20   **Abstract:** Although nucleation of magnetite and/or hematite along dislocations upon

21   oxidation of olivine has been observed by many workers, the effect of oxidation on the magnetic

22   properties of the sample with specific mineralogical alterations has not been studied. Therefore,

23   we investigate this problem using a set of time series 1 bar oxidation experiments at 600 °C and

24   900 °C. Results show rapid olivine oxidation and alteration at both 600 and 900 °C, forming

25   magnetite and hematite associated with a change from paramagnetic to ferromagnetic behavior

26   after oxidation. Magnetite and hematite nucleate along dislocations and impurities in the crystal

27   structure, along with surface coatings and within cracks in the crystals.

28   Fresh, unaltered mantle xenoliths containing magnetite have been interpreted as having

29   formed in cold tectonic regimes in the mantle, rather than through oxidation during or after

30   ascent. Mantle xenoliths rapidly ascend through the mantle with estimates of ascent of up to 90

31   km/hour (3 GPa/hour) based on the diffusion profile of water in mantle olivine. The rates

32   correspond to xenoliths ascending through the mantle over hours and not days or weeks. Our

33   results show that olivine oxidation and alteration can occur in days to weeks at 600 °C and

34   within minutes at 900 °C. Therefore, if the xenolithic material is transported to the surface in a

35   cold magma (at temperatures ≤600 °C), then the time scale of ascent is likely not long enough for

36   oxidation to cause magnetite formation or a ferromagnetic signature to occur. However, if the

37   material is transported in a hot oxidized basaltic magma (with temperatures ≥900 °C), then

38   oxidation can cause magnetite formation and a ferromagnetic signature.

39

40   **Keywords**: olivine, oxidation, hematite, magnetite, magnetic properties, xenoliths

Introduction

41

42   Olivine is typically the first mineral to crystallize from mafic and ultramafic magmas and

43   is also the first mineral to be modified in a typical alteration and oxidation sequence (e.g., Bowen

44   1928; Goldich 1938; Hausrath et al. 2008). Consequently, its degradation state in a rock can be

45   used as proxy for the length of time of alteration and oxidation (Hausrath et al. 2008). Olivine

46   typically alters to magnetite or hematite under oxidizing conditions (though laihunite may also

47   form), and iron oxyhydroxides, such as goethite, under hydrous conditions (e.g., Goode 1974;

48   Eggleton et al. 1987; Khisina et al. 1998; Oze and Sharma 2005; Syverson et al. 2017). In a

49   seminal paper, Kohlstedt et al. (1976) showed that magnetite and/or hematite can nucleate along

50   dislocations upon oxidation of olivine (so called 'olivine decoration' experiments). However,

51   this work did not investigate how oxidation affects changes in magnetic properties of the sample

52   with specific mineralogical alterations. Therefore, we here investigate the effect of oxidation on

53   the magnetic properties of olivine. The main motivation for combining oxidation experiments

54   with magnetic measurements arises from the recent work by Ferré et al. (2013); (2014) and

55   Friedman et al. (2014), which showed that fresh, unaltered mantle xenoliths contain magnetite

56   that is interpreted as having formed in cold tectonic regimes in the mantle, as opposed to having

57   formed through oxidation during or after ascent. Therefore, this work seeks to constrain both the

58   rates of magnetite formation during oxidation, and how this oxidation affects magnetic

59   properties, in order to assess if oxidation during or after ascent can account for the magnetic

60   properties of mantle xenoliths.

61   Olivine dislocation decoration experiments, originally used to investigate rates of creep

62   along dislocation as a mechanism for modeling mantle flow patterns, have also led to important

63   insights in magnetite formation from olivine oxidation (Kohlstedt et al. 1976). These

64   experiments were performed at atmospheric conditions (pressure and oxygen fugacity) and a

65   mantle-like temperature of 900 ºC for one hour. The results showed that oxidized phases formed

66   along lattice dislocations and produced reddish-colored olivine caused by the formation of either

67   magnetite or hematite (Kohlstedt et al. 1976). Subsequent experimental results on iron-rich

68   olivine (Fo_{50}) showed that oxidation followed a two-step process where the fayalitic component

69   first reacts to form magnetite, after which forsterite breaks down to form enstatite (Goode 1974).

70   For typical terrestrial mantle olivine ($\sim Fo_{90}$), this process may either be a partial or complete

71   reaction, replacing olivine with some combination of magnetite, pyroxene, and/or quartz (e.g.,

72   Goode 1974; Nitsan 1974).

73   In the presence of water, olivine oxidizes and alters to serpentine along with magnetite

74   potentially releasing H_2 gas (e.g., Oze and Sharma 2005; Syverson et al. 2017). If magnesium is

75   not lost, olivine may alter to saponite or nontronite (Eggleton et al. 1987). However, depending

76   on the environment, olivine may also oxidize to hematite or goethite (Goode 1974).

77   Alternatively, oxidation and alteration may produce both hematite and ferric iron in pyroxene in

78   the presence of a carbon dioxide rich atmosphere, as has been suggested for Venus (Fegley et al.

79   1995).

80   Magnetite has been reported in mantle xenoliths in several studies (e.g., Wasilewski et al.

81   1979; Wasilewski and Mayhew 1992; Warner and Wasilewski 1995; Callahan 2009; Ferré et al.

82   2013; Ferré et al. 2014; Friedman et al. 2014). In some cases, magnetite occurs in thin

83   impregnating veins due to basalt contamination. In other cases, magnetite occurs mainly along

84   the xenolith rim and probably results from supergene serpentinization. The origin of this

85   magnetite in mantle xenoliths is crucial to the in situ evaluation of the magnetic properties of the

86   upper mantle.

4

87   Olivine oxidation and magnetite formation can occur via several different processes

88 including (1) alteration and reaction with fluids after eruption of the host magma, (2) reaction

89 with the host magma upon ascent, or (3) metasomatism at depth (e.g., Banfield et al. 1990;

90 McGuire et al. 1991; Dyar et al. 1992; Canil et al. 1994; Luguet and Lorand 1998; Hausrath et al.

91 2008; Creighton et al. 2009).

92   (1) Alteration from reaction with a low temperature fluid specifically causes the

93   formation of Ti-poor magnetite with maghemite, hematite, laihunite, and/or goethite

94   (e.g., Banfield et al. 1990; Luguet and Lorand 1998).

95   (2) Metasomatic reactions in mantle xenoliths formed by interaction with a magmatic

96   dike occur when the magma is significantly more oxidized than the mantle xenolith

97   (e.g. McGuire et al. (1991)]. The Fe^{3+}/Fe^T ratios increased in olivine, pyroxene,

98   amphibole, and spinel near the magmatic dike, with this change being controlled by

99   the oxygen fugacity of the system; however in this case magnetite did not form but

100   instead metasomatic oxidized amphibole formed (McGuire et al. 1991).

101   (3) Finally, oxidation may occur at depth from mantle metasomatism where water and

102   CO_2-rich fluids in the mantle cause oxidation via a dehydrogenation reaction that

103   transfers the charge from H and changes Fe^{2+} to Fe^{3+} (e.g., Dyar et al. 1992; Canil et

104   al. 1994; Creighton et al. 2009; Dasgupta and Hirschmann 2010; Dasgupta et al.

105   2013). Such metasomatic olivine oxidation has been described in mantle xenoliths

106   from the Kamchatka island arc where subducted slab-derived fluids oxidized the

107   overriding mantle wedge (Ishimaru et al. 2009; Ferré et al. 2014). A recent study of

108   the oxidation state of Fe in inclusions of ultra-high pressure majoritic garnet in

109   diamond showed that Fe^{3+} actually increased with depth of garnet formation,

5

110   consistent with the presence of carbonated fluids oxidizing the deepest portion of

111   the upper mantle and transition zone, and not just the shallow mantle (Kiseeva et

112   al. 2018).

113   Recent studies have shown that magnetite can also be found in unaltered,

114   unmetasomatised, and unoxidized mantle xenoliths (Ferré et al. 2013; Ferré et al. 2014). These

115   'fresh' mantle xenoliths show no evidence for external oxidation along high energy grain

116   boundaries, making secondary oxidation and alteration during ascent and emplacement an

117   unlikely process for magnetite formation (Ferré et al. 2013; Ferré et al. 2014). Further, mantle

118   xenoliths tend to rapidly ascend from their mantle sources and likely would not have sufficient

119   time to oxidize during or after ascent (Nixon 1987; Haggerty and Sautter 1990; Demouchy et al.

120   2006; Peslier et al. 2015). The rapid ascent rates of mantle xenoliths, as recorded by water

121   diffusion signatures in the rims of mantle olivine, are on the order of up to 90 km/hr (Demouchy

122   et al. 2006; Peslier et al. 2015). Therefore, the magnetite found in these fresh xenoliths is

123   interpreted as having formed at upper mantle depths, particularly in cold geotherm settings such

124   as cratons regions (Ferré et al. 2013; Ferré et al. 2014; Friedman et al. 2014). This has led to the

125   hypothesis that the observed long wave-length magnetic anomalies (LWMA) in some craton

126   regions may partially originate from magnetite in the uppermost mantle (Ferré et al. 2013; Ferré

127   et al. 2014; Friedman et al. 2014). Long-wavelength magnetic anomalies (LWMA) are broad

128   scale features of the lithospheric magnetic field with half-wavelengths that are often greater than

129   250 km (Thébault et al. 2010). Previous work typically assumed that the magnetic anomalies

130   were solely derived from crustal sources in both forward and inversion models (e.g., Hemant and

131   Maus 2005; Masterton et al. 2013) based on studies of xenoliths (Wasilewski and Mayhew

132   1992). However, our recent work has shown that contributions from the mantle may be up to 30

133   % of the LWMA signature in some cratons (Idoko, 2017, MS Thesis; Idoko et al., in review).

134   We therefore investigate the rate of magnetite formation from olivine at mantle

135   temperatures to help constrain where oxidation in the xenoliths occurs, how quickly oxidation

136   will affect not only mineralogy but also the magnetic properties, and ultimately if the uppermost

137   mantle could contribute to LWMA. These experiments reveal whether diffusion rates of Fe in

138   olivine limit the growth of magnetite upon ascent. We report here on a set of time series heating

139   experiments on single grain gem quality olivine at 600 °C and 900 °C following the seminal

140   work of Kohlstedt et al. (1976). Our experiments were done in air (see methods below), which

141   imposes an fO_2 significantly higher than typical mantle conditions, but the results represent an

142   upper limit in terms of formation rates.

143

144   **Methods**

145   **Olivine High Temperature Oxidation Experiments:**

146   Single gem quality olivine crystals from San Carlos, Arizona and China were purchased

147   from mineral suppliers. Olivine crystals were investigated by optical microscopy and only those

148   olivine that did not display any evidence for alteration (brown colorations, cloudiness, etc) were

149   chosen for study. Olivine crystals were measured and photographed before experimentation for

150   comparison with post experimentation (**Supplemental Figure 1**). Further, all olivine samples

151   were measured by Vibrating Sample Magnetometer (VSM) for their magnetic properties and any

152   sample with a ferromagnetic signature was discarded (see below for more information).

153   All olivine samples were placed in a box furnace at atmospheric oxygen conditions at

154   600 °C and 900 °C. Samples at 900 °C were placed directly on the plate in the furnace; while the

155 600 °C were placed in open-ended Al-crucibles to keep sample pieces together after breaking.

156 Olivine in the 900 °C experiments broke apart during oxidation and therefore a change was made

157 to the protocol for the 600 °C experiments in order to keep the furnace clean. The upper

158 temperature was specifically chosen to parallel the seminal work of Kohlstedt et al. (1976),

159 where oxidized phases grew in only one hour.

160 The oxygen fugacity of our experiments was indirectly controlled by atmospheric

161 conditions. The oxygen fugacity of the atmosphere is ~ QFM + 10 (e.g., McCammon 2005),

162 which is 10 orders of magnitude higher than mantle conditions. This was chosen on purpose as

163 an extreme end member of how oxidizing olivine by contamination with a magma (~QFM +3 for

164 subduction zone magmas), the crust (QFM +2-3), or the atmosphere (QFM +10) (Parkinson and

165 Arculus 1999; McCammon 2005; Kelley and Cottrell 2009; Mullen and McCallum 2013) would

166 affect the mineralogy and magnetic signature.

167 For each temperature, twelve olivine crystals were placed in the furnace and two single

168 olivine grains were incrementally removed after 0.2, 1, 5, 25, 125, and 625 hours. Two grains

169 were removed quickly (typically in a few seconds) at each time interval to produce repeatable

170 results. The temperature of the furnace did not fluctuate significantly (< 20 °C) during sample

171 removal. Fragments of fractured samples from the 900 °C experiment after 625 hours were used

172 to make a thick section for textural analyses.

173 **Electron Microprobe Imaging:**

174 Backscattered electron (BSE) images and X-ray intensity maps of a thick section of

175 fragments from the 900 °C experiment after 625 hours were taken with the Cameca SX100

176 electron microprobe (EMP) at the Open University (OU) for textural analyses of the sample as a

177 representative. This sample was chosen because it contains the highest portion of oxidation. The

178   instrument is equipped with a Bruker EDX detector and five WDS spectrometers. Operating

179   conditions were 20 kV accelerating voltage, 20 nA current applying the smallest possible spot

180   size (~1 μm) for the mapping.

181   **Raman Spectroscopy:**

182   All oxidized samples were analyzed using a Bruker Optics, Inc. Bravo Raman

183   spectrometer at Mount Holyoke College. Samples were run as bulk and not crushed or powdered

184   before analyses. Samples China 21, China 12, Sc-23, and Sc-8 were not analyzed by Raman as

185   the samples were too small to measure. The Raman spectrometer was used for acquiring

186   mineralogical data through a dual laser (758 and 852 nm) excitation and fluorescence mitigation

187   strategy involving successive heating of the laser. With a scan time of 10s and wavenumber

188   range of 300-3350 cm^{-1}, each sample was run five times and the spectra were averaged. The

189   BRAVO spectrometer software produces baseline-subtracted data.

190   The spectrum for each sample was analyzed by matching peaks of mineral standards

191   from the RRUFF data base with the program Crystal Sleuth (Lafuente et al. 2016). Maghemite

192   does not have a catalogued standard; therefore, to determine if maghemite was present in the

193   samples, the results were compared with results with known maghemite detections (Hanesch

194   2009). Raman spectra from the previous experimental work show that maghemite produces

195   peaks at 350, 500, and 700 cm^{-1}, which do not correlate to any other Fe-oxide Raman peak (De

196   Faria et al. 1997; Hanesch 2009).

197   Crystal Sleuth gives a percentage for how well a spectrum matches different mineral

198   standards. The closer the percentage is to 100, the more confidence there is that the mineral is

199   present. Peaks matching with a confidence level of 90% are considered to be a major mineral

200   phase in a sample. Peaks that matched between 70 and 90% to a mineral standard are considered

201 to be a minor mineral phase. Peaks that are matched below 70% and above 50% are considered

202 trace (and may be at or near the detection limit depending on the Raman cross section of the

203 mineral).

204 **Vibrating Sample Magnetometer (VSM):**

205 The magnetic hysteresis properties of each sample were analyzed using the Princeton

206 Measurements Corporation Vibrating Sample Magnetometer 3900-04 (VSM) at SIU. The

207 measurement of magnetic hysteresis, the magnetic behavior of a material in and out of an applied

208 field, is useful in characterizing the remanence carriers of rocks. In addition, the analysis of

209 remanence, or residual magnetism, can determine the magnetic contribution of mineral grains in

210 a sample. Ferromagnets, sensu lato, will exhibit a strong response to a magnetic field, while

211 parmagnetic grains will display a weak response. For the purpose of this experiment, the

212 paramagnetic (i.e., olivine) and ferromagnetic (i.e., magnetite and hematite) contributions are of

213 principal concern, as these are the temperature-dependent reflections of magnetic order.

214 *1. Magnetic Hysteresis* – We applied DC fields up to 1 Tesla, at room temperature. The

215 variation of magnetization with applied ascending and descending fields follows a magnetic

216 hysteresis loop, or plot of the variation of magnetization within a magnetic field. These

217 experiments allow the quantification of the paramagnetic and ferromagnetic contributions. The

218 maximum induced magnetic moment, the magnetic field of saturation (H_s) was calculated after a

219 slope adjustment of 70 percent of the applied field. The high field data was linear in all samples

220 studied and corresponds to the paramagnetic contribution from olivine in the samples. This

221 paramagnetic contribution is corrected using the linear equations resulting from the 4 high field

222 slope curves generated during ascending and descending applied fields. The average slope from

223 each high field linear equation results in a high field slope correction. The magnetic hysteresis

224   parameters, magnetic saturation (M_s) which is measured after saturating a mineral in an applied

225   field of 1-2 Tesla (T), magnetic remanence at saturation (M_r) the magnetism persisting after an

226   applied field is reduced to zero, magnetic coercivity (H_c) the point at which magnetization is

227   returned to zero by applying a field in a negative direction, and coercivity of remanence (H_{cr}),

228   the reverse field that reduces M_r to zero after it is applied and removed, are plotted as ratios in

229   Dunlop (2002) plots. These plots illustrate the nature of the magnetic domain in the system.

230   Samples with larger M_r/M_s ratios have smaller grain sizes while samples with larger H_{cr}/H_c have

231   larger grain sizes.

232   *2. Isothermal Remanent Magnetization (IRM)* – IRM is the remanence left in a material after

233   a steady field (1-1000 mT) has been applied for a short time (~100 seconds) then removed.

234   These experiments allow the distinction of mineral phases of different magnetic coercivity. In

235   general minerals with larger coercivity (e.g., hematite) will require a larger applied magnetic

236   field (up to 2 T and higher) to reach magnetic saturation; while minerals with a smaller

237   coercivity (e.g., magnetite) saturate under lower field (<0.2 T). The IRM is normalized to the

238   highest magnetic saturation for each sample in order to investigate the approach to saturation

239   (e.g., Tauxe et al., 2015). The IRM data was used to also determine the relative proportions of

240   each magnetic phase which contributes to the total magnetization. This was done using MAX

241   UnMix, a program designed to separate coercivity spectra of different magnetic phases

242   (Maxbauer et al. 2016). The derivative of the IRM normalized curves shows peaks of different

243   coercivities corresponding to different Fe-oxide phases.

244   **Results**

11

245   For each time increment, two samples were simultaneously removed to ensure that the

246   results would be reproducible. As described below, samples that have spent an equal amount of

247   time in the furnace have virtually the same amount of alteration.

248   **Textural analyses:**

249   Before and after oxidation, samples from each time interval were photographed to show

250   how oxidation progressed with time at a constant temperature (**Figure 1; supplemental Figure**

251   **1**). After only 12 minutes (0.2 hours) at 900 °C, the olivine samples began to shows signs of

252   oxidation, forming red to brown coloration; however, the samples were still mostly unaltered.

253   Samples that spent 1 hour in the furnace began to show a metallic iridescent reddish-brown

254   coating. After 5 hours, the samples were completely altered, showed a complete metallic

255   iridescent reddish-brown coating, and no sign of the original olivine green coloring. All samples

256   oxidized longer than 5 hours were predominantly reddish-brown with the coloring becoming

257   darker with time. For experiments at 600 °C, the red/brown of the olivine and production of a

258   metallic iridescent coating followed the same pattern as the higher temperature experiments, but

259   the alteration effects took longer time to develop (**Figure 1**).

260   **Figure 2** displays the BSE image and X-ray element concentrations of a thick section of

261   a sample oxidized for 625 hours at 900°C. The sample shows three distinct morphologies of

262   oxidative alteration: 1) surface coating, 2) crack filling, and 3) within crystal lattice. The entire

263   crystal is coated with a surface coating visible as a bright phase in the BSE image and higher iron

264   concentration than the original olivine. Some of this surface coating has been broken away

265   during making of the thick section. The bright/high iron phase also is evident within irregular

266   cracks throughout the olivine grain. Finally, the bright/high iron phase also appears within the

12

267 crystal structure where it occurs as inclusions with perpendicular orientations suggesting it

268 formed along preferred crystallographic directions within the orthorhombic olivine structure.

269 **Mineralogy:**

270   Mineralogy for all samples was derived from Raman spectroscopy and was dominated by

271 olivine for all samples – including the most oxidized (**Figure 3; Table 1**). Importantly, there is

272 no detectable alteration in the unaltered crystals. However, with increasing duration of the

273 experiment, the Raman spectroscopy, and therefore mineralogy, showed significant changes. The

274 Raman spectrum for the 900 °C experiments shows evidence for hematite formation after only

275 12 minutes and hematite appears in all experiments (**Figure 3**). Interestingly, for some of the

276 long duration runs (>25 hours), there is also a trace amount of enstatite and quartz (**Figure 3**).

277 This mineralogy is consistent with the reactions reported by Goode (1974), which found

278 forsterite breaking down to iron-oxide plus enstatite and quartz. However, the Raman results

279 contain mainly hematite with limited evidence for magnetite (**Figure 3**). This is a consequence

280 of the temperatures of our experiments. With increasing temperatures, magnetite undergoes first

281 a phase transition to maghemite and then a transition from maghemite to hematite (e.g., Swaddle

282 and Oltmann 1980; De Boer 1999). Further, there is the possible presence of clinohumite ((Mg,

283 Fe)$_9$(SiO$_4$)$_4$(OH)$_2$) in some samples, which is most likely a product of humidity in the room that

284 provided water (as OH$^-$) to the experimental products while either conducting the experiment or

285 upon removal from the oven.

286   Experimental results at 600 °C show a similar mineralogy but the alteration takes longer

287 to occur. In the first five hours, all samples remain spectroscopically unaltered (olivine only in

288 the Raman spectra), even though visually small brown/red patches appear (**Figure 3**). After 5

289 hours of oxidation, hematite is the first alteration phase to form. No other alteration phase is

290   found in the Raman spectra of the lower temperature experiments over the course of our

291   experiments. This is consistent with kinetics, where higher temperatures facilitate diffusion in a

292   solid phase and thus increase reaction progress.

293   **Magnetic Data:**

294   **900 °C Experimental Results.** Before and after oxidation, samples were analyzed using

295   a magnetic hysteresis loop (**Figure 4**). Each sample showed paramagnetic behavior before

296   oxidation and ferromagnetic behavior after oxidation. This change in magnetic behavior occurs

297   after 12 minutes (0.2 hours) of oxidation and is persistent in all samples from the 900 °C

298   experiments. Normalized IRM curves for each sample (**Figure 5**), are similar because the same

299   ferromagnetic phase is producing the magnetic signature in each sample. The first derivative of

300   the IRM curves shows where the change in slope occurs for each sample because the derived

301   peaks represent the maximum change in slope of the IRM curve. Table 1 lists where these peaks

302   occur and how they relate to coercivity, which ranges from 0.15 to 0.4 tesla, and generally

303   increases with time of oxidation.

304   The MAX UnMix program and the same IRM derivatives were used to calculate the

305   relative proportions of the ferromagnetic components that contribute to the magnetic properties

306   of the sample (Table 1). In general, magnetite dominates the magnetic signature contributing as

307   much as 87 % of the magnetic remanence compared to 13 % contribution from hematite after

308   only 12 minutes. Magnetite's contribution increases after 1 hour to 99 % and is consistent until

309   the 125 hours where sample China 21 shows 95 % magnetite. This small decrease in magnetite

310   continues in the 625-hour samples which have 94 % magnetite compared to 6 percent hematite.

311   This small decrease in magnetite contribution after 125 hours is most likely due to magnetite

312   converting to maghemite or hematite with increasing temperature and time (e.g., De Faria et al.

313   1997).

314   **600 °C Experimental Results.** Samples before and after oxidation at 600 °C were

315   analyzed using a hysteresis loop. Each sample showed paramagnetic behavior before oxidation.

316   Interestingly, unlike the 900 °C experiments, only the samples run for the longest times (samples

317   SC-3 and China 1) had a ferromagnetic signature. The samples spent 625 hours oxidizing at 600

318   °C, and the hysteresis data is very noisy and at the detection limits of the VSM. The magnetic

319   signature of the samples is similar to the results of Olivine-22 and SC-6 which spent only 12

320   minutes (0.2 hours) at 900 °C. The H_{sat} values are difficult to determine for these samples

321   because the data is so noisy, but 0.1 to 0.2 tesla is a reasonable estimate. Following the same

322   steps as the 900 °C, coercivity in this sample was tested using the IRM data. The normalized

323   IRM data for the samples demonstrates the presence a ferromagnetic phase similar to the 0.2

324   hour 900 °C samples. Taking the first derivative for Sc-3 and China 11 shows coercivity peaks at

325   0.24 and 0.35 tesla, respectively. These values correspond to a presence of magnetite. Because of

326   the high noise levels for the data for our 600 °C experiments, UnMix was not used to calculate

327   the mineralogy.

328   **Domain of the Magnetite Grains.** The magnetic ratios of Mr/Ms versus Hcr/Hc were

329   plotted in a logarithmic scale to inform the domain state of the magnetic grains (Dunlop 2002).

330   In this experiment, magnetite grains formed along dislocations dominate the magnetic signature

331   while hematite, although present chemically, has a negligible contribution. Figure 6 shows a

332   Dunlop (2002)-style graph for our results, and indicates that most magnetite grains are single

333   domain (SD) to pseudo-single domain (PSD). The samples that spent a longer time at 900 °C

334   trend towards a more single domain-like behavior and a smaller grain size. This corresponds to a

335   proportionally larger Ms value than Mr with respect to time. The 600 °C samples that produced

15

336   ferromagnetic signatures are separated from the 900 °C with a higher Hcr/Hc value correlating to

337   an increased grain size.

Discussion

339   Our results show rapid olivine oxidation and alteration at both 600 and 900 °C, forming

340   magnetite and hematite. The oxides nucleate along dislocations and impurities in the crystal

341   structure, along with surface coatings and within cracks in the crystals. Interestingly, our results

342   are consistent with both hematite and magnetite formation, with Raman results showing hematite

343   dominated assemblages (**Figure 3**) and the CSM results suggesting magnetite-dominated (**Table

344   1**) assemblages. The difference between the results is caused by the sensitivity of the

345   instruments, and is consistent with magnetite dominating the magnetic signature but hematite

346   being the main oxidation product. The upper limit of the applied field that the VSM can produce

347   is lower than the Hsat value for hematite, which is 2.0 tesla. Therefore, the VSM will not detect

348   hematite with a hysteresis or IRM and the results will be dominated by magnetite.

349   Importantly, the coercivity of magnetite in any sample can be affected by the anisotropy

350   of the grain shape and orientation with respect to the applied fields of the VSM. As a result, our

351   altered samples have higher coercivities with increasing time of the experiment, because the

352   oxides formed along crystallographically oriented olivine dislocations (**Figure 2**), producing

353   anisotropic magnetite grains. The longer the experiment ran, the more the dislocations crisscross,

354   causing an increase in magnetite grain populations with opposite orientations. Samples with

355   greater magnetic anisotropy need a higher applied field from the VSM to saturate magnetite's

356   magnetic field. Therefore, samples that spent longer times in the oven developed more alteration

357   and a higher magnetic anisotropy, consistent with these samples having larger coercivities.

358   Olivine oxidation has been proposed as a method for forming magnetite at the crust-

359   mantle boundary and deeper mantle depths based on mantle xenoliths at tectonic localities with

360   suppressed geothermal gradients (Ferré et al. 2013; Ferré et al. 2014), which would require long

361   heating periods and slow exhumation. Our results now show that olivine oxidation and alteration

362   occurs rapidly at both 600 and 900 °C with the rate of oxidation depending on the temperature.

363   At higher temperatures, oxidation occurs within minutes; while at the lower temperature,

364   oxidation occurs within weeks. Whether oxidation and formation of magnetite and hematite is

365   happening over days or weeks, this is incredibly fast on geologic time scales for in situ mantle

366   material, but it does make a difference in considering oxidation during ascent. Decompression of

367   xenoliths through the mantle has been estimated at up to 90 km/hour based on water

368   concentrations in the rims of mantle olivine, which corresponds to decompression occurring over

369   hours and not days or weeks (Demouchy et al. 2006; Peslier et al. 2015). Therefore, if the

370   xenolithic material is transported to the surface at temperatures ≤600 °C, the time scales are

371   likely not long enough for oxidation and magnetite formation to occur; however, if the material

372   is transported in an oxidized basaltic magma with temperatures ≥900 °C, then oxidation and

373   magnetite formation could occur.

374   One important caveat is that our experiments were conducted at oxidation states (~ QFM

375   +10) above those typically found in the mantle (~QFM, e.g., McCammon 2005). We chose this

376   oxygen fugacity to promote oxidation and the formation of oxidized phases in order to

377   investigate if it can cause a magnetic signature. We are aware that this makes direct applications

378   to mantle processes difficult and note that instead, our results are directly applicable to oxidation

379   after eruption and in contact with air. Further, our experimental results are comparable to

380   oxidation from contamination with either a magmatic host or metasomatic fluids in an arc

17

381   setting: typical subduction zone magma liquidus temperatures and mantle melting temperatures

382   are > 1000 °C (as summarized by Stern 2002; Gaetani and Grove 2003) with initial eruption

383   temperatures (based on mineral crystallization) of ~ 900 °C (e.g., Rutherford and Hill 1993;

384   Mullen and McCallum 2013 for Mt St Helens and Mt Baker); therefore our higher temperature

385   experiments are applicable as an upper limit in terms of formation rates during ascent and

386   eruption and the lower temperature results are applicable as the magmatic system cools. Further,

387   subduction zone magmas are typically more oxidized than mantle oxidation states (Parkinson

388   and Arculus 1999; Gaetani and Grove 2003; McCammon 2005; Kelley and Cottrell 2009).

389   Subduction zone magmas can have an oxygen fugacity up to ~ QFM +3; this is lower than the

390   atmospheric conditions of our experiments (~QFM +10; McCammon 2005; Gaetani and Grove

391   2003; Mullen and McCallum 2013). The higher oxygen fugacity of our experiments will promote

392   oxidation and nucleation of hematite at the expense of magnetite (e.g., Swaddle and Oltmann

393   1980; De Boer 1999). With that caveat in mind (hematite vs magnetite), our experiments are

394   applicable to the investigation of contamination from an oxidized arc magma during ascent and

395   eruption on the surface.

396   However, in addition to the observation of magnetite occurrence alone, it is vital to

397   investigate the geometry, textures, and location of the magnetite within the xenolith as well as its

398   mineral assemblage. Magnetite formed by oxidation of olivine forms in three distinct locations:

399   as coating along the periphery of grains, within cracks, and as crystallographically-oriented

400   inclusions within a grain. Therefore, any magnetite or hematite found in mantle xenoliths in

401   these sites is likely from oxidation on ascent. In contrast, magnetite found within an olivine grain

402   adjacent to exsolution lamellae of other mafic phases (orthopyroxene, amphibole; see Fig. 1 of

403   Ferré et al 2013) and at distance from grain boundaries and cracks, were likely not formed during

18

404　oxidation and presumably represent magnetite that was stable at mantle depths (Ferré et al.

405　2013). In terms of alteration assemblage, our samples contain both magnetite and hematite, while

406　the natural xenolith samples are dominated by magnetite (Ferré et al. 2013). In addition, when

407　found in the natural xenoliths, grains of magnetite only occurred within olivine and pyroxene in

408　orientations parallel to distinct crystallographic planes (Ferré et al. 2013), in contrast to the

409　geometries found in our experimental results, which include oxidation coatings, within cracks, as

410　well as those along crystallographically-oriented inclusions. Finally, the IRM results are

411　significantly different between the natural xenolith samples and our experimental results (Ferré

412　et al. 2013; Ferré et al. 2014; Friedman et al. 2014). These differences are consistent with the

413　magnetite found within unaltered xenoliths deriving from mantle conditions, implying that

414　magnetite endemic to the mantle could contribute to long wave length anomalies in cratonic and

415　other tectonic environments which have a thicker lithospheric mantle (Idoko, 2017, MS thesis).

Implications

417　　　Our results show olivine oxidation and alteration to occur within minutes to days at both

418　600 and 900 °C forming magnetite and hematite associated with a change from paramagnetic to

419　ferromagnetic behavior after oxidation. The oxide phases nucleate along dislocations and

420　impurities in the crystal structure, along with surface coatings, and within cracks in the crystals.

421　The experimental formation of ferromagnetic behavior happens quickly compared to most

422　geologic time scales of processes taking thousands to millions of years to complete. However,

423　when compared with the rapid rate of xenolith decompression through the mantle, the

424　experimental time scale (especially for our 600 °C experiments) is still *slower* than the estimated

425　90 km/hr decompression rate for xenoliths. Therefore, if the xenolithic material is transported to

426　the surface at low temperatures, the time scales would not be long enough for oxidation to cause

427   magnetite formation or a ferromagnetic signature to occur. Alternatively, if the material is

428   transported in a high temperature (≥900 °C) oxidized magma (>>QFM), then oxidation from

429   reaction with the magma, atmosphere, or low to moderate temperature aqueous fluids could

430   cause magnetite formation and a ferromagnetic signature to occur. We therefore suggest that

431   magnetite in olivine of mantle xenoliths can represent either in situ oxidation of olivine in the

432   mantle or during ascent, and that textural relationships and magnetic measurements can assist in

433   distinguishing magnetite formation at depth vs. during ascent.
