Zn speciation in two Fe-Mn banded systems

Zn speciation in two Fe-Mn banded system

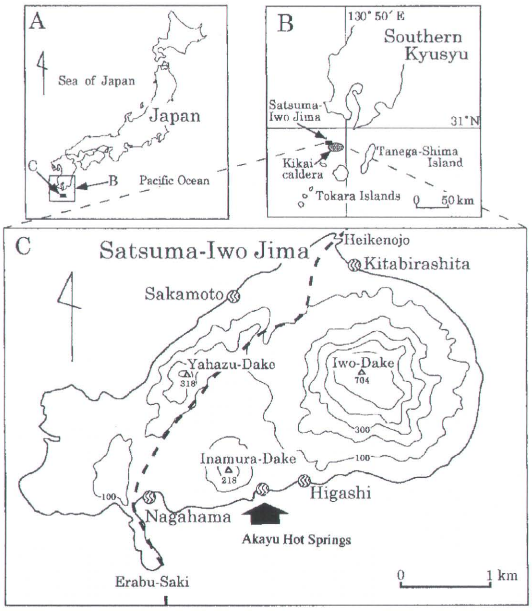
What we did: Micro-XRF and micro-EXAFS at Zn and Mn on two Fe-Mn banded systems: looking at Fe/Mn/Zn distribution and Mn and Zn speciation.

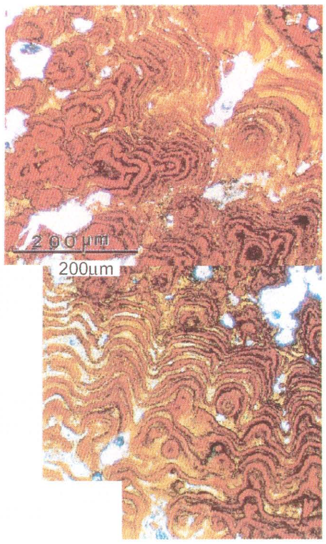
Why we care: Fe-Mn banded systems are ubiquitous, occurring in soils, shallow oceans, deep oceans, hotsprings,...
They have similarities despite differences in formation. Some are biogenic, some not.
Question: Are there common themes? How transferrable is the structural information? Does it matter if bacteria were involved?

Acknowledgements: This work was done at the Advanced Light Source, Beamline 10.3.2, and at the ESRF FAME beamline. The authors thank Robert Sublett for help with data collection. M. Kersten acknowledges support by Jan Harff from the Baltic Sea Research Institute.

Samples

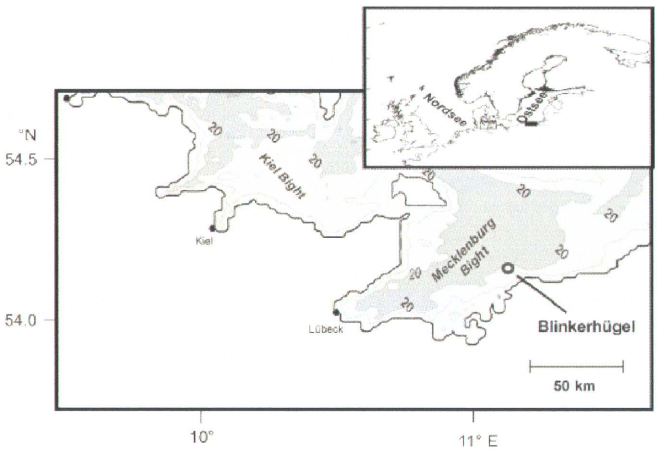
Bacterial mat from Japan

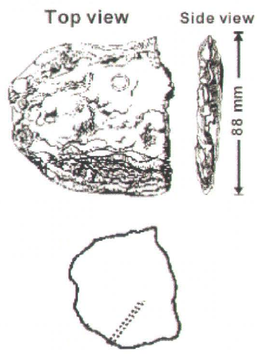




Ref: Tazaki, K., *Clays and Clay Minerals* 48, 511-520 (2002)

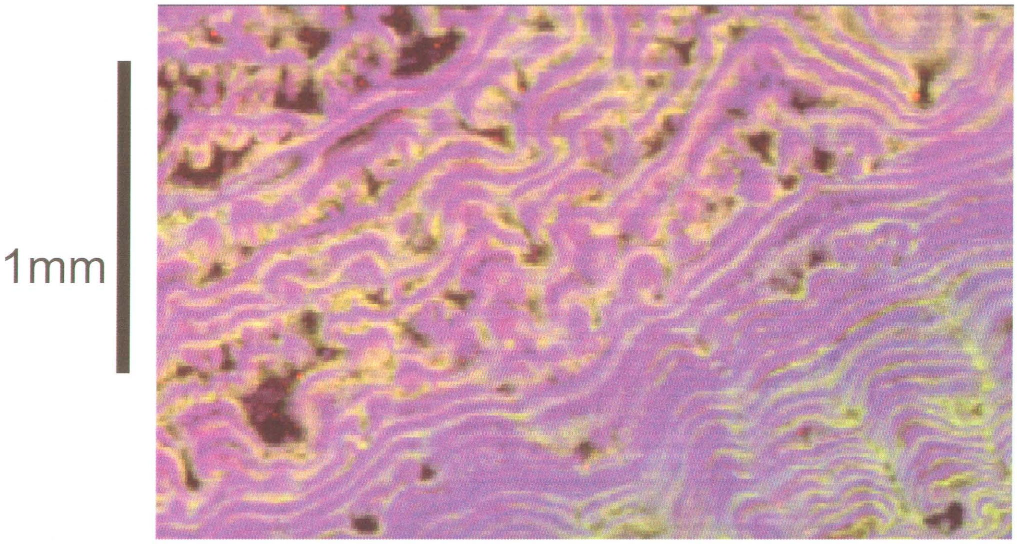
Shallow-ocean nodule from Baltic





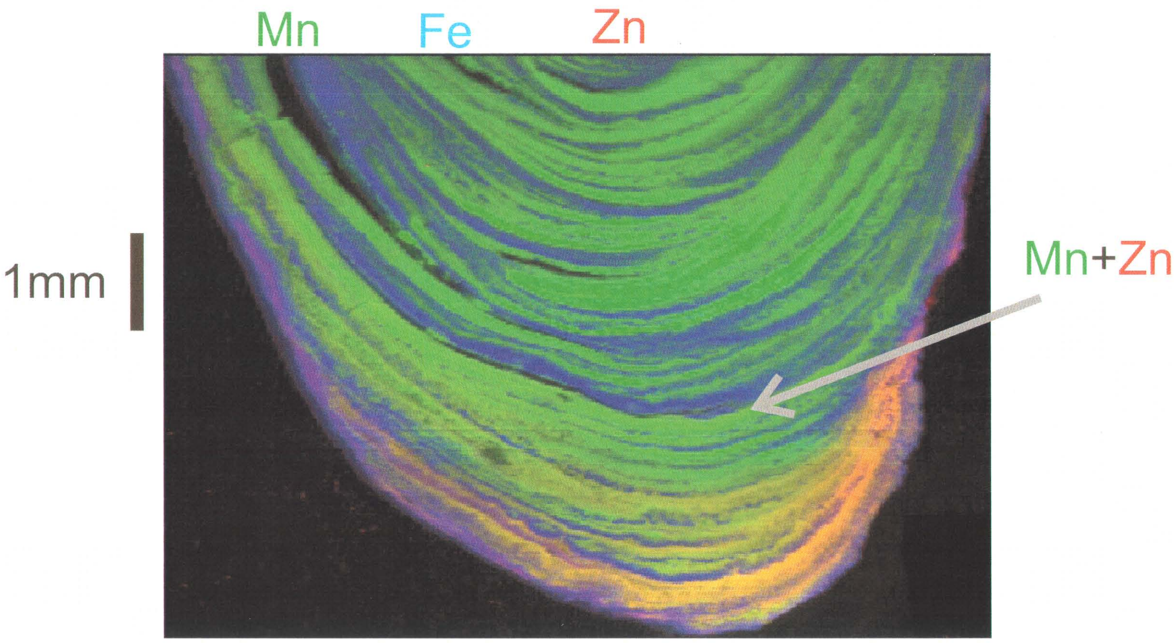
Ref: S. Hlawatsch, T. Neumann, C. M. G. van den Berg, M. Kersten, J. Harff, E. Suess, *Marine Geology* 182, 373-387 (2002)

Elemental maps



Bacterial mat from hotsprings at seashore
Zn is at natural abundance.

Tricolor elemental maps



Zn at rim is anthropogenic and was deposited only when outer layers were growing.

Similarities: Fe/Mn alternation due to oscillating chemistry. Zn prefers Mn to Fe.

Differences: Japanese sample has Zn everywhere; Baltic one mostly in rim,due to natural/anthropogenic Zn source.

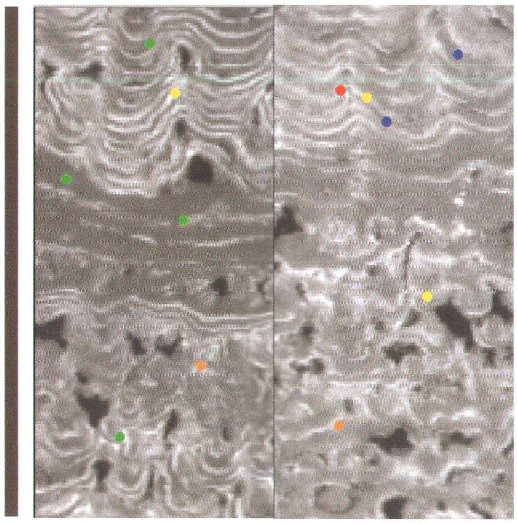
Zn less segregated in Japan sample than Baltic.

Zn XANES: Japan

Look at different points and analyzed by XANES.
Use PCA to characterize spectra

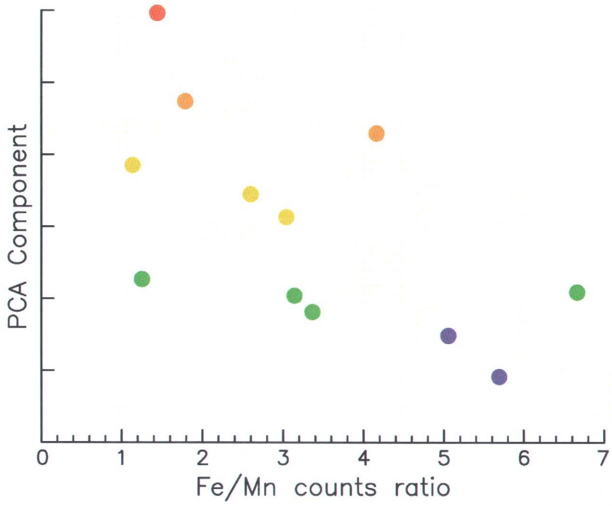
Colored points mark where spectra were taken. Colors match those on XANES and PCA plots

2 mm



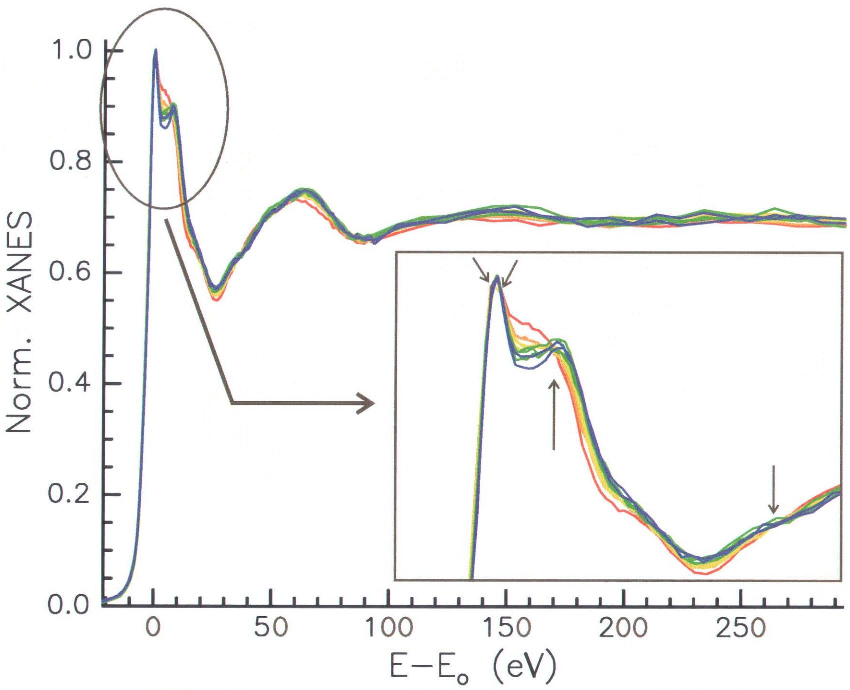
Mn map (high Mn=light)

Result rincipal Components Analysis
Points colored according to PCA component strength



Zn extended XANES from spots shown above

Isosbestic points (arrowed in insert) show that data approximates linear combinations of two components (end-members)

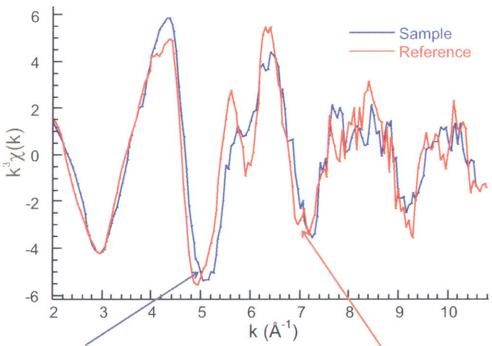


Results: XANES shows a clear variation with location on sample. Data are approximately described as linear combinations of two end-members, with fractions (related to PCA 2 nd component strength) correlated with Fe/Mn ratio.

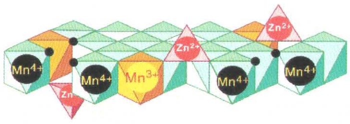
This is consistent with EXAFS picture of competing sorption on hydrous ferric oxides and phyllomanganates.

Zn EXAFS: Baltic

Zn and Mn EXAFS and XANES is uniform over area tested, unlike Japan sample.



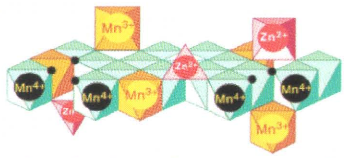
Sample



Zn sorbed on turbostratic birnessite: Tetrahedral Zn and some Mn^{3+}

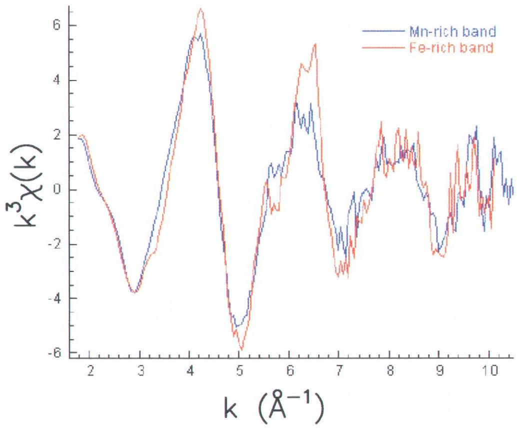
Lab-made reference

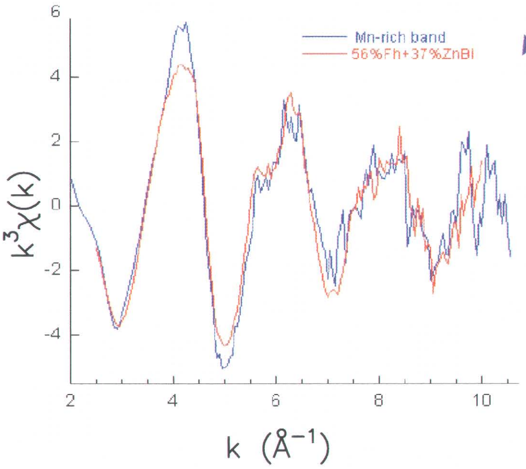
Birnessite, [Zn]/[Mn]=0.008



Tetrahedral and some octahedral Zn, with Mn^{3+}

Zn EXAFS: Japan





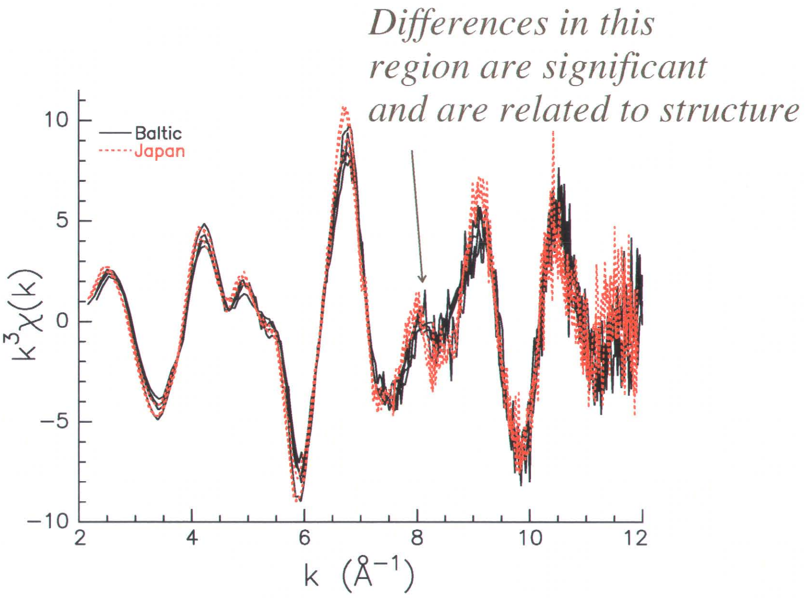
EXAFS differs from place to place, unlike in Baltic nodule.

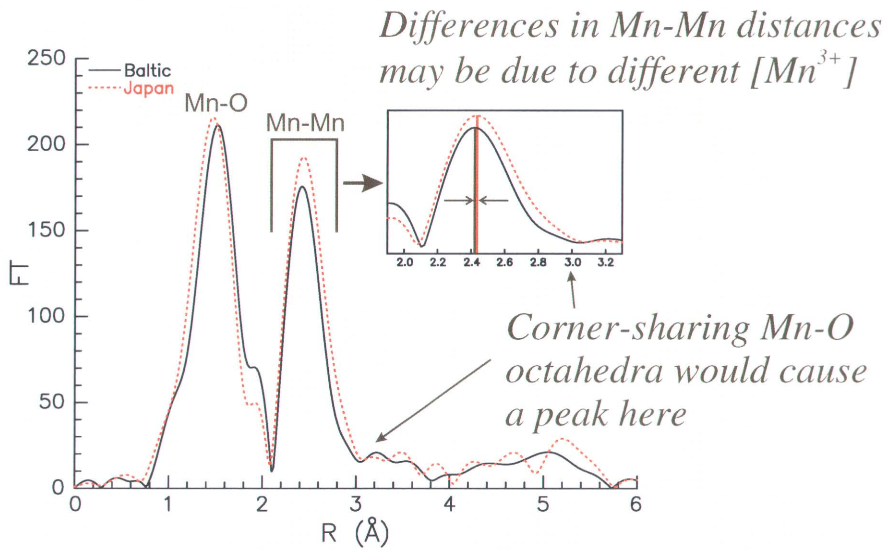
Fit of Mn-rich spot consistent with mixture of Zn-sorbed ferrihydrite (Note: XRD finds 6-line Fh) and Zn-sorbed birnessite (similar to Baltic).

Fit of Fe-rich area not yet clear Possible phosphate component.

Zn in Japanese sample is coordinated to ferrihydrite, birnessite, and at least one other species, in proportions depending on Fe/Mn ratios.

Mn EXAFS
Comparison of Baltic and Japan





Mn EXAFS from the two samples look mostly alike, but with differences. Analysis shows:

Baltic: *Turbostratic (from XRD) birnessite with some Mn^{3+}*

Japan: *Consistent with mixture of birnessite and lithiophorite. Slight Mn-Mn distance expansion suggesting more Mn^{3+} in layer than in Baltic.*

Both: *Uniform over several spots of varying composition.*
