Abstract

We show that every heptagon is a section of a 3-polytope with 6 vertices. This implies that every n -gon with $n \geq 7$ can be obtained as a section of a $(2 + \lfloor \frac{n}{7} \rfloor)$ -dimensional polytope with at most $\lceil \frac{6n}{7} \rceil$ vertices; and provides a geometric proof of the fact that every nonnegative $n \times m$ matrix of rank 3 has nonnegative rank not larger than $\lceil \frac{6 \min(n,m)}{7} \rceil$. This result has been independently proved, algebraically, by Shitov (J. Combin. Theory Ser. A 122, 2014).

Keywords: polygon; polytope projections and sections; extension complexity; non-negative rank; nonrealizability; pseudo-line arrangements

1 Introduction

Let P be a (convex) polytope. An *extension* of P is any polytope Q such that P is the image of Q under a linear projection; the *extension complexity* of P , denoted $\text{xc}(P)$, is the minimal number of facets of an extension of P . This concept is relevant in combinatorial optimization because if a polytope has low extension complexity, then it is possible to use an extension with few facets to efficiently optimize a linear functional over it.

A *section* of a polytope is its intersection with an affine subspace. We will work with the polar formulation of the problem above, which asks for the minimal number of vertices of a polytope Q that has P as a section. If we call this quantity the *intersection complexity* of P , $\text{ic}(P)$, then by definition it holds that $\text{ic}(P) = \text{xc}(P^\circ)$, where P° is the polar dual

of P . However, extension complexity is preserved under polarity (see [4, Proposition 2.8]), so these four quantities actually coincide:

$$\text{ic}(P) = \text{xc}(P^\circ) = \text{xc}(P) = \text{ic}(P^\circ).$$

Despite the increasing amount of attention that this topic has received recently (see [3], [4], [5], [8] and references therein), it is still far from being well understood. For example, even the possible range of values of the intersection complexity of an n -gon is still unknown. Obviously, every n -gon has intersection complexity at most n , and for those with $n \leq 5$ it is indeed exactly n . It is not hard to check that hexagons can have complexity 5 or 6 (cf. [4, Example 3.4]) and, as we show in Proposition 4, it is easy to decide which is the exact value.

By proving that a certain pseudo-line arrangement is not stretchable, we show that every heptagon is a section of a 3-polytope with no more than 6 vertices. This reveals the geometry behind a result found independently by Shitov in [8], and allows us to settle the intersection complexity of heptagons.

Theorem 22. Every heptagon has intersection complexity 6.

In general, the minimal intersection complexity of an n -gon is $\theta(\log n)$, which is attained by regular n -gons [2][3]. On the other hand, there exist n -gons whose intersection complexity is at least $\sqrt{2n}$ [3]. As a consequence of Theorem 22 we automatically get upper bounds for the complexity of arbitrary n -gons.

Theorem 26. Any n -gon with $n \geq 7$ is a section of a $(2 + \lfloor \frac{n}{7} \rfloor)$ -dimensional polytope with at most $\lceil \frac{6n}{7} \rceil$ vertices. In particular, $\text{ic}(P) \leq \lceil \frac{6n}{7} \rceil$.

Of course, this is just a first step towards understanding the intersection complexity of polygons. By counting degrees of freedom, it is conceivable that every n -gon could be represented as a section of an $O(\sqrt{n})$ -dimensional polytope with $O(\sqrt{n})$ vertices. For sections of 3-polytopes, our result only shows that every n -gon is a section of a 3-polytope with not more than $n - 1$ vertices, whereas we could expect an order of $\frac{2}{3}n$ vertices.

There is an alternative formulation of these results. The *nonnegative rank* of a nonnegative $n \times m$ matrix M , denoted $\text{rank}_+(M)$, is the minimal number r such that there exists an $n \times r$ nonnegative matrix R and an $r \times m$ nonnegative matrix S such that $M = RS$. A classical result of Yannakakis [10] states that the intersection complexity of a polytope coincides with the nonnegative rank of its slack matrix. In this setting, it is not hard to deduce the following theorem from Theorem 26 (it is easy to deal with matrices of rank 3 that are not slack matrices).

Theorem 1 ([8, Theorem 3.2]). *Let M be a nonnegative $n \times m$ matrix of rank 3. Then $\text{rank}_+(M) \leq \lceil \frac{6 \min(n,m)}{7} \rceil$.*

This disproved a conjecture of Beasley and Laffey (originally stated in [1, Conjecture 3.2] in a more general setting), who asked if for any $n \geq 3$ there is an $n \times n$ nonnegative matrix M of rank 3 with $\text{rank}_+(M) = n$. While this paper was under review, Shitov improved Theorem 26 and provided a sublinear upper bound for the intersection/extension complexity of n -gons [9].

1.1 Notation

We assume throughout that the vertices $\{p_i \mid i \in \mathbb{Z}/n\mathbb{Z}\}$ of every n -gon P are cyclically clockwise labeled, i.e., the edges of P are $\text{conv}\{p_i, p_{i+1}\}$ for $i \in \mathbb{Z}/n\mathbb{Z}$ and the triangles (p_{i+2}, p_{i+1}, p_i) are positively oriented for $i \in \mathbb{Z}/n\mathbb{Z}$.

We regard the p_i as points of the Euclidean plane \mathbb{E}^2 , embedded in the real projective plane \mathbb{P}^2 as $\mathbb{E}^2 = \{(x, y, 1)^\top \mid x, y \in \mathbb{R}\}$. For any pair of points $p, q \in \mathbb{E}^2$, we denote by $\ell_{p,q} = p \wedge q$ the line joining them. It is well known that $\ell_{p,q}$ can be identified with the point $\ell_{p,q} = p \times q$ in the dual space $(\mathbb{P}^2)^*$, where

$$p \times q = \left(\begin{vmatrix} p_2 & p_3 \\ q_2 & q_3 \end{vmatrix}, - \begin{vmatrix} p_1 & p_3 \\ q_1 & q_3 \end{vmatrix}, \begin{vmatrix} p_1 & p_2 \\ q_1 & q_2 \end{vmatrix} \right)^\top$$

denotes the cross-product in Euclidean 3-space. Similarly, the meet $\ell_1 \vee \ell_2$ of two lines $\ell_1, \ell_2 \in (\mathbb{P}^2)^*$ is their intersection point in \mathbb{P}^2 , which has coordinates $\ell_1 \times \ell_2$.

2 The intersection complexity of hexagons

As an introduction for the techniques that we use later with heptagons, we study the intersection complexity of hexagons. Hexagons can have intersection complexity either 5 or 6 [4, Example 3.4]. In this section we provide a geometric condition to decide among the two values. This section is mostly independent from the next two, and the reader can safely skip it.

First, we introduce a lower bound for the 3-dimensional intersection complexity of n -gons that we will use later.

Proposition 2. *No n -gon can be obtained as a section of a 3-polytope with less than $\lceil \frac{n+4}{2} \rceil$ vertices.*

Proof. Let Q be a 3-polytope with m vertices such that its intersection with the plane H coincides with P , and let k be the number of vertices of Q that lie on H .

By Euler's formula, the number of edges of Q is at most $3m - 6$, of which at least $3k$ have an endpoint on H . Moreover, the subgraphs G^+ and G^- consisting of edges of Q lying in the open halfspaces H^+ and H^- are both connected. Indeed, if $H = \{x \mid \langle a, x \rangle = b\}$, then the linear function $\langle a, x \rangle$ induces an acyclic partial orientation on G^+ and G^- by setting $v \rightarrow w$ when $\langle a, v \rangle < \langle a, w \rangle$. Following this orientation we can connect each vertex of G^+ to the face of Q that maximizes $\langle a, x \rangle$, and following the reverse orientation, each vertex of G^- to the face that minimizes $\langle a, x \rangle$ (compare [11, Theorem 3.14]).

Hence, there are at least $m - k - 2$ edges in $G^+ \cup G^-$. These are edges of Q that do not intersect H . There are also at least $3k$ edges that have an endpoint on H . Now, observe that every vertex of P is either a vertex of Q in H or is the intersection with H of an edge of Q that has an endpoint at each side of H . Hence,

$$n - k \leq (3m - 6) - (3k) - (m - k - 2) = 2m - 4 - 2k, \tag{1}$$

and since $k \geq 0$, we get the desired bound. \square

The lower bound of Proposition 2 is optimal: for every $m \geq 2$ there are $2m$ -gons appearing as sections of 3-polytopes with $m + 2$ vertices (Figure 1).

Figure 1: For $m \geq 2$, the join of an m -path with an edge is the graph of a stacked 3-polytope with $2m + 2$ vertices that has a $2m$ -gon as a section (by a plane that truncates the edge).

Corollary 3. *The intersection complexity of a hexagon is either 5 or 6.*

Proposition 4. *The intersection complexity of a hexagon is 5 if and only if the lines ℓ_{p_0, p_5} , ℓ_{p_1, p_4} and ℓ_{p_2, p_3} intersect in a common point of the projective plane for some cyclic labeling of its vertices $\{p_i \mid i \in \mathbb{Z}/6\mathbb{Z}\}$.*

Proof. The only 4-polytope with 5 vertices is the simplex, which only has 5 facets; thus, none of its 2-dimensional sections is a hexagon. Therefore, if P is a hexagon, then $\text{ic}(P) = 5$ if and only if it is the intersection of a 2-plane H with a 3-polytope Q with 5 vertices.

There are only two combinatorial types of 3-polytopes with 5 vertices: the quadrangular pyramid and the triangular bipyramid. By (1), H does not contain any vertex of Q . Hence, H induces a cut of the graph of Q into two (nonempty) disjoint connected components. A small case-by-case analysis (cf. Figure 2) tells us that the only possibility

(a) Non-hexagonal cuts.

(b) The only hexagonal cut.

Figure 2: All cuts of the quadrangular pyramid and the triangular bipyramid into two connected components, up to symmetry.

is that Q is the bipyramid and H cuts its graph as shown in Figure 2b. However, in every

geometric realization of such a cut (with the same labeling), the lines ℓ_{p_0,p_5} , ℓ_{p_1,p_4} and ℓ_{p_2,p_3} intersect in a common (projective) point: the point of intersection of ℓ_{q_0,q_1} with H (compare Figure 3).

Figure 3: A hexagon as a section of a triangular bipyramid.

For the converse, we prove only the case when the point of intersection is finite (the case with parallel lines is analogous). Then we can apply an affine transformation and assume that the coordinates of the hexagon are

$$\begin{array}{lll} p_0 = (0, \alpha), & p_1 = (\beta x, \beta y), & p_2 = (\gamma, 0) \\ p_3 = (1, 0), & p_4 = (x, y), & p_5 = (0, 1); \end{array}$$

for some $x, y > 0$ and $\alpha, \beta, \gamma > 1$.

Now, let $K > \max(\alpha, \beta, \gamma)$ and consider the polytope Q with vertices

$$\begin{aligned} q_0 &= (0, 0, -K), & q_1 &= (0, 0, -1), & q_2 &= \frac{((K-1)\gamma, 0, K(\gamma-1))}{K-\gamma}, \\ q_3 &= \frac{(x(K-1)\beta, y(K-1)\beta, K(\beta-1))}{K-\beta}, & q_4 &= \frac{(0, (K-1)\alpha, K(\alpha-1))}{K-\alpha}. \end{aligned}$$

If H denotes the plane of vanishing third coordinate, then q_0 and q_1 lie below H , while q_2 , q_3 and q_4 lie above. The intersections $\ell_{q_i,q_j} \cap H$ for $i \in \{0, 1\}$ and $j \in \{2, 3, 4\}$ coincide with the vertices of $P \times \{0\}$. This proves that $P \times \{0\} = Q \cap H$, and hence that $\text{ic}(P) = 5$. \square

Remark 5. Let P be a regular hexagon, and let Q be a polytope with 5 vertices such that $Q \cap H = P$ for some plane H . By the proof of Proposition 4, Q is a triangular bipyramid and one of the two halfspaces defined by H contains only two vertices of Q : q_0 and q_1 . Even more, since P is regular, the line ℓ_{q_0,q_1} must be parallel to one of the edge directions of P because, as we saw in the previous proof, the projective point $\ell_{q_0,q_1} \cap H$ must coincide with the intersection of two opposite edges of P (at infinity in this case). This means

that there are three different choices for the direction of the line ℓ_{q_0, q_1} ; and shows that the set of minimal extensions of P (which can be parametrized by the vertex coordinates) is not connected, even if we consider its quotient space obtained after identifying extensions related by an admissible projective transformation that fixes P and those related by a relabeling of the vertices of Q . A similar behavior was already observed in [6] for the space of nonnegative factorizations of nonnegative matrices of rank 3 and nonnegative rank 3.

Remark 6. Consider the set of all hexagons with 5 fixed vertices. The position of the last vertex determines its intersection/extension complexity. This is depicted in Figure 4. The hexagon fulfills the condition of Proposition 4 if and only if the last point lies on any of the three dark lines. Hence, $\text{ic}(P) = 5$ if the last point lies on a dark line and $\text{ic}(P) = 6$ otherwise. Actually, an analogous picture appears for any choice for the position of the initial 5 points (the dark lines are always concurrent because of Pappus's Theorem). In addition, the dark lines depend continuously on the coordinates of the first 5 points. This implies that, if we take two realizations that have the last point in two different $\text{ic}(P) = 6$ regions in Figure 4, then we cannot continuously transform one into the other. Said otherwise, the realization space of the hexagon (as considered by Richter-Gebert in [7]) restricted to those that have intersection complexity 6 is disconnected.

Figure 4: The intersection complexity of P according to the position of the last vertex.

3 The complexity of heptagons

In this section we prove our main result, Theorem 22, in two steps. The easier part consists of showing that a special family of heptagons, which we call standard heptagons, always have intersection complexity less than or equal to 6 (Proposition 8). The remainder of the section is devoted to proving the second step, Proposition 17: every heptagon is projectively equivalent to a standard heptagon.

3.1 A standard heptagon

Here, and throughout this section, P denotes a heptagon and $\{p_i \mid i \in \mathbb{Z}/7\mathbb{Z}\}$ is its set of vertices, cyclically clockwise labeled.

Definition 7. We say that P is a *standard heptagon* if $p_0 = (0, 0)$, $p_3 = (0, 1)$ and $p_{-3} = (1, 0)$; and the lines ℓ_{p_1, p_2} and $\ell_{p_{-1}, p_{-2}}$ are respectively parallel to the lines ℓ_{p_0, p_3} and $\ell_{p_0, p_{-3}}$ (see Figure 5a).

We can easily prove that standard heptagons have intersection complexity at most 6.

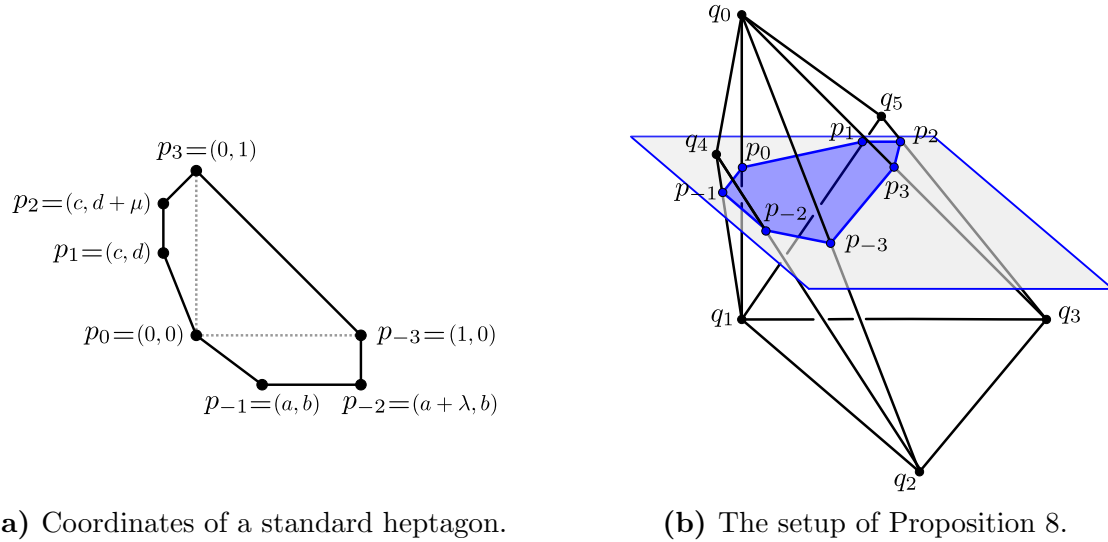

Figure 5: Standard heptagons.

Proposition 8. *Every standard heptagon P is a section of a 3-polytope Q with 6 vertices. In particular $\text{ic}(P) \leq 6$.*

Proof. For any standard heptagon P , there are real numbers $b, c < 0 < a, d, \lambda, \mu$ such that the coordinates of the vertices of P are

$$\begin{aligned} p_0 &= (0, 0), & p_1 &= (c, d), & p_2 &= (c, d + \mu), & p_3 &= (0, 1), \\ p_{-1} &= (a, b), & p_{-2} &= (a + \lambda, b), & p_{-3} &= (1, 0). \end{aligned}$$

Fix some $K > \max(\lambda - 1, \mu - 1)$ and consider the points

$$\begin{aligned} q_0 &:= (0, 0, 1), & q_1 &:= (0, 0, -K), & q_2 &:= (1 + K, 0, -K), & q_3 &:= (0, 1 + K, -K), \\ q_4 &:= \frac{(a(1 + K), b(1 + K), \lambda K)}{(1 + K) - \lambda}, & q_5 &:= \frac{((1 + K)c, (1 + K)d, \mu K)}{(1 + K) - \mu}. \end{aligned}$$

We claim that P is the intersection of the 3-polytope $Q := \text{conv}\{q_0, q_1, \dots, q_5\}$ with the plane $H := \{(x, y, z) \in \mathbb{R}^3 \mid z = 0\}$:

$$Q \cap H = P \times \{0\}.$$

Observe that every vertex of $Q \cap H$ corresponds to the intersection of H with an edge of Q that has one endpoint on each side of the plane. Since q_0, q_4 and q_5 lie above H

and q_1 , q_2 and q_3 lie below, the intersections of the relevant lines ℓ_{q_i, q_j} with H are (see Figure 5b):

$$\begin{aligned} \ell_{q_0, q_1} \cap H &= (0, 0, 0), & \ell_{q_0, q_2} \cap H &= (1, 0, 0), & \ell_{q_0, q_3} \cap H &= (0, 1, 0), \\ \ell_{q_4, q_1} \cap H &= (a, b, 0), & \ell_{q_4, q_2} \cap H &= (a + \lambda, b, 0), & \ell_{q_4, q_3} \cap H &= (a, b + \lambda, 0), \\ \ell_{q_5, q_1} \cap H &= (c, d, 0), & \ell_{q_5, q_2} \cap H &= (c + \mu, d, 0), & \ell_{q_5, q_3} \cap H &= (c, d + \mu, 0). \end{aligned}$$

These are the vertices of $P \times \{0\}$ together with $(a, b + \lambda, 0)$, $(c + \mu, d, 0)$, which proves that $Q \cap H \supseteq P \times \{0\}$. To prove that indeed $Q \cap H = P \times \{0\}$, we need to see that both $(a, b + \lambda)$ and $(c + \mu, d)$ belong to P .

The convexity of P implies the following conditions on the coordinates of its vertices by comparing, respectively, p_{-1} with the lines ℓ_{p_0, p_3} and $\ell_{p_0, p_{-3}}$, p_{-1} with p_{-2} , and p_{-2} with the line $\ell_{p_3, p_{-3}}$:

$$a > 0, \quad -b > 0, \quad \lambda > 0, \quad 1 - a - b - \lambda > 0.$$

Hence, the real numbers $\frac{1-a-b-\lambda}{1-b}$, $\frac{a}{1-b}$ and $\frac{\lambda}{1-b}$ are all greater than 0. Since they add up to 1, we can exhibit $(a, b + \lambda)$ as a convex combination of p_{-1} , p_{-2} and p_3 :

$$\frac{1 - a - b - \lambda}{1 - b} p_{-1} + \frac{a}{1 - b} p_{-2} + \frac{\lambda}{1 - b} p_3 = (a, b + \lambda).$$

This proves that $(a, b + \lambda) \in P$. That $(c + \mu, d) \in P$ is proved analogously. □

3.2 Standardization lines of heptagons

Our next goal is to show that every heptagon is projectively equivalent to a standard heptagon. For this, the key concept is that of a standardization line.

Definition 9. Consider a heptagon P , embedded in the projective space \mathbb{P}^2 , whose vertices are cyclically labeled $\{p_i \mid i \in \mathbb{Z}/7\mathbb{Z}\}$. For $i \in \mathbb{Z}/7\mathbb{Z}$, and abbreviating $\ell_{i,j} := \ell_{p_i, p_j}$, construct

$$p_i^+ := \ell_{i+1, i+2} \vee \ell_{i, i+3}, \quad p_i^- := \ell_{i-1, i-2} \vee \ell_{i, i-3}, \quad \ell_i := p_i^+ \wedge p_i^-.$$

We call the line ℓ_i the i th *standardization line* of P . If $\ell_i \cap P = \emptyset$, it is a *non-crossing* standardization line.

Figure 6 shows a heptagon and its standardization lines ℓ_0 and ℓ_{-3} . Observe that ℓ_0 is a non-crossing standardization line, while ℓ_{-3} is not.

Lemma 10. *A heptagon P is projectively equivalent to a standard heptagon if and only if it has at least one non-crossing standardization line.*

Proof. The line at infinity of a standard heptagon must be one of its standardization lines, which is obviously non-crossing. Conversely, the projective transformation that sends a non-crossing standardization line of P to infinity, followed by a suitable affine transformation, maps P onto a standard heptagon. □

Figure 6: The standardization lines ℓ_0 and ℓ_{-3} .

Hence, having a non-crossing standardization line characterizes standard heptagons up to projective equivalence. Our next step is to show that every heptagon has a non-crossing standardization line (Proposition 17). But to prove this, we still need to introduce a couple of concepts.

Observe that ℓ_i cannot cross any of the lines $\ell_{p_{i+1},p_{i+2}}$, $\ell_{p_{i+0},p_{i+3}}$, $\ell_{p_{i-1},p_{i-2}}$ and $\ell_{p_{i+0},p_{i-3}}$ in the interior of P , since by construction their intersection point is p_i^\pm , which lies outside P (compare Figure 6). In particular, if ℓ_i intersects P , either it separates p_{i+1} and p_{i+2} from the remaining vertices of P , or it separates p_{i-1} and p_{i-2} .

Definition 11. If the standardization line ℓ_i separates p_{i+1} and p_{i+2} from the remaining vertices of P , we say that it is *+crossing*; if it separates p_{i-1} and p_{i-2} it is *--crossing*. In the example of Figure 6, ℓ_{-3} is *--crossing*.

Definition 12. The lines $\ell_{p_i,p_{i+3}}$ and $\ell_{p_{i+1},p_{i+2}}$ partition the projective plane \mathbb{P}^2 into two disjoint angular sectors (cf. Figure 7a). One of them contains the points p_{i-1} , p_{i-2} and p_{i-3} , while the interior of the other is empty of vertices of P . We denote this empty sector S_i^+ . Similarly, S_i^- is the sector formed by $\ell_{p_i,p_{i-3}}$ and $\ell_{p_{i-1},p_{i-2}}$ that contains no vertices of P .

These sectors allow us to characterize \pm -crossing standardization lines.

Lemma 13. *The standardization line ℓ_i is +crossing if and only if $p_i^- \in S_i^+$. Analogously, ℓ_i is --crossing if and only if $p_i^+ \in S_i^-$.*

Proof. The line ℓ_i is +crossing when it separates p_i and p_{i+1} from the rest of P ; this happens if and only if $\ell_i \subset S_i^+$. Since $\ell_{p_{i-1},p_{i-2}} \cap \ell_i = p_i^-$, this is equivalent to $p_i^- \in S_i^+$. The case of --crossing follows analogously. \square

(a) The sector S_0^+ (shaded). The point p_0^- lies in S_0^+ if and only if ℓ_0 is $+$ -crossing.

(b) The point p_0^- cannot lie in both shaded sectors simultaneously.

Figure 7: The relevant angular sectors.

With this characterization, we can easily prove the following compatibility condition.

Lemma 14. *If ℓ_i is $+$ -crossing, then ℓ_{i-3} cannot be $-$ -crossing. Analogously, if ℓ_i is $-$ -crossing, then ℓ_{i+3} cannot be $+$ -crossing.*

Proof. Both statements are equivalent by symmetry. We assume that ℓ_i is $+$ -crossing and ℓ_{i-3} is $-$ -crossing to reach a contradiction.

Observe that $p_i^- = p_{i-3}^+$ by definition. By Lemma 13, p_i^- must lie both in the sector formed by $\ell_{p_i, p_{i+3}}$ and $\ell_{p_{i+1}, p_{i+2}}$ and in the sector formed by $\ell_{p_{i-3}, p_{i+1}}$ and $\ell_{p_{i+3}, p_{i+2}}$. However, the intersection of these two sectors lies in the interior of the polygon (cf. Figure 7b), while p_i^- lies outside. \square

Corollary 15. *If all the standardization lines ℓ_i intersect P , they are either all $+$ -crossing or all $-$ -crossing.*

3.3 Every heptagon has a non-crossing standardization line

We are finally ready to present and prove Proposition 17. In essence, we prove that the combinatorics of the pseudo-line arrangement in Figure 8 are not realizable by an arrangement of straight lines in the projective plane. Here the “combinatorics” refers to the order of the intersection points in each projective pseudo-line. However, any heptagon that had only $+$ -crossing standardization lines would provide such a realization (compare the characterization of Lemma 13).

For the proof, we will need the formula

$$(a \times b) \times (c \times d) = [a, b, d]c - [a, b, c]d, \quad (2)$$

where $[a, b, c] = \det(a, b, c)$ is the 3×3 -determinant formed by the homogeneous coordinates of the corresponding points. That is, $[p_x, p_y, p_z] = \pm 2 \text{Vol}(\text{conv}\{p_x, p_y, p_z\})$.

Figure 8: A non-stretchable pseudo-line arrangement.

Observe that, since the vertices of the heptagon are labeled clockwise and are in convex position, $[p_x, p_y, p_z] > 0$ whenever z lies in the interval (x, y) . To simplify the notation, in what follows we abbreviate $[p_{i+x}, p_{i+y}, p_{i+z}]$ as $[x, y, z]_i$, for any $x, y, z, i \in \mathbb{Z}/7\mathbb{Z}$.

Lemma 16. *With the notation from above, the standardization line ℓ_i is $+$ -crossing if and only if*

$$[p_{i+2}, p_{i+1}, p_i^-] = [-1, -2, -3]_i [2, 1, 0]_i - [-1, -2, 0]_i [2, 1, -3]_i \geq 0; \quad (3)$$

and is $--$ -crossing if and only if

$$[p_{i-2}, p_{i-1}, p_i^+] = [1, 2, 3]_i [-2, -1, 0]_i - [1, 2, 0]_i [-2, -1, 3]_i \geq 0. \quad (4)$$

Proof. Using (2), the coordinates of the standardization point p_i^- are given by

$$\begin{aligned} p_i^- &= (p_{i-1} \wedge p_{i-2}) \vee (p_i \wedge p_{i-3}) = (p_{i-1} \times p_{i-2}) \times (p_i \times p_{i-3}) \\ &\stackrel{(2)}{=} [-1, -2, -3]_i p_i - [-1, -2, 0]_i p_{i-3}. \end{aligned}$$

Observe that $[p_{i+3}, p_i, p_i^-] < 0$ since

$$\begin{aligned} [p_{i+3}, p_i, p_i^-] &= [-1, -2, -3]_i [3, 0, 0]_i - [-1, -2, 0]_i [3, 0, -3]_i \\ &= -[-1, -2, 0]_i [3, 0, -3]_i < 0, \end{aligned}$$

because $[3, 0, 0]_i = 0$ and $[-1, -2, 0]_i > 0$, $[3, 0, -3]_i > 0$ by convexity.

Therefore, in view of Lemma 13, requiring ℓ_i to be $+$ -crossing reduces to the equation $[p_{i+2}, p_{i+1}, p_i^-] \geq 0$, since otherwise p_i^- would not lie in the desired sector. This expression can be reformulated as (3). The proof of (4) is analogous. \square

Proposition 17. *Every heptagon has at least one non-crossing standardization line.*

Proof. We want to prove that P has at least one non-crossing standardization line. By Corollary 15 (and symmetry), it is enough to prove that it is impossible for all ℓ_i to be +-crossing. We will assume this to be the case and reach a contradiction.

If ℓ_i is +-crossing for all $0 \leq i \leq 6$, then by Lemma 16, the coordinates of the vertices of P fulfill (3) for all $i \in \mathbb{Z}/7\mathbb{Z}$. Moreover, if ℓ_i is +-crossing then it cannot be --crossing. Therefore, again by Lemma 16, one can see that the coordinates of the vertices of P fulfill

$$[2, 1, 0]_i[-1, -2, 3]_i - [2, 1, 3]_i[-1, -2, 0]_i > 0, \quad (5)$$

for all $i \in \mathbb{Z}/7\mathbb{Z}$.

Therefore, if all the ℓ_i are +-crossing, the addition of the left hand sides of (3) and (5) for all $i \in \mathbb{Z}/7\mathbb{Z}$ should be positive.

With the abbreviations

$$\begin{aligned} A_i &:= [-1, -2, -3]_i, & B_i &:= [2, 1, 0]_i, & C_i &:= [-1, -2, 0]_i, \\ D_i &:= [2, 1, -3]_i, & E_i &:= [2, 1, 0]_i, & F_i &:= [-1, -2, 3]_i, \\ G_i &:= [2, 1, 3]_i, & H_i &:= [-1, -2, 0]_i; \end{aligned}$$

this can be expressed as

$$\sum_{i \in \mathbb{Z}/7\mathbb{Z}} A_i B_i - C_i D_i + E_i F_i - G_i H_i > 0. \quad (6)$$

However, it turns out that for every heptagon the equation

$$\sum_{i \in \mathbb{Z}/7\mathbb{Z}} A_i B_i - C_i D_i + E_i F_i - G_i H_i = 0 \quad (7)$$

holds by the upcoming Lemma 18. This contradiction concludes the proof that every heptagon has at least one standardization line. \square

Lemma 18. *Let A be a configuration of 7 points in $\mathbb{E}^2 \subset \mathbb{P}^2$ labeled $\{a_i \mid i \in \mathbb{Z}/7\mathbb{Z}\}$. Denote the determinant $[a_{i+x}, a_{i+y}, a_{i+z}]$ as $[x, y, z]_i$, for any $x, y, z, i \in \mathbb{Z}/7\mathbb{Z}$. Finally, let*

$$\begin{aligned} A_i &:= [-1, -2, -3]_i, & B_i &:= [2, 1, 0]_i, & C_i &:= [-1, -2, 0]_i, \\ D_i &:= [2, 1, -3]_i, & E_i &:= [2, 1, 0]_i, & F_i &:= [-1, -2, 3]_i, \\ G_i &:= [2, 1, 3]_i, & H_i &:= [-1, -2, 0]_i; \end{aligned}$$

Then,

$$\sum_{i \in \mathbb{Z}/7\mathbb{Z}} A_i B_i - C_i D_i + E_i F_i - G_i H_i = 0. \quad (7)$$

Figure 9: The determinants involved in Lemma 18.

Proof. Although (7) can be checked purely algebraically, we provide a geometric interpretation. Observe that $[x, y, z]_i = \pm 2 \text{Vol}(a_{i+x}, a_{i+y}, a_{i+z})$, which implies that the identity in (7) can be proved in terms of (signed) areas of certain triangles spanned by A . Figure 9 depicts some of these triangles when the points are in convex position.

To see (7), we show the stronger result that both

$$\sum_{i \in \mathbb{Z}/7\mathbb{Z}} A_i B_i = \sum_{i \in \mathbb{Z}/7\mathbb{Z}} G_i H_i \quad \text{and} \quad (8)$$

$$\sum_{i \in \mathbb{Z}/7\mathbb{Z}} E_i F_i = \sum_{i \in \mathbb{Z}/7\mathbb{Z}} C_i D_i. \quad (9)$$

Indeed, the identity (8) is easy, because $A_i B_i = G_{i+3} H_{i+3}$ for all $i \in \mathbb{Z}/7\mathbb{Z}$ since $A_i = G_{i+3}$ and $B_i = H_{i+3}$.

Moreover, it is straightforward to check that

$$C_i = E_{i-2}, \quad (10)$$

and it is also not hard to see that

$$D_i + C_{i-3} = F_{i-2} + E_{(i+3)-2}. \quad (11)$$

Finally, we subtract the right-hand side of (9) from the left hand side:

$$\begin{aligned} & \sum_{i \in \mathbb{Z}/7\mathbb{Z}} E_i F_i - \sum_{i \in \mathbb{Z}/7\mathbb{Z}} C_i D_i = \sum_{i \in \mathbb{Z}/7\mathbb{Z}} E_{i-2} F_{i-2} - \sum_{i \in \mathbb{Z}/7\mathbb{Z}} C_i D_i \\ &= \sum_{i \in \mathbb{Z}/7\mathbb{Z}} E_{i-2} (F_{i-2} + E_{i+1} - E_{i+1}) - \sum_{i \in \mathbb{Z}/7\mathbb{Z}} C_i (D_i + C_{i-3} - C_{i-3}) \\ &\stackrel{(10)}{=} \sum_{i \in \mathbb{Z}/7\mathbb{Z}} C_i \underbrace{(F_{i-2} + E_{i+1} - D_i - C_{i-3})}_{=0 \text{ by (11)}} - \sum_{i \in \mathbb{Z}/7\mathbb{Z}} E_{i-2} E_{i+1} + \sum_{i \in \mathbb{Z}/7\mathbb{Z}} C_i C_{i-3} \\ &\stackrel{(10)}{=} - \sum_{i \in \mathbb{Z}/7\mathbb{Z}} C_i C_{i+3} + \sum_{i \in \mathbb{Z}/7\mathbb{Z}} C_i C_{i-3} = 0, \end{aligned}$$

and this concludes our proof of (9). \square

Observation 19. *In contrast to Proposition 17, there exist heptagons with 6 crossing standardization lines. For example, the convex hull of*

$$\begin{array}{llll} p_0 = (\frac{7}{5}, \frac{1}{2}), & p_1 = (\frac{6}{5}, \frac{1}{10}), & p_2 = (1, 0), & p_3 = (0, 0), \\ p_{-3} = (0, 1), & p_{-2} = (1, 1), & p_{-1} = (\frac{6}{5}, \frac{9}{10}) & \end{array}$$

has 6 crossing standardization lines (Figure 10). Notice that the symmetry about the x -axis makes ℓ_2 and ℓ_{-2} coincide.

Figure 10: A heptagon with 6 crossing standardization lines.

3.4 The intersection complexity of heptagons

Using projective transformations to standardize heptagons is the last step towards Theorem 22.

Lemma 20. *Projective equivalence preserves intersection complexity.*

Proof. Let $\sigma : P_1 \rightarrow P_2$ be a projective transformation between k -dimensional polytopes. Let $Q_1 \subset \mathbb{R}^d$ be a polytope with $\text{ic}(P_1)$ many vertices and let H be an affine k -flat such that $Q_1 \cap H = P_1$. Finally, let τ be a projective transformation of \mathbb{R}^d that leaves invariant both H and its orthogonal complement, and such that $\tau|_H = \sigma$. Then $\tau(Q_1) \cap H = \sigma(P_1) = P_2$. \square

Lemma 21. *Any heptagon P is a section of a 3-polytope with no more than 6 vertices.*

Proof. Let P be a heptagon. By Proposition 17 it has a non-crossing standardization line, which implies that P is projectively equivalent to a standard heptagon by Lemma 10. Our claim follows by combining Lemma 20 with Proposition 8. \square

The combination of this lemma with the lower bound of Proposition 2 finally yields our claimed result.

Theorem 22. *Every heptagon has intersection complexity 6.*

4 The intersection complexity of n -gons

We can use Lemma 21 to derive bounds for the complexity of arbitrary polygons. We begin with a trivial bound that presents n -gons as sections of 3-polytopes.

Theorem 23. *Any n -gon P with $n \geq 7$ is a section of a 3-polytope with at most $n - 1$ vertices.*

Proof. The proof is by induction. The case $n = 7$ is Lemma 21. For $n \geq 8$, let $x = (a, b)$ be a vertex of P , and consider the $(n - 1)$ -gon P' obtained by taking the convex hull of the remaining vertices of P . By induction there is a 3-polytope Q' with at most $n - 2$ vertices such that $Q' \cap H_0 = P' \times \{0\}$, where $H_0 = \{(x, y, z) \in \mathbb{R}^3 \mid z = 0\}$. Then $Q = \text{conv}(Q' \cup (a, b, 0))$ satisfies $Q \cap H_0 = P \times \{0\}$, and has $n - 1$ vertices. \square

Question 24. Which is the smallest $f(n)$ such that any n -gon is a section of a 3-polytope with at most $f(n)$ vertices? Is $f(n) \sim \frac{2}{3}n$?

We can derive more interesting bounds when we allow ourselves to increase the dimension. We only need the following result (compare [4, Proposition 2.8]).

Lemma 25. *Let P_1 and P_2 be polytopes in \mathbb{R}^d , and let $P = \text{conv}(P_1 \cup P_2)$. If P_i is a section of a d_i -polytope with n_i vertices for $i = 1, 2$, then P is a section of a $(d_1 + d_2 - d)$ polytope with not more than $n_1 + n_2$ vertices. In particular, $\text{ic}(P) \leq \text{ic}(P_1) + \text{ic}(P_2)$.*

Proof. For $i = 1, 2$, let Q_i be a polytope in \mathbb{R}^{d_i} with n_i vertices and such that $Q_i \cap H_i = P_i$, where $H_i = \{x \in \mathbb{R}^d \mid x_j = 0 \text{ for } d_i - d < j \leq d\}$ is the d -flat that contains the points with vanishing last $d_i - d$ coordinates. Now consider the following embeddings of Q_1 and Q_2 in $\mathbb{R}^{d_1+d_2-d}$:

- for $q \in Q_1$ let $f_1(q) = (q_1, \dots, q_d, q_{d+1}, \dots, q_{d_1}, 0, \dots, 0)$, and
- for $q \in Q_2$ let $f_2(q) = (q_1, \dots, q_d, 0, \dots, 0, q_{d+1}, \dots, q_{d_2})$.

Finally, consider the polytope $Q := \text{conv}(f_1(Q_1) \cup f_2(Q_2))$, which has at most $n_1 + n_2$ vertices, and the d -flat $H := \{x \in \mathbb{R}^{d_1+d_2-d} \mid x_j = 0 \text{ for } d < j \leq d_1 + d_2 - d\}$; then $P = Q \cap H$. \square

Theorem 26. *Any n -gon with $n \geq 7$ is a section of a $(2 + \lfloor \frac{n}{7} \rfloor)$ -dimensional polytope with at most $\lceil \frac{6n}{7} \rceil$ vertices. In particular, $\text{ic}(P) \leq \lceil \frac{6n}{7} \rceil$.*

Proof. This is a direct consequence of Lemmas 21 and 25. \square

Question 27. Which is the smallest $f(n)$ such that any n -gon is a section of a $g(n)$ -dimensional polytope with at most $f(n)$ vertices? Are $f(n) = O(\sqrt{n})$ and $g(n) = O(\sqrt{n})$?
