and its so-called lookalikes,
with description of *Elianella brasiliiana* n.sp.**

Revision of the Juliette PFENDER Collection. Part 1

Bruno GRANIER¹

Dimas DIAS-BRITO²

Abstract: According to some authors, the three fossil algal forms discussed in this paper, *Cordilites cretus* (REUS, 1846), *Elianella elegans* PFENDER & BASSE, 1948, and *Parachaetetes asvapati* PIA in RAO & PIA, 1936, are synonyms. However, we document that they represent three discrete species. The genus *Elianella* PFENDER & BASSE, 1948, gets unique features that make it easy to discriminate; we describe a new species from Albian limestones of Brazil. The other two genera, *Cordilites* POČTA, 1887, and *Parachaetetes* DENINGER, 1906, share some common features, such as having a thallus made of a lattice-network with columns (filaments) and rows. However, on the basis of their diagnostic criteria, the species *Cordilites cretus* and *Parachaetetes asvapati* should not be confused.

Key Words: Rhodogorgonales; Elianellaceae; Solenoporaceae; *Cordilites*; *Elianella*; *Parachaetetes*.

Citation: GRANIER B. & DIAS-BRITO D. (2016).- On the fossil alga *Elianella elegans* PFENDER & BASSE, 1948, and its so-called lookalikes, with description of *Elianella brasiliiana* n.sp. Revision of the Juliette PFENDER Collection. Part 1.- *Carnets Geol.*, Madrid, vol. 16, no. 6, p. 213-229.

Résumé : À propos de l'algue *Elianella elegans* PFENDER & BASSE, 1948, et ses soi-disants semblables, avec la description de *Elianella brasiliiana* n.sp. Révision de la Collection Juliette PFENDER. 1e partie.- D'après certains auteurs, les trois formes fossiles algaires discutées dans cette publication, *Cordilites cretus* (REUS, 1846), *Elianella elegans* PFENDER & BASSE, 1948, et *Parachaetetes asvapati* PIA in RAO & PIA, 1936, sont synonymes. Nous démontrons cependant qu'elles constituent trois espèces distinctes. Le genre *Elianella* PFENDER & BASSE, 1948, a des caractéristiques uniques qui le rendent facile à identifier. Nous décrivons d'ailleurs une nouvelle espèce provenant de calcaires albiens du Brésil. Les deux autres genres, *Cordilites* POČTA, 1887, et *Parachaetetes* DENINGER, 1906, partagent quelques caractères communs, notamment celui d'avoir un thalle constitué par un réseau de cellules ayant l'aspect d'une grille avec des colonnes (filaments) et des rangées. Toutefois, sur la base de leurs critères diagnostiques, les espèces *Cordilites cretus* et *Parachaetetes asvapati* ne devraient normalement pas être confondues.

Mots-clés : Rhodogorgonales ; Elianellaceae ; Solenoporaceae ; *Cordilites* ; *Elianella* ; *Parachaetetes*.

Introduction

The present paper focuses on *Elianella elegans* PFENDER & BASSE, 1948, and two "lookalikes": *Cordilites cretus* (REUS, 1846), and *Parachaetetes asvapati* PIA in RAO & PIA, 1936. Paleophycologists, *i.e.*, those people assuming they were dealing with fossil algae, and other paleontologists, *i.e.*, those considering they were dealing with Cnidaria or Porifera, have treated these three taxa either as individual species (*e.g.*, POIGNANT & AMAUDRIC du CHAFFAUT, 1970) or as synonyms. In the latest case they have treated either the three of them or only a pair as synonyms. For instance, regarding *Eli-*

nella elegans and *Cordilites cretus*, POIGNANT (1980a) stated that "il s'agit en fait de la même forme" [as a matter of fact it is the same form]; the same year, POIGNANT (1980b) again concluded that "ces trois formes sont synonymes" [these three forms are synonymous]. According to MOUSSAVIAN (1989) and STOCKAR (2000), *Elianella elegans* is "a younger synonym of *Parachaetetes asvapati*". However, in our opinion, they represent three discrete species that have often been misidentified. For instance, the *Elianella elegans* reported by DELOFFRE (1967) from the Danian interval in the SNPA exploration well Bastennes-Lonné I (FB1, Aquitaine, SW France) is a genuine *Parachaetetes* DENINGER, 1906 (cf.

Parachaetetes asvapati), as documented hereafter. We report and illustrate below the main features of these three species in order to prevent them being confused again in the future.

Material studied

Ideally, this kind study would have required access to all the type materials, which was not feasible in the present case. However, the material studied here comprises thin sections from several researchers' collections: PFENDER (topotypic material), JOHNSON, and EMBERGER – DELOFFRE, as well as Brazilian material collected more recently, which display well-preserved specimens documenting diagnostic features.

Considering *Elianella elegans* PFENDER & BASSE, 1948, the first author (B.G.) found only one thin section in the Juliette PFENDER Collection (Fig. 1.A). It is not one of the thin sections with the specimens originally illustrated by the authors (PFENDER & BASSE, 1948, PI. XII, figs. 1-3), because this set is probably lost, but this thin section is marked "37 EB16", "NW de Lohaosy" (Ampanihy, Toliary), and "Calc. à Algues", i.e., it is a topotypic material from the Paleocene of S Madagascar. This specimen (Fig. 1.B) is selected here as the neotype.

While investigating the JOHNSON Collection at the Smithsonian National Museum of Natural History, the first author identified within a small set of thin sections nice specimens of *Cordilites cretus* (REUS, 1846) in one thin section marked D619-a-629 and bearing "Puerto Rico" as geographical label. The remaining thin sections yield "mid" Cretaceous (=Aptian-Cenomanian) foraminifera, i.e., undetermined orbitolinids.

The material from the DELOFFRE Collection was combined with that of the EMBERGER Collection as both consist of 27 thin sections of similar origin (core samples from the intervals 222.36-233.75 with a BGh1 label and 223.03-233.53 with a Bastennes 1 label, Danian in age, and both from the SNPA exploration well Bastennes-Lonné I - FB1, Aquitaine, SW France).

Most of the studied Brazilian Albian-Cenomanian material is registered in the collection of the "UNESPetro - Centro de Geociências Aplicadas ao Petróleo, UNESP - Universidade Estadual Paulista, Rio Claro" (São Paulo, Brazil); another part, consisting of a limited number of thin sections, is deposited with LPB ("Laboratoire de Paléontologie de Brest") numbers in the collections of the "Département des Sciences de la Terre et de l'Univers, Université de Bretagne Occidentale, Brest" (France).

Figure 1: A) Scan of the thin section marked "37 EB16", "NW de Lohaosy", and "Calc. à Algues", Juliette PFENDER Collection; B) photomicrograph of the neotype; C) detail with longitudinal sections of filaments. [B scale bar 5 mm ; C scale bar 500 µm]

Taxonomic affinities

The three forms studied were formerly ascribed to the Family Solenoporaceae PIA, 1927, a group of extinct "calcareous algae", because they share some morphological features: A) they are either encrusting or forming free structures; B) their framework is made of erected filaments, more or less densely juxtaposed, with common to rare horizontal partitions (i.e., they are pluricellular algae), defining a more or less preserved lattice-network with columns and rows; C) their mineralization is intracellular, centripetal (starting from the cell walls inwards), and consists of elongated fibrous calcite (probably high-Mg calcite) crystals, another feature that justifies their ascription to the red algae. However, D) reproductive organs (possibly external) are unknown contrary to the records in its sister families, e.g., Hapalidiaceae GRAY, Sporolithaceae VERHEIJ or Graticulaceae RIDING & BROOKE.

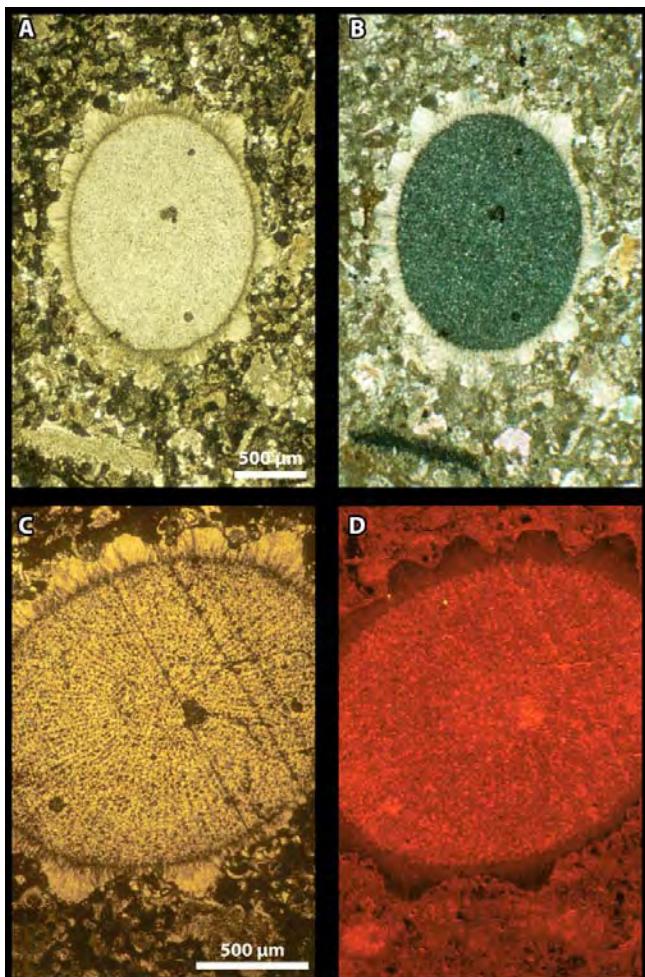

Figure 2: Section of a Cidaroida spine. A & C) conventional transmitted light/plane polarized light (C is an enlargement of A); B) cross polarized light; D) cathodoluminescence. The view under cross nicols (B) illustrates the spine core with a single-crystal behaviour (dark) and its fibrous rim with a radial behaviour (as documented by a faint extinction cross). Under cathodoluminescence, the crests forming the rim record various shades of colour suggesting that they grew slowly enough to record slight changes in the chemical composition of the spine calcite. Sample A10-3660, Paleocene, Libya. Similar material was illustrated by MIŠÍK (1966, Pl. LXXXIII, fig. b) and SAMUEL *et al.* (1972, Pl. CLI, figs. 1-2). [A-B scale bar 500 µm ; C-D scale bar 500 µm]

After having reviewed earlier records of suspected reproductive structures in the Family Solenoporaceae and concluding that there were none, AGUIRRE and BARATTOLO (2001) describe structures that they interpret as "nemathecia" on a *Parachaetetes asvapati* PIA in RAO & PIA, 1936. Unfortunately, this unique specimen proves to be a Cidaroida spine. The stereom of the echinoid spine was misinterpreted as the algal structure and the longitudinal crests forming the ornamentation of the spine were misinterpreted as nemathecia (GRANIER *et al.*, 2009): see Fig. 2, for example.

Last but not least, RIDING (2004) demonstrated that the type of the genus *Solenopora*, *S. spongiodes* DYBOWSKI, 1877, is actually "a chaetetid sponge, not an alga". The first author (B.G.) introduces hereafter the Family Elianellaceae nov. fam. in replacement of the Family Solenoporaceae because, further to RIDING's (2004) report, the type of the latter is currently ascribed to the Animal Kingdom. This new family is tentatively assigned to the Order Rhodogorgonales FREDERICQ & NORRIS, 1995, a sister group to the Sporolithales, which to date includes few living representatives with two genera only arranged into one family, the Rhodogorgonaceae FREDERICQ & NORRIS, 1995.

Systematics

Preliminary remark: The "synonymy lists" below are not as comprehensive as one could expect. The main difficulty stands in the magnification of the original photomicrographs that is often insufficient to allow discrimination of *Elianella elegans* from *Parachaetetes asvapati*, for instance. Actually, in such photomicrographs, it is easier to say which one is not displaying diagnostic features rather than to accurately identify a species. Another issue is that the type-material of *Parachaetetes asvapati* might be composite, consisting of pieces of both *Parachaetetes* and ? *Elianella*. Both taxa are partly coeval and share the same living environment: for instance, in our Albian Brazilian material, representatives of *Elianella* and *Parachaetetes* are commonly found together. Largely for this reason, our standard for *Parachaetetes asvapati* will be limited to the sole photomicrograph referred to as representing the "type-specimen" by its author (PIA in RAO & PIA, 1936: Pl. III, fig. 3), which illustrates a genuine representative of the genus *Parachaetetes* (DENINGER, 1906), but it will not comprise any of the accompanying figures (PIA in RAO & PIA, 1936: Figs. 35-38; Pl. III, figs. 1-2 & 4-5).

Neotype (defined here): Fig. 1.B, details in Fig. 1.C ; Pl. 1, figs. A-F. Thin section "37 EB16", "NW de Lohaosy", "Calc. à Algues", Juliette PFENDER Collection; Paleocene; S Madagascar.

Original description (BASSE (†) in PFENDER & BASSE, 1948, p. 275-276): "À l'extérieur, dans la roche, *Elianella* se montre sous forme de ta-

ches claires, jaunâtres, d'aspect porcelané, sur lesquelles la structure est généralement indiscernable macroscopiquement.

Il s'agit de thalles arrondis ou lobés, composés de files cellulaires, juxtaposées plus ou moins étroitement suivant les points, et qui, au lieu de présenter des parois rectilignes, sont moniliiformes ; ce sont comme de petits tonnelets disposés bout à bout, les cloisons sont très arquées, en forme de verre de montre. Elles peuvent arriver, suivant l'orientation de la coupe, à se montrer superposées comme une pile d'écuelles ; elles sont disposées sans ordre, et non pas linéairement. Cependant, lorsqu'un thalle, qui débute toujours avec un contour circulaire, arrive à former une sorte de rameau ou de digitation, les tonnelets s'allongent, dans l'axe de la poussée, et tendent à se disposer en rangées concentriques. On voit parfois subsister ces lignes d'accroissement du thalle, alors même que tout le tissu a été détruit par cristallisation, au cours de la fossilisation. En section longitudinale, les tonnelets ont 45 µ de large, avec 50 à 60 µ de long ; ils atteignent toutefois 100 x 50 µ sur le rachis (axe des digitations). La section transversale des filaments est arrondie et devient polygonale quand ils sont plus serrés. Parfois on voit les sections rondes des tubes paraître en sombre au centre d'hexagones hyalins, quand la cristallisation envahit les parois."

"From outside, in the rocks, *Elianella* shows up as bright spots, yellowish, porcelain-like, on which the structure is usually macroscopically invisible.

It forms rounded or lobed thalli, consisting of lines of cells, more or less closely juxtaposed depending on the area, and that, instead of having rectilinear walls, are moniliiform; they look like small drums placed end-to-end, the cross partitions are highly-arched, with a watchglass shape. Depending on the angle of the section they may look stacked like a pile of bowls; they are arranged without order, non-linearly. However, because a thallus, which always begins with a circular outline, comes to form some sort of branch or digitation, the drums get longer along the growth axis and tend to form a set of concentric rows. Sometimes such growth lines of the thallus remain visible, even though the tissue has been destroyed by crystallization in the course of the fossilization process. In longitudinal sections, the drums are 45 µm wide and 50 to 60 µm long; however they reach 100 x 50 µm in the rachis (digitation axis). Transverse sections of the filaments are round-shaped, becoming polygonal-shaped as they tighten. Sometimes, when crystallization invades the walls, the rounded sections of the tubes appear as dark spots at the center of hyaline hexagons."]

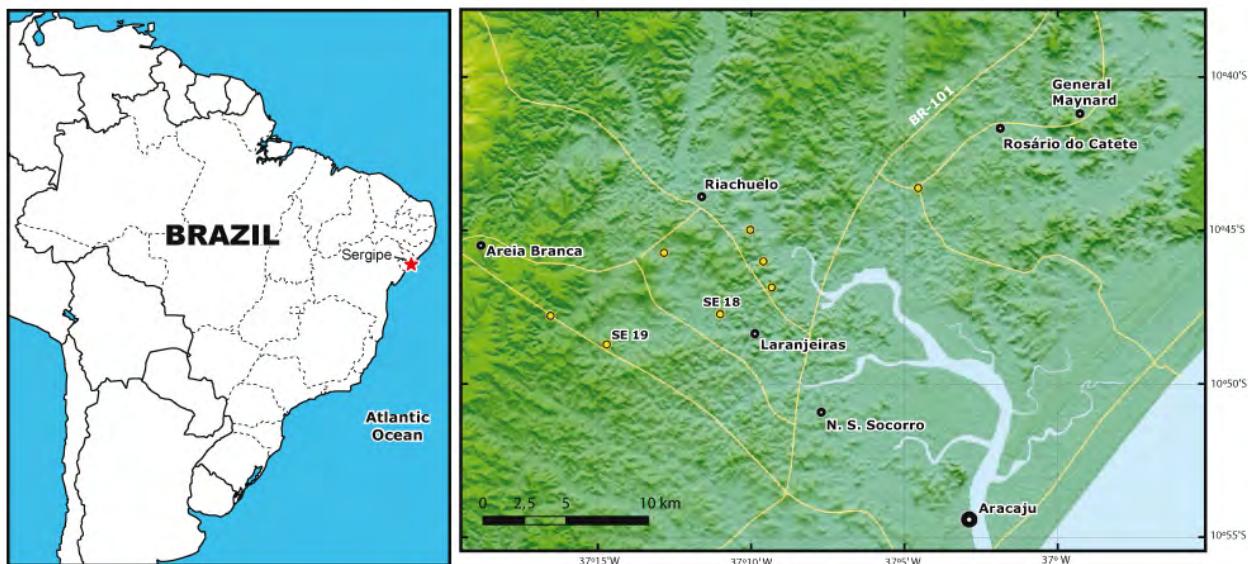

Figure 3: *Elianella brasiliiana* collection localities in the Sergipe Basin, Brazil. SE18 = 2.5 km NW of Laranjeiras; SE19 = 9 km W of Laranjeiras and 10 km SE of Areia Branca; both localities NW of Aracaju, State of Sergipe, Brazil.

Additional remarks: A key diagnostic feature, *i.e.*, the round outline of the transverse sections of the erected filaments, is directly correlated to the loose arrangement of the filaments. Cells may vary in length (and growth rates may have varied accordingly) within a single filament or from one filament to the neighbouring ones; filaments grew independently from each other.

Elianella brasiliiana n.sp.

(Pl. 2, figs. B-C, E & G)

2015 *Elianella* sp.- GRANIER, p. 527, Pl. 7

Holotype: Pl. 2, fig. B, detail in Pl. 2, fig. C (longitudinal section); paratype: Pl. 2, fig. G (transverse section). Thin section UPAFSE 049a.

Locus typicus (Fig. 3): locality SE18 (latitude: $10^{\circ}47'44.017''S$; longitude: $37^{\circ}11'0.290''W$), 2.5 km NW of Laranjeiras, some 20 km NW of Aracaju (Sergipe, Brazil). It is also present in SE19 (latitude: $10^{\circ}48'43.033''S$; longitude: $37^{\circ}14'42.330''W$), 9 km W of Laranjeiras and 10 km SE of Areia Branca, some 25 km NW of Aracaju.

Stratum typicum: Lower part of the Riachuelo Formation, Albian.

Description: It is a typical *Elianella* with rather large diameter filaments (100 μm in average, up to 150 μm , twice those of *E. elegans*) and cell lengths of 40 μm in average (and up to 160 μm). The filaments are separated and the open space between them was later filled by a hyaline calcitic drusy cement. As for the type-species, the transverse cell-walls are upward-concave (downward-convex) and the files of cells may branch dichotomously. Both features can be used to identify the thallus growth direction.

Paleophycological association: The limestones studied are either algal framestones or algal floatstones with grainstone matrices, resulting from the breakage and erosion of former framestones. This new species is found there is associated with *Elianella elegans* PFENDER & BASSE, 1948, *Lithothamnion* sp., *Parachaetetes* cf. *tornquisti* (DENINGER, 1906), *Pycnoporidium sinuosum* JOHNSON & KONISHI, 1960, *Marinella lugeoni* PFENDER, 1939, the problematic *Bacinella*, and *Neomeris cretacea* STEINMANN, 1899.

Genus *Parachaetetes* (DENINGER, 1906)

Type: *Parachaetetes tornquisti* (DENINGER, 1906), p. 65-66, Pl. VI, fig. 6.

- ? 2005 *Parachaetetes asvapatii*.- BUČEK & KÖHLER, p. 305, Pl. II, figs. 1-2

Description: The definition that follows is an excerpt from PIA (in RAO & PIA, 1936, p. 34):

"*Parachaetetes asvapatii* builds small calcareous nodules measuring a few millimetres only, composed of several more or less broad and blunt lobes. The tissue is fairly well differentiated into a hypothallium and a perithallium. The latter shows in longitudinal sections a "lattice-work" formed by the transverse cell-walls (situated at identical height in adjoining cell-rows) and by the longitudinal ones. The cells measure 0.04 to 0.06 mm. across and are one to three times as long as broad.

Type-specimen – G.S.I. Type Number 15,769 and Plate III, fig. 3."

Additional remarks: The specimens found in the DELOFFRE - EMBERGER Collections show "transverse cell-walls" (...) "situated at identical height in adjoining cell-rows", which ascribes them to a genuine representative of the genus *Parachaetetes* (DENINGER, 1906). In longitudinal section, the side-walls of the cells were either poorly calcified or may have suffered some dissolution; consequently, the rows of the alga "lattice-work" are commonly better expressed than the columns. In transverse section, the thalli of these *Parachaetetes cf. asvapatii* show wavy concentric zones identical to those observed in the generotype, *P. tornquisti* (DENINGER, 1906: Pl. VI, fig. 6a; PETERHANS, 1929: Pl. IV, fig. 1).

Genus *Cordilites* PočTA, 1887

Type: *Chaetites cretosus*.- REUSS, 1846, p. 63, Pl. XLIII = VIIIL, fig. 4.a-d.

Description: The description that follows is an excerpt from YABE (1912, p. 6-7), the first author to treat this fossil as an alga under "*Petrophyton miyakoense* gen. et sp. nov.":

"Die manchmal 12 cm. erreichenden Knollen zeichnen sich durch die auf der frischen Bruchfläche deutlich hervortretenden Radialfasern aus, welche gegen die konzentrischen Schichten weit hervortreten; auf der verwitterten Oberfläche aber ist dieses Verhältnis ganz umgekehrt. Die meisten mir vorliegenden Exemplare sind abgerundet und deshalb ist die Gestalt der vollständigen Stöcke sowie die Anfangsstelle ihres Wachstums nicht leicht zu erkennen. Es scheint mir aber höchst wahrscheinlich dass die Stöcke welche mehr oder weniger birnförmig sind, gewöhnlich zu einer grösseren Masse mit der nierenförmigen Oberfläche, zusammenwachsen. (Textfig. 4, a-c).

Die Stöcke sind aus feinen, im Durchschnitt 0.04 mm. breiten, prismatischen, dicht aneinander liegenden Zellröhren von wesentlich gleichartiger Beschaffenheit zusammengesetzt. Die Zellröhrenwände sind doppelt und nicht einfach bei der vorhergehenden Art. Da ist eine Medianlamelle, welche erst bei starker Vergrösserung als wirklich vorhanden wahrnehmbar ist; sie ist gleichmässig sehr dünn und scheinbar undurchbohrt. An beiden Seiten dieser Lamelle findet immer eine Verdickung statt, welche in bestimmten Abständen sehr regelmässig sich verengen und sich dann wieder verbreitep. Die erstere Kalkschichte scheint ein Absatz ausserhalb der Zellmembran zu sein, während die zweite eine innerhalb der Zellmembran stattgefundene Verkalkung repräsentiert. Die Querböden sind zahlreich, aber sehr schwach entwickelt; sie sind etwas nach

oben concav und finden sich gewöhnlich dort, wo die Wandverdickung beinahe ganz verschwunden ist. Zumeist treten sie in einem Abstand von 0.055 bis 0.035 mm. nicht selten aber auch ganz dicht aufeinander auf (Fig. 2). In den gesammten Zellröhren erscheinen sie in derselben Höhe und infolgedessen bilden sich die zahlreichen concentrischen Schichten welche wie oben gesagt, auf den ausgewitterten Bruchflächen deutlich sichtbar werden. Es kommt auch bei dieser Form die Diskordanzlagerung der neuen Zellröhrenreihen auf den alten vor, gerade so wie bei *Lithothamnium*, *Solenopora* und *Metasolenopora* (Fig. 2).

Die Vermehrung der Zellröhren findet statt: erstens durch die Einschaltung neuer Zellen an der Ecke, wo drei oder vier Röhren zusammenstoßen, und zweitens durch die Teilung, welche ihre Entstehung der neuen Bildung einer Wand in der Mitte eines Rohres verdankt.

Die sehr feinen Zellröhren dieser Form schliessen ihre Zugehörigkeit zu einer Bryozoen- oder Tabulaten-Gattung aus, obwohl die Verdickung der Wände stark an *Stenopora* erinnert. Ueberhaupt wird die Stock einem Kalkgebilde von einem Tier nicht angehören; vielmehr scheint ihr gesammter Habitus sowie Struktur den Kalkalgen wie *Lithothamnium* und *Solenopora* sich näher anzuschliessen. Die Wandverdickung ausgenommen, stimmt die Wandstruktur unserer Form mit der von *Solenopora* besonders gut überein; bei beiden sind die Zellröhren langgestreckt und prismatisch, und mit schwach entwickelten Querböden versehen; sie sind auch gerade so breit bei unserer Form wie bei *Solenoporella jurassica* und *Metasolenopora Rothpletzi*.

Da diese Form einen ganz neuen Kalkalgentypus zu representieren scheint, werde ich diese *Petrophyton* nennen."

[The tubers are as large as 12 cm in size. On the freshly broken surface clearly visible radial fibers stand out against concentric layers. On the weathered surface this shape is reversed. Most of the samples available to me are rounded. Therefore, the shape of the original samples as well as the initial place of their growth cannot be easily discerned. However, I conclude that the original specimens were probably pear-shaped fused into a larger mass with a kidney-shaped surface (text-fig. 4, a-c).]

The samples are composed of fine, 0.04 mm diameter, prismatic, tightly packed homogenous cellular tubes. The walls of the tubes are double compared to the single ones in the previous species. A median lamella can be observed only at high magnification because it

is very thin throughout; it is apparently continuously without holes. A thickening on both sides of the lamella gets alternately narrower and wider in certain distances. The first layer of lime seems to be deposited outside the cell membrane while the second layer of calcification has been deposited inside. The numerous cross walls are very thin; they are sometimes upwardly concave and are usually located where the wall is thinnest. Most frequently they appear at a distance of 0.055 to 0.035 mm, but usually not close to each other (Fig. 2). They are observed at the same level in the cell tubes, and because of this the numerous concentric layers are clearly recognizable on the weathered surfaces, as mentioned above. As in *Lithothamnium*, *Solenopora* and *Metasolenopora* there is also in this sample unequal disposition of the new rows of cell tubes upon the old ones (Fig. 2).

Reproduction of the cell tubes occurs: first by insertion of new cells at the junction where three or four tubes meet, and then followed by division to form a wall in the middle of a tube.

The very fine cell tubes of this specimen exclude it being *Bryozoa* or *Tabulata* although the thickening of the walls is characteristic of the genus *Stenopora*. In any case, the sample is different from the calcified construction of an animal; the basic habit and the structure are similar to calcareous algae such as *Lithothamnium* and *Solenopora*. Except for the wall structure, our specimen corresponds especially well to the genus *Solenopora*; both have long, prismatic cell tubes and are supported by thin cross walls. Also they have exactly the same width as those in *Solenoporella jurassica* and *Metasolenopora Rothpletzi*.

Since the specimen seems to represent a completely new type of calcareous algae I will name it *Petrophyton*. [translated from the German by Sigrid BERGER]

Additional remarks: The thallus pattern is similar to that of a genuine *Parachaetetes*, except for the thicker calcification. In addition, "septal projection" sensu RIDING (2004) or incomplete walls (Pl. 4, figs. B-D) are more common than in *Elianella elegans*.

Comparisons (Fig. 5)

Thalli of *Cordilites cretosus* and *Parachaetetes asvapati*, as the peripheral parts of the vegetative thalli of both the Sporolithaceae and the Haplidiaceae, display a lattice-pattern defined by columns made of files of cells and rows resulting from the concurrent growth of these cells in adjacent filaments.

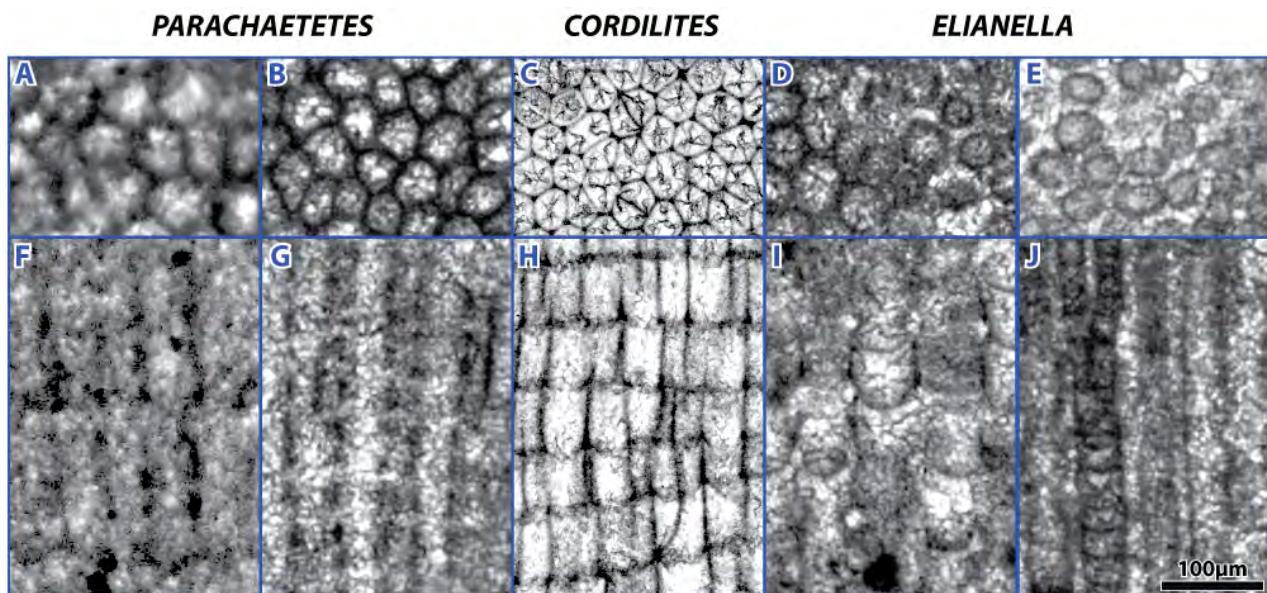

Figure 5: A-E) transverse sections, F-J) longitudinal sections. A & F) *Parachaetetes* cf. *asvapati* PIA in RAO & PIA, 1936, Paleocene, SW France; B & G) *Parachaetetes* cf. *tornquisti* (DENINGER, 1906), "Middle" Cretaceous, Brazil; C & H) *Cordilites cretosus* (REUS, 1846), "Middle" Cretaceous, Puerto Rico; D) densely packed filaments of *Elianella elegans* PFENDER & BASSE, 1948, "Middle" Cretaceous, Brazil; E) loosely arranged filaments of *Elianella elegans* PFENDER & BASSE, 1948, "Middle" Cretaceous, Brazil; I) densely packed filaments of *Elianella brasiliiana* n.sp., "Middle" Cretaceous, Brazil; J) loosely arranged filaments of *Elianella brasiliiana* n.sp., "Middle" Cretaceous, Brazil. [All photos with 100 µm scale bar]

In transverse section, the thallus of *Parachaetetes tornquisti* displays wavy concentric zones (DENINGER, 1906: Pl. VI, fig. 6a; PETERHANS, 1929: Pl. IV, fig. 1). A darker band corresponds to random cuts of cells at or near the junction of two successive rows and the next lighter bands to random cuts of cells above and below the junction, in the median part of the upper or lower rows. Similar features are also documented in our *Parachaetetes* cf. *asvapati*, as well as in *Cordilites cretosus* and in *Elianella elegans* (in *Elianella*, the zoning is related to changes in the width and density of the cells). Transverse partitions in our *Parachaetetes* cf. *asvapati* are commonly upward-concave, as it is the case for many Elianellaceae (see *Solenoporella jurassica* (BROWN, 1894) documented by HARLAND & TORRENS, 1982, for instance); accordingly, this feature is not exclusive of *Elianella elegans*.

In longitudinal sections, the side walls of the cells in *Cordilites cretosus* are heavily calcified. On the opposite, secondary pit connections, i.e., connections of the cells of adjacent filaments, or diagenetic alteration of their side walls are commonly observed in our *Parachaetetes* cf. *asvapati*.

Transverse and longitudinal sections of *Cordilites cretosus* show the common occurrence of "septal projection" sensu RIDING (2004) or incomplete walls, tending to split individual cells longitudinally (Pl. 4, figs. B-D). We could not observe any "septal projection" in our *Parachaetetes* cf. *asvapati* (but there are possibly some in *Elianella elegans* at the level of fila-

ment dichotomous branchings: Pl. 2, fig. I).

In contrast, the pattern of the thallus of *Elianella elegans* is unique. As already stated by its authors (PFENDER & BASSE, 1948), the filaments of *Elianella elegans* are moniliform, whereas those of *Cordilites cretosus* and those of our *Parachaetetes* cf. *asvapati*, when they are well preserved, look like straight-sided polygonal tubes. In addition, most of the time the files of cells of *Elianella* are not adjacent and consequently their transverse sections are commonly (but not always) rounded. Filaments of the new species, *E. brasiliiana* n.sp., are much thicker with a diameter double that of the type-species, *E. elegans*. Because cells belonging to close-set filaments and located at the same level do rarely or never share any side wall in both species, and because their thicknesses/lengths significantly vary, their growths were not necessarily simultaneous and the growth rates of neighbouring filaments might have varied too. A filament grew independently from its neighbouring ones. As a consequence, even if the column pattern is still visible in *Elianella*, a row pattern may be detected only on some occasions.

Conclusions

RIDING (2004) pointed out the need for a "comprehensive review" of the artificial group labelled "Solenoporaceae". Our study, which focuses on some Cretaceous and Paleocene algal forms, represents just one more step toward a better knowledge of these fossil organisms ascribed to the Family Elianellaceae nov. fam.

and including *Marinella* PFENDER, 1939 (GRANIER & DIAS-BRITO, 2016) and *Pycnoporidium* YABE & TOYAMA, 1928, among other forms. We demonstrate that the three forms considered in this paper, *Cordilites cretosus* (REUS, 1846), *Elianella elegans* PFENDER & BASSE, 1948, and *Parachaetetes* cf. *asvapatii* PIA in RAO & PIA, 1936, correspond to three discrete species (Fig. 5). The genera *Cordilites* and *Parachaetetes* share some architectural patterns with distinct columns and rows whereas rows are present only on rare occasions in the genus *Elianella*, which gives it its unique structure.

Acknowledgments

In 2015, the first author (B.G.) was the laureate of a Franco-Brazilian professorship at the UNESPetro in Rio Claro (São Paulo State, Brazil) that enabled him to work on Brazilian material. Earlier, in 2012, he also benefited from a Smithsonian Fellowship allowing him to investigate the J. Harlan JOHNSON Collection stored in the premises of the Smithsonian Institution. He would like to thank the staff of the Department of Paleobiology at the Smithsonian National Museum of Natural History, particularly William A. DiMICHELE and Jonathan G. WINGERATH for their hospitality and having facilitated his work there. He is also grateful for the support provided by the successive curators of paleontological collections at the Université Pierre et Marie CURIE, first Jean-Pierre BELLIER, then Isabelle ROUGET. Special thanks go to Sigrid BERGER who kindly translated the original German text on *Petrophyton miyakoense* by YABE (1912). Phil SALVADOR helped polishing the English text. This research is associated with the "Carbonatos do Brasil Project" linked to the Brazilian Sedimentology/Stratigraphy Net sponsored by Petrobras; it was also partly sponsored by the Foundation "Carnets de Géologie".
