---

**Objective:** The purpose of this work was to develop functional parameters to analyze regional cardiac function using ECG-gated  $^{99m}\text{Tc}$ -tetrofosmin SPECT. Our goal was to develop a methodology that used slice thickness correction, the generation of a time-activity curve and a polar map.

**Methods:** Fourteen normal patients without evidence of coronary artery disease were studied. One hour after intravenous injection of 740–1110 MBq (20–30 mCi)  $^{99m}\text{Tc}$ -tetrofosmin, ECG-gated SPECT data were acquired by dividing a cardiac cycle into 12 frames. The SPECT data were reconstructed from 11 of 12 frames into 3 views. The reconstruction of these images was repeated after performing slice thickness correction. Excluding the effect of different apex-to-base lengths at any frame during a cardiac cycle, 10 short-axis images with the same slice thickness were obtained. Each short-axis image was divided by 40 radii into 40 segments. The time-activity curve was generated from the total counts included in each segment plus both neighboring segments. Subsequently the curve fitting was performed using the second Fourier function.

**Results:** From fitted curves and their differentials, we calculated end-systolic count, end-diastolic count, percent count increase, uptake, peak contraction rate, peak distention rate and contraction time.

**Conclusion:** The functional polar maps visually demonstrated regional myocardial function. This method is expected to be helpful for assessing regional cardiac function using  $^{99m}\text{Tc}$ -tetrofosmin.

**Key Words:** regional cardiac function; ECG-gated SPECT;  $^{99m}\text{Tc}$ -tetrofosmin; functional polar map

---

It is important to evaluate cardiac function as well as myocardial perfusion in most patients with coronary artery disease (CAD). Myocardial perfusion has been evaluated with  $^{201}\text{Tl}$  and

$^{99m}\text{Tc}$  myocardial imaging agents (1–4). The simultaneous assessment of myocardial perfusion and cardiac function is preferable for convenience and cost (5–7). Electrocardiographic (ECG) gated SPECT has the potential to provide simultaneous assessment of myocardial perfusion and cardiac function. Since Moore et al. (8) first reported ECG-gated SPECT for cardiac blood-pool scintigraphy, various parameters have been derived to estimate cardiac function, including left ventricular ejection fraction (LVEF), amplitude, phase, percent count increase (%CI) and percent wall thickening (%WT) (9–16). Many authors have estimated absolute values and the curve patterns of these parameters. However, there are not many reports on functional images using these parameters (9–10, 17). The aim of this study was to develop functional polar map displays using parameters derived from  $^{99m}\text{Tc}$ -tetrofosmin ECG-gated SPECT data.

## MATERIALS AND METHODS

### Study Population

The study population consisted of 14 patients (10 men and 4 women) without known CAD. Their ages ranged from 24–61 y (mean age:  $40.6 \pm 13.7$  y). All patients had echocardiography. All of the ECGs demonstrated normal sinus rhythm. We then performed ECG-gated SPECT after administering 740–1110 MBq (20–30 mCi)  $^{99m}\text{Tc}$ -tetrofosmin.

### Preparing Technetium-99m-Tetrofosmin

Technetium-99m-tetrofosmin (Nihon Medi+Physics Corp., Tokyo, Japan) was prepared from a freeze-dried kit by reconstitution with approximately 740–1110 MBq (20–30 mCi) in 2 mL of a sterile pertechnetate solution. Each preparation met or exceeded the manufacturer's quality control recommendations.

### Imaging Protocol

One hour after injecting 740–1110 MBq (20–30 mCi)  $^{99m}\text{Tc}$ -tetrofosmin, ECG-gated SPECT studies were performed using a rotating gamma camera (4000 XC/T–Starcam; General Electric, Milwaukee, WI) equipped with a low-energy all-

purpose collimator. The energy discriminator was centered on 140 keV with a 20% window. Thirty-two projections for 50 s per projection were acquired over a 180° semicircular arc extending from the 45° right anterior oblique (RAO) position to the 45° left posterior oblique (LPO) position. Twelve frames per cardiac cycle were acquired at each projection. All images were obtained with a 64 × 64 matrix and a zoom of 1.33. The SPECT data were prefiltered with a Hanning filter (cutoff 0.8). The SPECT images were reconstructed with a filtered backprojection algorithm and ramp filter (cutoff 0). No attenuation correction was performed.

#### Procedure for Creating the Polar Map Display

**Step 1: Reconstruction of the SPECT Images.** The cardiac cycle was divided into 12 frames, and the horizontal long-axis, vertical long-axis and short-axis images were reconstructed from the SPECT data. Figure 1 shows the alignment of short-axis images from the apex to the base for each frame during a cardiac cycle. The 12th frame was excluded from the analysis because it had greater variation in counts than the first 11 frames.

**Step 2: Performing the Slice Thickness Correction.** Ten short-axis images with the same slice thickness were obtained from each frame (Fig. 2) to exclude the effect of the different apex-to-base lengths at any frame during a cardiac cycle. After performing the slice thickness correction, the reconstruction of these images was repeated.

**Step 3: Identification of End-Systole and End-Diastole.** The apex and the base in the end-systolic (ES) and the end-diastolic (ED) images were manually determined. From these locations, the apex (A) and the base (B) at each frame was automatically determined because these locations at the remaining frames can be approximated by trigonometric function using the least square method (Fig. 3):

$$Y = A \times \cos(X + B) + d \quad (1)$$

$$A = (Y_{ED} - d) / \cos(X_{ED} + B) \quad (2)$$

$$\tan(B) = \frac{Y_{ED} \times \cos(X_{ES}) - Y_{ES} \times \cos(X_{ED})}{Y_{ED} \times \sin(X_{ES}) - Y_{ES} \times \sin(X_{ED})} \quad (3)$$

$$d = (Y_{ED} + Y_{ES}) / 2, \quad (4)$$

where X and Y are the locations of the apex (A) and the base (B), respectively, at any frame. Examples of ES and ED are shown in Figure 3.

**Step 4: Slice Reframing Process.** The short-axis images were aligned after reconstruction using the slice thickness correction (Step 2). Each frame was divided into 10 slices (Fig. 4).

**Step 5: Generation of Time-Activity Curve.** The centers and the radii on the apical and the basal images at ES and ED were manually determined (Fig. 5). The myocardium of the left ventricle was defined as the area whose counts were more than 20% (threshold value) of the maximum counts. The centers and the radii in the remaining slices were determined by Equation 1 above. Each short-axis image was divided by 40 radii into 40 segments. The time-activity curve (TAC) from each segment was generated from the total counts included in each segment plus both neighboring segments. A total of 400 TACs were used for analysis for each patient.

**Step 6: Curve Fitting and Derivation of Functional Parameters.** Each time-activity curve was fitted to the second order Fourier function. By analyzing fitted curves and these differential curves (Fig. 6), the following parameters were obtained: ES count (MAX); ED count (MIN); count increase (CI); percent count increase (%CI); uptake; peak contraction rate (PCR); peak distention rate (PDR); and contraction time (CT), where:

MAX = the maximum count on the fitted curve

MIN = the minimum count on the fitted curve

**FIGURE 1.** The alignment of short-axis images from the apex to the base (left to right) for each frame during a cardiac cycle. Thirty-two projections were acquired.

**FIGURE 2.** Technique for slice thickness correction. The apex-to-base length of each frame was divided into 10 slices with the same thickness.

Count increase (CI) = MAX - MIN

$$\text{Percent count increase (\% CI)} = \frac{(\text{MAX} - \text{MIN})}{\text{MIN}} \times 100$$

Uptake = the average count in the fitted curve

Peak contraction rate (PCR) = the peak counting rate increase at ES

Peak distention rate (PDR) = the peak counting rate decrease at ED

Contraction time (CT) = the time interval from ED to ES

**Step 7: Generation of Polar Maps.** Each functional polar map was made of 10 slices from the apex to the base and was estimated after dividing the polar map into 5 regions, representing the apex, anterior, septal, inferior and lateral regions of the myocardium. The means in each region were calculated. Percent  $ES_{\text{Max}}$  (% $ES_{\text{Max}}$ ), percent  $ED_{\text{Min}}$  (% $ED_{\text{Min}}$ ) and percent uptake (%Uptake) were obtained by dividing  $ES_{\text{Max}}$ ,  $ED_{\text{Min}}$  and Uptake, respectively, by the maximum of each parameter in the 5 regions. Percentage CT (%CT) was obtained by dividing CT by the minimum in the 5 regions. Percentage PCR (%PCR) and %PDR were obtained by dividing the PCR and the PDR, respectively, by each Min value in 5 regions. Finally, the functional polar maps were interpreted by visual analysis.

#### Statistical Analysis

All results were expressed as mean  $\pm$  1 SD. The significant difference was assessed with Fisher's protected least significant difference (Fisher's PLSD). Significance was defined at the level of  $P < 0.05$ .

#### RESULTS

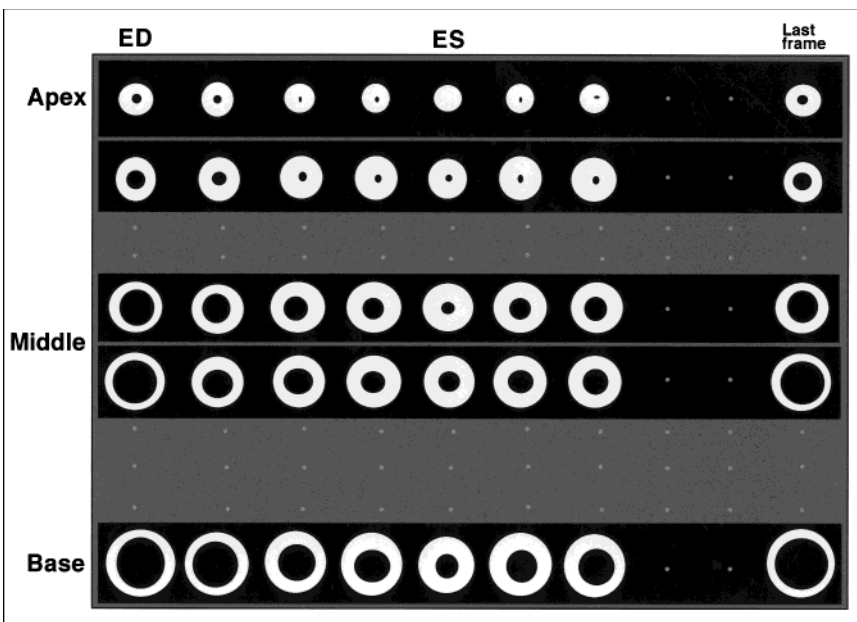

Figure 7 shows an example of the functional polar maps generated from 1 individual. Figures 8 and 9 show the mean values of the functional parameters by myocardial region in the normal subjects.

#### % Max

The mean %Max (Fig. 8A) was greater in the anterior and the septal regions, but lower in the inferior region. There was a statistically significant difference between the inferior and the anterior septal region (91.4% versus 96.2%,  $P < 0.01$ ; 91.4% versus 96.8%,  $P < 0.006$ ).

**FIGURE 3.** After the manual identification of the apex and the base at both end-diastole (ED) and end-systole (ES), the locations of the ED and ES frames were automatically determined using the function  $Y = A \times \cos(X + B) + d$ .

**FIGURE 4.** The realignment of the short-axis images after reconstruction with slice thickness correction. Each frame was divided into 10 slices.

#### % Min

The mean %Min (Fig. 8B) was greater in the apex (93.6%) and lateral (96.9%) regions. The mean %Min was significantly lower in the septal (87.3%) and inferior (85.2%) regions.

#### % CI

The mean %CI (Fig. 8C) was  $81.6\% \pm 19.6\%$  in the apex,  $98.4\% \pm 18.0\%$  in the anterior,  $101.8\% \pm 21.5\%$  in the septal,  $94.9\% \pm 17.1\%$  in the inferior, and  $76.6\% \pm 15.4\%$  in the lateral region. There was a significant difference between the septal and lateral regions ( $P < 0.0006$ ).

**FIGURE 5.** The centers and the radii of the apical and the basal images at end-diastole (ED) and end-systole (ES) were determined manually. ED and ES at all other frames were automatically determined after selection of the 20% maximum count threshold level.

#### % Uptake

The %Uptake (Fig. 8D) in the inferior region was significantly lower than that in the lateral region (89.3% versus 96.4%,  $P < 0.0009$ ).

#### % PCR

The mean %PCR (Fig. 9A) was greater in the septal (4.17%), anterior (3.99%) and inferior regions (3.88%). This pattern also was shown in the %CI results. There was a significant difference between the septal and the lateral regions ( $P < 0.0002$ ).

#### % PDR

The mean %PDR (Fig. 9B) in the apex (3.58%) and the lateral (3.23%) regions was slightly lower than the values in the other regions, although there was no significant difference between the regions.

#### % CT

The mean %CT (Fig. 9C) was greater in the apex (110.5%), inferior (108.5%) and the lateral (110.5%) regions. It was significantly lower than in the septal region (101.5%;  $P < 0.002$ ).

## DISCUSSION

Since the first report on ECG-gated SPECT in cardiac blood-pool scintigraphy (8), many parameters have been derived (9–16). There are few reports of quantitative methods using these parameters and the generation of functional images (9–10,17).

The main improvements our method employs are the use of slice thickness correction and the generation of the time-activity curve. For the slice thickness correction, we made 10 short-axis images with the same thickness per frame to exclude the effect of different apex-to-base lengths during a cardiac cycle. For the

**FIGURE 6.** A curve obtained by fitting the second order Fourier function to a time-activity curve, and its differential curve. The following parameters were derived from these curves: end-systolic count (Max); end-diastolic count (Min); percentage count increase (%CI); uptake; peak contraction rate (PCR); peak distension rate (PDR); and contraction time (CT).

generation of the time-activity curve, we used the total counts included in each segment plus both neighboring segments.

In previous reports the mean or the maximal counts only were used for generating the time-activity curve (10,12,16,17). Since we used the total counts to generate the time-activity curve, we were able to derive new parameters including PCR, PDR and CT. These parameters may prove to be helpful in evaluating the cardiac function.

It has been noted that the center of short-axis images moves

toward the apex along the long axis from ED to ES and that the left ventricle has different sizes (13). The center of the short-axis images, therefore, should be determined according to the size of the left ventricle. For this reason, we manually determined the centers of the apical and the basal images at ED and ES and developed the software so that the centers of the remaining images were automatically determined by the formula given in Equation 1.

Technetium-99m myocardial imaging agents have character-

**FIGURE 7.** Functional polar maps of %CI, %Uptake, %Max, %Min, %PCR, %PDR and %CT in a normal subject shows the differences between each segment. The scale for each parameter was normalized to 100% of the maximum of each parameter, except for %CI, which was normalized to 100% at the delayed contraction time.

**FIGURE 8.** Bar graphs show mean  $\pm$  1 SD of each parameter in 14 normal subjects: (A) %Max; (B) %Min; (C) %CI; and (D) %Uptake. Segment abbreviations are: Ant. = anterior, Sep. = septal, Inf. = inferior and Lat. = lateral.

istic increased extracardiac activity. After manually determining the effective radius within the myocardium, the myocardial area was determined by the threshold value of 20% of the maximum counts to reduce the influence of scatter from hepatic activity.

Normal subjects showed different %CI in different segments. The %CI was greater in the septal (101.8%), anterior (98.4%) and inferior (94.9%) regions, and significantly lower in the apex (81.6%) and inferior (76.6%) regions. There was a significant difference between the septal and lateral regions ( $P < 0.0006$ ). Our results were slightly higher than those reported by other authors. The difference seems to be caused by the difference in the way the myocardial counts were used for the generation of the time-activity curve. Mochizuki (10) and Shirakawa et al. (18) used the maximal and mean counts, respectively, to

generate the time-activity curve. We used the total counts included in each region plus both neighboring regions.

The cardiac function has been estimated using parameters, such as peak ejection rate (PER) and peak filling rate (PFR), that is, the maximal up and down slopes of the left-ventricular volume curve, normalized to ED counts (19). A comparison between these parameters and our results should be performed.

In this study the effect of rotation of the left ventricle was ignored. It is known that contraction of the obliquely oriented fibers results in a counterclockwise twist of the left ventricle on the long axis (20–23). The correction of twist phenomenon should be analyzed.

It took 27 min for data acquisition with a single-head rotating gamma camera. Acquisition time would be reduced if a multihead rotating gamma camera were used. It took 20 min per patient to

**FIGURE 9.** Bar graphs show mean  $\pm$  1 SD of each parameter in 14 normal subjects: (A) %PCR; (B) %PDR; and (C) %CT. Segment abbreviations are: Ant. = anterior, Sep. = septal, Inf. = inferior and Lat. = lateral.

perform the data processing. The consumption of so much time restricted the routine use of this protocol. It was performed only in the institution where a supercomputer was available.

## CONCLUSION

We developed an automatic software program to calculate several parameters including Max, Min, %CI, Uptake, PCR, PDR and CT and displayed functional images as polar maps. This method may prove to be helpful for accurately assessing cardiac function. Additional study, of normal individuals and patients with CAD and other diseases that adversely affect myocardial function, needs to be performed.
