33

1 Microarrays are widely used in many fields of biological and biomedical research as well as
2 in medical diagnostics.^[1-6] For reliable use, the microarrays should be stable, homogeneous
3 and easy to read out, while at the same time, miniaturizing is desired for reduced use of
4 consumables and sample. Recently, we have shown the advantageous properties of
5 nanoporous HEMA-EDMA polymer for the generation of miniaturized microarrays in
6 comparison to conventional spotting substrates.^[7] The microarrays fabricated on the
7 nanoporous HEMA-EDMA polymer could feature smaller spot sizes (at least one order of
8 magnitude less than in typical ink jet printing) while retaining sharper feature edges when
9 compared to other commonly used substrates for spotting as paper, nitrocellulose and nylon
10 membranes. This higher pattern fidelity allows for the reduction of spot size, while still
11 obtaining well-defined features, thus facilitating readout of the arrays and saving materials.
12 However, a substrate with similar properties but functionality for covalent binding of spotted
13 substances would be of great importance to many applications in spotting and sensing,
14 nanostructured surfaces being e.g. used for enhanced capture and detection of bacteria.^[8]
15 Alkyne modification of glass substrates^[9] allowed for the formation of covalently bound
16 microarrays by spotting with molecules functionalized with the azide group.^[10] To combine
17 the favorable properties of the nanoporous polymeric substrates (average pore size 150 nm)^[7]
18 with the covalent binding demonstrated on the glass substrates, we here present an alkyne
19 modification of the porous polymer (alkyne-HEMA-EMDA) allowing for click-chemistry
20 coupling of azides via copper(I)-catalyzed azide-alkyne cycloaddition (CuAAC).^[11-13] This
21 prominent click reaction found many applications, e.g. in the generation of nanosized
22 molecular junctions.^[14] The polymer retains its desirable spotting properties and covalently
23 immobilized high quality microarrays can be generated. The three dimensional impregnation
24 of the polymer with a fluorescently labeled azide is quantified by confocal microscopy and
25 leads to considerably higher spot fluorescence intensities compared to strictly 2-dimensional
26 surfaces as modified glass. Furthermore, the microarrays can be multiplexed and used for

1 binding of proteins, as is demonstrated by selective binding of streptavidin and specific
2 antibody on an allergen array.

3 **Figure 1a** shows the schematic spotting setup as used in the present work. A quill-like
4 microchannel cantilevers, called surface patterning tools (SPTs)^[15] is brought into contact with
5 the alkyne-HEMA-EMDA surface for defined time lengths allowing the imbibition of
6 spotting solution into the polymer. By high precision scanning in x- and y- direction via the
7 stage of a dip-pen nanolithography (DPN) platform (NLP 2000, NanoInk, USA), the spot
8 features of the microarray are generated one after the other. The spotting solution is based on
9 water with admixing of glycerol to prevent drying out. It contains an azide-modified molecule
10 for immobilization, sodium ascorbate and copper sulfate to catalyze the CuAAC reaction. The
11 chemical structure of the used azides is given in Figure 1b for tetramethylrhodamine
12 (TAMRA) azide and Figure 1c for biotin azide, respectively.

13 A typical outcome of a spotting with TAMRA azide is shown in **Figure 2a**. This pattern of
14 100 spots arranged in a square with a pitch of 50 μm (yielding an array area of $500 \times 500 \mu\text{m}^2$)
15 was written with a dwell time of 0.5 s by a single quill-like pen in about one minute.
16 Generally, the spotting procedure can be parallelized by introduction of pen arrays,^[16] yielding
17 even higher throughput with larger areas and additional possibility of intrinsic multiplexing.
18 In our present setup, we realized multiplexing by subsequent writing with tip changing for the
19 different inks, which could principally automated as alternative route to multiplexed arrays.
20 Due to the CuAAC mediated covalent immobilization of desired molecules the pattern
21 becomes highly stable in solution (see Supporting Information, **Figure S1** and **Figure S2**).
22 The average radius of a dot feature in such arrays is $(9.9 \pm 0.5) \mu\text{m}$, a histogram of the radius
23 distribution is given in Figure 2f. To demonstrate the three-dimensional structure of the
24 generated patterns due to imbibition of ink into the three dimensional porous polymer layer,
25 we employed confocal microscopy. A 3D representation of a typical array as obtained from

1 confocal microscopy is shown in Figure 2b with a cross-section through one row of dots
2 shown in Figure 2c. The outlines of the dot features as obtained by a thresholding of
3 fluorescent intensity are added to the section and from this the hemispherical shape of the
4 deposited dot features within the polymer film becomes obvious. To characterize the ink
5 transport process during lithography, dot patterns with varying dwell times were spotted
6 (Figure 2e). The radius of the dot features increases from about 8 μm up to 14 μm with
7 increasing dwell time from 0.1 s to 2.0 s (Figure 2g). For imbibition of a fluid into a porous
8 substrate, theory predicts a dependence on time proportional to $t^{1/3}$.^[17] The spot radius vs.
9 dwell time dependence in our system follows this prediction, deviating only for smaller dwell
10 times especially in the case of 0.1 s (smallest dwell time possible in our setup). This could be
11 an artifact introduced by a combination of the DPN system used contacting the surface some
12 time longer than intended for this small dwell times near the system's limit and the deviation
13 of our SPT (which has an opening at the apex of about 1 μm) from a point source as assumed
14 in the theoretical description. Figure 2d contains a section through one row of the dot array in
15 Figure 2e and shows that also the functionalized volume within the polymer film is dependent
16 on dwell time as expected. With the radius r being proportional to $t^{1/3}$ it is expected that the
17 volume V of functionalized polymer (being a half sphere) should be direct proportional to t .
18 Plotting of the dot feature volume against dwell time (Figure 2h) reveals that our system
19 exhibits a linear dependence on dwell time. Likewise to the radius, even at short dwell time
20 the deposited volume does not reach zero, again reflecting a minimum volume of ink transfer
21 just by touching the surface with a SPT. The volume character of the microarray features
22 leads to a strong increase in fluorescence intensity compared to the strictly 2D nature of the
23 features on glass slides. In the TAMRA-azide spots a 20-fold increase in signal intensity
24 could be observed (**Figure S3**).

1 To demonstrate the capability of the approach for multiplexing and the stability of the
2 microarrays for analyte binding from solution, we created bi-color patterns with alternating
3 TAMRA-azide and biotin-azide spots. This was done by writing TAMRA-azide spots as
4 described above, but leaving each second spot free and then subsequently filling these empty
5 spaces with biotin-azide spots after replacing of the SPT. Biotin can serve as a strong binding
6 motive for streptavidin,^[18] effectively immobilizing the protein onto the biotin-azide
7 functionalized spots in the array (**Figure 3a**). Since the biotin-azide is not fluorescent, only
8 the TAMRA-azide spots are visible in fluorescent images of the array prior to fluorescently
9 labeled streptavidin binding (Figure 3b). After incubation of the microarray with a solution
10 containing fluorescein conjugated streptavidin, the prior invisible biotin-azide spots light up
11 in the green channel of the fluorescent imaging indicating successful and selective binding of
12 the protein.

13 To further elucidate the prospects of the polymer coating based microarrays for sensing and
14 binding of biological relevant proteins, we compared the binding of antibodies to antigen-
15 arrays on glass slides and alkyne-HEMA-EDMA polymer substrates (**Figure 4**). Glass was
16 chosen as comparison for its broad use in similar assays, and to clearly contrast the 3D
17 infused arrays to purely 2D ones (no diffusion in or swelling of substrate). For this
18 experiment, microarrays of dinitrophenol (DNP)-azide were patterned on alkyne modified
19 glass and alkyne-HEMA-EDMA substrates as described above. DNP can act – among other
20 uses^[19] - as a model allergen for the activation of mast cells,^[20-23] here we use it as target for
21 specific antibody binding.^[24,25] After spotting and washing of the samples, solutions with
22 different concentrations of fluorescently labelled anti-DNP antibodies (starting from 10 µg/ml
23 in the highest concentration and then diluted 1:1 by volume with PBS for each following
24 dilution step). Figure 4a shows a typical outcome of such antibody binding to a DNP
25 microarray on an alkyne-HEMA-EDMA sample, showing clearly preferential binding of the

1 antibody to the DNP features of the array. Quantifying the resulting fluorescence signals for
2 the series of antibody dilutions on alkynized HEMA-EDMA and comparison with the analog
3 experiment on glass substrate samples further validates the discussed feature volume effect
4 (Figure 4b): while for low antibody concentrations (0.125 and 0.250 relative antibody
5 concentration) both substrate systems behave similar, the signal on the glass substrate levels
6 off, while on alkyne-HEMA-EDMA substantially higher intensities are found for increasing
7 antibody concentration (0.500 and 1.000 relative concentration). This behavior indicates, that
8 the accessible binding sites (i.e. DNP moieties) on the glass slide are already completely
9 saturated on the glass slide at the 0.250 relative antibody concentration. Therefore, further
10 increase in antibody concentration cannot result in an increased fluorescence signal. On the
11 alkyne-HEMA-EDMA substrate, additional binding sites are available in the bulk volume of
12 the feature, hence enabling further increase in binding and fluorescence intensity on higher
13 relative concentrations.

14 In conclusion, we present a novel platform for the immobilization of azide functionalized
15 compounds and subsequently protein binding. The use of quill-like pens enables the delivery
16 of higher ink volumes than e.g. microcontact printing or similar methods, therefore allowing
17 infiltration into the porous substrate. This gives increased intensity from fluorescent
18 compounds since the whole functionalized volume can contribute to the signal. Additionally,
19 the method allows for multiplexed arrays with different compounds within one array. The
20 micropatterns show high stability under immersion in solvents and can be used for selective
21 binding of proteins as e.g. streptavidin or antibodies. The volume nature of the microarray
22 features on alkyne-HEMA-EDMA substrate allows for additional binding sites when using
23 the arrays as protein targets, resulting in a higher dynamic range of quantifiable
24 concentrations when compared to 2D microarrays on non-porous substrates. While the porous
25 nature of the functionalized volume limits the access by liquid exchange and diffusion speed

1 to this additional sensitive area, the higher dynamic range gained enables testing of a much
2 wider range of target concentrations, allowing easier application of such assays. As the overall
3 size of pores is in the range of 150 nm, this sets an upper limit of target size, though typical
4 protein targets will be not inflicted, as they are much smaller. Overall, these properties make
5 the presented porous polymer film an attractive substrate for microarraying e.g. for bio-
6 medical or environmental testing.

7 **Experimental Section**

8 *Substrate preparation:* The fabrication of alkyne-HEMA-EDMA polymer film was described
9 in our previous work.^[26] Briefly, a 12.5 μm thin, hydrophilic porous polymer film was firstly
10 prepared on a glass substrate using photoinitiated copolymerization of 2-hydroxyethyl
11 methacrylate and ethylene dimethacrylate in the presence of porogens (non-alkynized HEMA-
12 EDMA).^[27] This procedure leads to the formation of a thin film of a highly cross-linked and
13 porous (due to the presence of porogens) polymethacrylate layer. The porous structure is
14 permeable network of interconnected polymer nanoglobules with pores of around 150 nm.
15 The polymer surface was esterified by immersing into a dichloromethane solution containing
16 4-pentynoic acid (22.8 mM), coupling reagent *N,N'*-diisopropylcarbodiimide (22.8 mM), and
17 catalyst 4-(dimethylamino)pyridine (9.2 mM) and stirring at RT for 4 h. A porous HEMA-
18 EDMA layer functionalized with alkyne groups (alkyne-HEMA-EDMA) was produced.

19 *Spotting Setup:* The spotting procedures were done on a NLP 2000 system (NanoInk, USA)
20 equipped with SPT pens (SPT-S-C10S, Bioforce Nanosciences). Prior to use, the SPTs were
21 freshly plasma cleaned by oxygen plasma (10 sccm O₂, 100 mTorr, 30 W for 2 min) and used
22 immediately. The SPT was mounted onto the tip holder by double-sided sticky tape, and the
23 pen reservoir was filled with 1 μL of azide solution. All spotting procedures were
24 implemented at a relative humidity of 60% and with the sample stage tilted by 8° with respect
25 to the SPT tip to minimize the chance of contact between the ink reservoir and the sample

1 surface. For all patterns, except for the pattern used for spot size versus dwell time analysis, a
2 dwell time of 0.5 s was used.

3 *Streptavidin binding*: After the spotting process, the samples were washed extensively with DI
4 water (18.2 M Ω cm) to remove excess ink. Prior to adding the streptavidin solution, samples
5 were blocked with 5% bovine serum albumin (BSA)^[28] (Sigma-Aldrich) in phosphate
6 buffered saline (PBS) (Gibco) for 10 minutes. Subsequently, the samples were washed 3 times
7 by pipetting on and off 100 μ l of PBS (3 times each) and then incubated for 10 minutes with a
8 solution of 5 μ g/ml of streptavidin fluorescein conjugate (Calbiochem/Merck). After repeating
9 the washing steps, samples were imaged with fluorescence microscopy.

10 *Antibody Binding*: Microarrays of DNP-azide were generated on alkyne-HEMA-EMDA and
11 glass substrates (glass substrates alkyne modification was performed as described in the
12 literature)^[9,10] as described above and washed with DI water (18.2 M Ω cm) to remove excess
13 ink. Then, the samples were blocked with 5% BSA (Sigma-Aldrich) in PBS (Gibco) for 10
14 minutes. Subsequently, the samples were washed 3 times by pipetting on and off 100 μ l of
15 PBS (3 times each) and then incubated with different concentrations of mouse anti-DNP
16 antibody previously fluorescently labelled by a Mix-n-Stain CF 488A antibody labelling kit
17 (both Sigma-Aldrich, Germany) for 60 minutes. The highest concentration of antibody was
18 10 μ g/ml and more and more diluted solutions were created by admixing the previous solution
19 1:1 by volume with PBS, resulting in relative concentrations of 0.500, 0.250, and 0.125,
20 respectively, compared to the highest concentration. After incubation, the samples were
21 washed 3 times again and then imaged by fluorescence microscopy.

22 *Imaging setup*: Fluorescent microscopic images were obtained on an Eclipse 80i upright
23 fluorescence microscope (Nikon) equipped with an Intensilight (Nikon) for illumination and a

1 CoolSNAP HQ2 camera (Photometrics). The confocal images were recorded using a Leica
2 TCS SP5 confocal microscope.

3 *Image analysis*: The fluorescent microscopy images used for the determination of size
4 distribution and influence of dwell time were analysed with ImageJ.^[29,30] After converting the
5 images to black and white by a threshold filter, the spot sizes were obtained by particle
6 analyses. Particles smaller than 20 pixels were excluded from analysis to exclude noise-
7 induced artefacts. To determine the functionalized polymer volume from the confocal images,
8 this procedure was applied to each layer of the image stack, the resulting areas multiplied with
9 the thickness of one layer and associated volume slices for each point were summed up.
