. interrogans cells measured by PMA-qPCR in soil and spring water

143 To determine whether the leptospiral DNA markers were suitable surrogates for live 144 cells, we monitored the decay curves of heat-killed L. interrogans and L. biflexa in spring water 145 and Brazil soil. In spring water, both L. interrogans and L. biflexa markers showed an almost flat 146 decay curve indicating that the DNA from dead cells was being degraded at a very slow pace 147 (Fig. S1). The long persistence of DNA in spring water evidenced that the markers were not 148 suitable surrogates for live cells. In contrast, in soil the persistence of DNA from heat-killed cells 149 was shorter with a 3 log₁₀ unit reduction in the first 4 to 6 days (Fig. S1), which indicated that 150 DNA from dead cells was being quickly degraded.

151 To discriminate between live and dead *L. interrogans* cells in the microcosms, we 152 optimized a PMA-based qPCR (Supplementary Methods). Briefly, PMA-qPCR is a viability 153 qPCR in which propidium monoazide (PMA), a DNA-binding dye, is added to the sample before 154 DNA extraction. PMA penetrates cells whose membrane is compromised and binds covalently to 155 DNA upon photoactivation interfering with its amplification. Therefore, the PMA treatment 156 allows for the selective detection of DNA from membrane-intact "live" cells (25). After 157 optimization of the PMA-qPCR procedure, we compared the persistence of markers in spring 158 water and Brazilian soil using qPCR and PMA-qPCR. In addition, we tested sterile and non-159 sterile microcosms to explore the role of the autochthonous microbial communities on the

160 survival. As anticipated by the previous experiment, the behavior of the markers in spring water

161 was completely different when measured by qPCR or PMA-qPCR. In the first case, an almost

Applied and Environmental Microbiology

162	flat decay was observed, indicating a long persistence of the markers in the system. Conversely,
163	when using PMA-qPCR the decay rates of <i>L. interrogans</i> markers were faster ($\phi = 25.8$) and
164	there were no long-term persisting markers (α not statistically different from 0) (Fig. 3A and 3B;
165	Table 1). These results indicate that L. interrogans cells were dying in the microcosm, but the
166	extracellular DNA persisted for a long time in spring water without being degraded.
167	Consequently, the qPCR measurement did not represent appropriately the fate of live L.
168	interrogans cells in spring water. In addition, we did not observe major differences in decay
169	parameters between sterile and non-sterile microcosms, which suggested that the spring water
170	microbiota was not a major factor involved in the persistence of L. interrogans. Regarding the
171	isolation of cells by culture, positive results were obtained in all sterile and non-sterile
172	microcosms up to day 21. At day 28 only two replicates each showed still positive results, in
173	agreement with the results obtained with PMA-qPCR (Table 2).
174	In Brazilian soil, the decay of markers measured by PMA-qPCR was also faster than that
175	measured by qPCR (ϕ = 8.2 and 16.3, respectively). At days 16 and 21 we detected markers by
175 176	measured by qPCR ($\phi = 8.2$ and 16.3, respectively). At days 16 and 21 we detected markers by qPCR in all the experiments in both sterile and non-sterile microcosms, but when using PMA-
176	qPCR in all the experiments in both sterile and non-sterile microcosms, but when using PMA-
176 177	qPCR in all the experiments in both sterile and non-sterile microcosms, but when using PMA- qPCR most replicates were negative (Fig. 3C and 3D), in agreement with the prediction of the
176 177 178	qPCR in all the experiments in both sterile and non-sterile microcosms, but when using PMA- qPCR most replicates were negative (Fig. 3C and 3D), in agreement with the prediction of the model that no cells were long-term persistent ($\alpha = 0$). Overall, these results showed that DNA
176 177 178 179	qPCR in all the experiments in both sterile and non-sterile microcosms, but when using PMA- qPCR most replicates were negative (Fig. 3C and 3D), in agreement with the prediction of the model that no cells were long-term persistent ($\alpha = 0$). Overall, these results showed that DNA markers persisted better than live <i>L. interrogans</i> cells in soil. However, as opposed to spring
176 177 178 179 180	qPCR in all the experiments in both sterile and non-sterile microcosms, but when using PMA- qPCR most replicates were negative (Fig. 3C and 3D), in agreement with the prediction of the model that no cells were long-term persistent ($\alpha = 0$). Overall, these results showed that DNA markers persisted better than live <i>L. interrogans</i> cells in soil. However, as opposed to spring water, the decay shape was similar. Indeed, the average difference between the concentrations
176 177 178 179 180 181	qPCR in all the experiments in both sterile and non-sterile microcosms, but when using PMA- qPCR most replicates were negative (Fig. 3C and 3D), in agreement with the prediction of the model that no cells were long-term persistent ($\alpha = 0$). Overall, these results showed that DNA markers persisted better than live <i>L. interrogans</i> cells in soil. However, as opposed to spring water, the decay shape was similar. Indeed, the average difference between the concentrations quantified by qPCR and PMA-qPCR before reaching the detection limit is 0.69±0.34 log ₁₀ units,
176 177 178 179 180 181 182	qPCR in all the experiments in both sterile and non-sterile microcosms, but when using PMA- qPCR most replicates were negative (Fig. 3C and 3D), in agreement with the prediction of the model that no cells were long-term persistent ($\alpha = 0$). Overall, these results showed that DNA markers persisted better than live <i>L. interrogans</i> cells in soil. However, as opposed to spring water, the decay shape was similar. Indeed, the average difference between the concentrations quantified by qPCR and PMA-qPCR before reaching the detection limit is 0.69±0.34 log ₁₀ units, with a maximum of 1.15 log ₁₀ units at day 4 (Fig 3C). These relatively small differences

Applied and Environ<u>mental</u>

Microbiology

185 isolated by culture up to day 12 in all sterile microcosms and two of three non-sterile ones. At 186 day 16, two sterile and two non-sterile microcosms were still positive (Table 2). Altogether, 187 these data indicate that despite the decay of live L. interrogans in soil, culturable cells were still present in Brazilian soil after 16 days at concentrations under the limit of detection by PMA-188 189 qPCR. 190

191 DISCUSSION

192 In this study, we aimed to characterize the survival of the pathogenic spirochete L. 193 interrogans Copenhageni in the environment. As with other environmentally dispersed bacteria, 194 the transmission from host to host depends largely on the pathogen's ability to survive and 195 remain infectious for a certain time outside of the host. Our findings indicate that this species cannot survive at high concentrations in soil, spring water or sewage. Yet, it exhibits a prolonged 196 197 persistence in the environment that extends for over 3 weeks in soil and spring water. 198 L. interrogans did not show any net growth in the microcosms after spiking. The 199 concentration of DNA markers decayed in all the environmental matrices. We observed that after 200 approximately 14 and 5 days of incubation in spring water and soil microcosms, respectively, the 201 initial concentration of 10⁶ L. interrogans serovar Copenhageni cells/mL or g decreased by 3 202 log₁₀ units (Table 1 and Fig. 3). This leads us to hypothesize that *L. interrogans* cannot multiply 203 in the environment after excretion from its animal reservoirs and thus, the environment is not a 204 reservoir from an epidemiological point of view, but rather a temporary carrier of the pathogen. 205 Consequently, although the environment is essential for the dispersion of the pathogen (4, 6, 26-206 29), it might not be sufficient to solely sustain the transmission cycle of the pathogen from 207 animal to animal and the spillover infections to humans.

208	The experimental data collected in the microcosms fitted an exponential model with a
209	decreasing decay rate over time. Various explanations have been proposed to explain this
210	behavior that has been reported for Salmonella enterica, E. coli, Enterococcus spp.,
211	Campylobacter jejuni and Bacteroidales, among other microorganisms (30-32) such as the
212	regulation of the population though quorum-sensing (33). Alternatively, initial populations may
213	be rapidly reduced due to predation or nutrient limitation until the carrying capacity of the
214	ecosystem is reached (34). The mechanisms of survival of Leptospira in the environment are still
215	poorly understood (8, 35), but the formation of biofilms and the interaction with other
216	microorganisms (20, 23) could explain the decreasing decay rates observed. Unfortunately, after
217	12 and 21 days the concentrations in soil and spring water reached the limit of detection of the
218	molecular methods (\approx 100 cells/g or mL) and the fate of <i>L. interrogans</i> serovar Copenhageni
219	could not be followed quantitatively thereafter. We succeeded, however, in culturing L.
220	interrogans serovar Copenhageni from non-sterile field-capacity soils and spring water in all
221	microcosms for at least 16 and 28 days, respectively (Table 2), even after the molecular approach
222	yielded negative results. Furthermore, the decay model predicted that a small proportion of the
223	initial population persisted in soil microcosms beyond the time at which the limit of detection
224	was reached (Table 1; Fig 3C). These low concentrations are consistent with those reported in
225	waters and soils in surveys of the pathogen in endemic areas (27, 36, 37). Overall, this suggests
226	that prolonged persistence at low concentrations may be sufficient to enable the transmission of
227	the disease.
228	Our culture-based results for soil microcosms fall within the ranges reported previously

days in moist silt loams from Australia (15), and *L. interrogans* serovar Hardjo was successfully

for other L. interrogans serovars. For instance, L. interrogans serovar Australis survived for 15

23	33	under field conditions in New Zealand (16). Conversely, previous studies have found longer
23	34	survival times in water than the ones reported in this study. L. interrogans serovar
2	35	Icterohaemorragiae remained culturable for 316 days when incubated in spring water at 30°C
23	36	(13). However, the addition of 1% of culture medium in their tested water clouds the
23	37	interpretation of the results. In distilled water at lower temperature (20°C), L. interrogans
23	38	serovar Canicola showed longer persistence (up to 110 days) (22). Despite the methodological
23	39	differences with these studies, our results suggest that L. interrogans may have a shorter
24	40	persistence in water at higher temperatures. This finding may be relevant to understand the role
24	41	of freshwater and other aquatic matrices in the transmission dynamics of L. interrogans in
24	42	tropical countries.
24	43	Sewage was not a suitable carrier for L. interrogans serovar Copenhageni. Although in
24	44	this case our data were based exclusively on qPCR results, the decays of L. interrogans in
24	45	sewage was faster than in soil and spring water (Fig. 2E). This decay is in agreement with Chang
24	46	et al. (1948), who reported that <i>L. interrogans</i> serovar Icterohaemorrhagiae was viable for no

231

232

241	of freshwater and other aquatic matrices in the transmission dynamics of L. interrogans in
242	tropical countries.
243	Sewage was not a suitable carrier for L. interrogans serovar Copenhageni. Although in
244	this case our data were based exclusively on qPCR results, the decays of L. interrogans in
245	sewage was faster than in soil and spring water (Fig. 2E). This decay is in agreement with Chang
246	et al. (1948), who reported that L. interrogans serovar Icterohaemorrhagiae was viable for no
247	more than 2-3 days after spiking in undiluted sewage. Despite this relatively short persistence,
248	exposure to sewage and flooding water after seasonal rainfall are widely recognized risk factors
249	for leptospirosis infection (3, 38–40). Thus, the role that sewage plays in the pathogen
250	mobilization, transportation and distribution, especially during heavy rainfall and flooding events
251	and, consequently, in the transmission of the disease, should not be disregarded.
252	Unexpectedly, L. biflexa serovar Patoc did not survive at high concentrations in any of

cultured for up to six days from Malaysian moist loam and clay soils under natural shaded

conditions (11). L. interrogans serovar Pomona survived for 42 days in saturated sterile soils

253 the conditions tested (Fig. 2). Nevertheless, the decay rate of L. biflexa markers was slower than

AEM

254	that of L. interrogans in soil and sewage (Fig 2 and 3). Specifically, the proportion of markers
255	that persisted beyond the experimental time (α) was significantly higher for <i>L</i> . <i>biflexa</i> than for <i>L</i> .
256	interrogans (Table 1). This suggests that a small proportion of the inoculated L. biflexa persisted
257	in soil and sewage 4 weeks post-inoculation at low concentrations ($<10^3$ cells/g or mL). The
258	concentration of naturally occurring L. biflexa or other saprophytic Leptospira in the
259	environment has not been determined, but it is likely lower than the starting concentration of 10^7
260	cells/mL or g used in the microcosms to simulate the presumed excretion of L. interrogans by
261	animal reservoirs. As indicated by the α parameters, <i>L. biflexa</i> may be decaying until the
262	carrying capacity of the ecosystem is reached at concentrations close to the limit of detection by
263	qPCR and surviving at low concentrations thereafter. Since we did not attempt to culture L.
264	biflexa in the microcosms beyond the experimental time of 4 weeks, this hypothesis remains to
265	be verified. Alternatively, L. biflexa may require a specific ecological niche to thrive different
266	from the conditions tested here to simulate the environmental phase of L. interrogans in a
267	tropical urban slum. Finally, future studies should preferably use recent isolates as the L. biflexa
268	strain has been preserved in laboratory conditions for decades after isolation (41), which might
269	have reduced its ability to thrive in the environment.
270	Microcosms are a convenient tool to study the persistence of microorganisms under
271	controlled conditions, although the decay rates estimated using these systems might not perfectly
272	predict the ones found in a variety of real settings (42, 43). For instance, we kept the microcosms

273 at a constant incubation temperature of 29 °C, which is a common temperature in standing water,

small open sewers and sun-exposed soil surfaces in tropical areas (44). In a real situation,

275 however, this temperature may oscillate throughout the day and across different areas. Further

276 studies should validate the results obtained here in more realistic settings that account for the

variability of natural conditions. Another limitation of this study is that the long-term persistence
of *L. interrogans* serovar Copenhageni seems to occur at concentrations close or below to the
limit of detection by qPCR. Other alternative techniques should be developed to better explore
the concentrations occurring in this phase of the decay and the mechanisms behind this survival.
Moreover, future research should also explore the potential loss or reduction in infectivity of *L. interrogans* during its environmental phase using animal models of infection.

283 Despite these limitations, we succeeded in characterizing quantitatively the survival of L. 284 interrogans in environmental matrices. Our results showed that L. interrogans exhibits a 285 prolonged survival in the environment for periods ranging from a few days in sewage to at least 286 4 weeks in spring water. Although it does not survive at high concentrations in the environment, small subpopulations might persist in concentrations below 100 cells/g or mL for a prolonged 287 288 time. Since the infectious dose in humans and animal reservoirs is unknown, the role that these 289 small populations play in the spillover infections to humans and the maintenance of the pathogen 290 within the animal reservoir should not be underestimated. Altogether our results provide novel 291 information that may have important ramifications regarding the life cycle of pathogenic 292 Leptospira. The decay parameters reported here need to be integrated into models of the 293 distribution of pathogenic Leptospira in the environment to improve the predictions of human 294 infection risks and inform public health interventions to reduce the transmission of leptospirosis. 295 MATERIAL AND METHODS 296

2

_

297 Bacterial strains and culture

Leptospira interrogans serovar Copenhageni strain Fiocruz L1-130 (45) and *Leptospira biflexa* serovar Patoc strain Patoc1 (41) were cultured in liquid Ellinghausen-McCullough-

300	Johnson-Harris (EMJH) (46, 47) in agitation (100rpm) at 29°C for 3 to 5 days. A late-
301	exponential culture was used in all the assays. After the incubation, 5 mL of the culture were
302	centrifuged at 4,000 g for 5 min and the pellet was washed twice with the same volume of sterile
303	spring water. The number of cells was determined using a Petroff-Hausser counting chamber
304	(Hausser Scientific, PA) under dark-field microscopy and the culture was adjusted to a
305	concentration of 10 ⁸ cells/mL with sterile spring water. For experiments requiring heat-killed
306	cells, cultures were placed at 80°C for 15 min in a water bath and immediately cooled at room
307	temperature for 20 min.
308	
309	Soil and water samples
310	The persistence of Leptospira spp. was investigated in two soils: a sandy loam soil (60%
311	sand, 35% silt, 5% clay and 3.17% organic matter) collected in an urban slum in Salvador
312	(Bahia, Brazil) and a loam soil (40% sand, 35% silt, 25% clay and 12.3% of organic matter)
313	collected in New Haven (Connecticut, US). In addition, two water matrices were evaluated:

bottled spring water obtained from a local retailer, and sewage collected from the New Haven wastewater facility after the bar screen and grit removal. For the sterile controls, spring water was autoclaved once at 121°C for 20 minutes and soil was autoclaved three times with 24h of incubation at 29°C between cycles.

318

319 Microcosms

Microcosms were prepared by distributing either 40 g of soil or 40 mL of water or sewage in sterile Pyrex glass beakers. The surface of the microcosm was spiked by dispersing droplets of *Leptospira spp.* suspensions to achieve a concentration of 10⁶ cells/g or mL and

323	thoroughly mixed. The volume of spiking suspension varied to adjust the moisture of the soils to
324	25% and 35% for the Brazilian and US soil respectively, which corresponded approximately to
325	their field capacity. To create mud conditions, soil moisture was increased to 35% and 45%,
326	respectively. After spiking, microcosms were thoroughly homogenized, sealed with plastic
327	paraffin film to protect them from external inputs and prevent evaporation, and placed in a humid
328	thermostatic chamber at 29°C under dark conditions. Samples of 1 g or 1 mL were withdrawn
329	from each microcosm at 0, 1, 2, 4, 6, 7, 12, 16, 21 and 28 days, for a total of 10 sampling time
330	points. A growth control was carried out using EMJH medium instead of the environmental
331	matrix. All microcosms were conducted in three independent biological replicates for L.
332	interrogans serovar Copenhageni and in two for L. biflexa serovar Patoc.
333	
334	DNA extraction methods
335	Three DNA extraction methods for both spring water and soil samples were evaluated
336	and compared (Supplementary Methods). Based on those results, soil samples and sewage were

337 subsequently extracted using the Power Soil[™] DNA Isolation Kit (Mobio), with minor

338 modifications. Spring water and EMJH samples were extracted using a bead beating method with

339 CTAB and phenol/chloroform/isoamyl alcohol. For the PMA assays, spring water was extracted

340 with the automated Maxwell® 16 Cell DNA Purification Kit (Promega).

341

342 qPCR assays

lipL32 gene was selected as a marker for *L. interrogans* and quantified using a TaqMan®
assay described elsewhere (48) with minor modifications (27). *rpoB* gene was selected as a
marker for *L. biflexa* and was quantified using a newly designed SYBR-Green® reaction

346 (Supplementary Methods). Calibration curves were constructed using genomic DNA obtained from strains Fiocruz L1-130 or Patoc1 with concentrations ranging from 10⁷ to 10⁰ genomic 347 348 equivalents (GE)/5µL, based on its respective genome size (49, 45). A standard curve was run on 349 each plate and used to transform quantification cycles (Cq) to concentrations (GE/reaction). 350 Non-template controls were randomly included in all rows of each plate to discard the presence 351 of contaminating DNA. All negative controls were negative in all cases. qPCR inhibition was 352 monitored using a previously described Internal Amplification Control (IAC) plasmid tested in 353 singleplex reactions (27). There was no evidence of inhibition of the molecular assays. See 354 Supplementary Material for further details on the qPCR assay, calibrators and inhibition assay. 355

356 Isolation of Leptospira spp. cells by culture

357 From soil microcosms, 1 g sample was mixed for 1h with 4 mL of PBS in a horizontal 358 mixer followed by sedimentation of the big particles for 30 min. Then, 3 mL of the supernatant 359 were recovered and inoculated into 3 mL of 2X concentrated EMJH supplemented with 500 µL 360 of a 10X concentrated antimicrobial combination (sulfamethoxazole, 400µg/mL; trimethoprim, 200 µg/mL; amphotericin B, 50 µg/mL; fosfomycin, 4 mg/mL; 5-fluoroacil, 1 mg/mL) (50). 361 362 From spring water microcosm, 1 mL sample was inoculated into 5 mL of EMJH liquid medium. 363 When a culture showed contamination, 1mL sample was filtered through a 0.45 µm filter and the 364 filtrate inoculated into 5mL of EMJH containing the antibiotic cocktail. All cultures were incubated at 29°C with agitation and checked twice a week for Leptospira growth by dark-field 365 microscopy. Samples were considered negative when no growth was observed after 30 days. 366

Applied and Environmental

Microbioloav

374 Statistical modeling

369

370

371

372

373

375 To model the survival curves of Leptospira markers and determine decay differences 376 between species (L. interrogans and L. biflexa), medium (spring water, soil, mud and sewage), 377 treatment (sterile and non-sterile), and quantification method (qPCR and PMA-qPCR), we 378 assumed that cell death and marker disappearance from the microcosms were probabilistic events 379 (51, 52). Thus, to describe the survival curves, a probabilistic Weibull distribution function was 380 applied to the experimental data:

The ability of propidium monoazide (PMA) to selectively amplify DNA from membrane-

intact L. interrogans cells in spring water and Brazilian soil was investigated. After optimization,

a 60-min treatment with $5 \mu M PMA$ was selected for spring water and a 15-min treatment with

100 µM PMA was selected for Brazilian soil (Supplementary Methods).

$$S(t;\phi,k) = P(T > t) = \exp\left(-\left(\frac{t}{\phi}\right)^k\right): t \ge 0$$

381 where k = 1 is a special case of the exponential function with a scale parameter ϕ . k defines the 382 shape of the survival curve and ϕ defines how stretched the shape is. Now, considering a set of 383 experiments i=1,..,r, which *ith* is defined by the values of a set of covariates x_i and the 384 concentration of the bacteria were measured at each time t_i : j = 1, 2, ..., m. Therefore, the 385 concentration expected in a given time *jth* is based on the initial concentration (μ_0), the proportion of cells that survive beyond the time of the experiments (α), and the family of survival 386 387 functions, in this case Weibull distributions:

 $\mu_{ij} = \mu_0 * (\alpha_i + (1 - \alpha_i) * (S(t_j; \phi_i, \kappa)))$

AEM

Applied and Environmental Microbiology 388

389	if there were any difference between species, treatment, method of quantification and substrates.
390	Maximum likelihood methods were used to estimate the parameters, assuming normality of the
391	residuals. The log-likelihood function was optimized using optim function in the R software
392	package (53). See Supplementary Methods for a full description of the survival model and the
393	incorporation of samples below detection limits in the analysis.
