**Authorship statement:** EB, EL, and ES developed and framed the research question; JF led chemical  
analyses; EB, EL, and ES performed statistical analyses. All authors performed the experiment at their  
sites and collected data used in these analyses; EB, ES, and EL also coordinated the experiment. EB  
wrote the first draft of the manuscript, and all other authors contributed substantially to revisions. See  
Table SI 11 for details.

**Data information:** All data contributors are listed in SI Table 12.

## ABSTRACT

Sodium is unique among abundant elemental nutrients, because most plant species do not require it for growth or development, whereas animals physiologically require sodium. Foliar sodium influences consumption rates by animals and can structure herbivores across landscapes. We quantified foliar sodium in 201 locally-abundant, herbaceous species representing 32 families and, at 26 sites on four continents, experimentally manipulated vertebrate herbivores and elemental nutrients to determine their effect on foliar sodium. Foliar sodium varied taxonomically and geographically, spanning five orders of magnitude. Site-level foliar sodium increased most strongly with site aridity and soil sodium; nutrient addition weakened the relationship between aridity and mean foliar sodium. Within sites, high sodium plants declined in abundance with fertilization, whereas low sodium plants increased. Herbivory provided an explanation: herbivores selectively reduced high nutrient, high sodium plants. Thus, interactions among climate, nutrients, and the resulting nutritional value for herbivores determine foliar sodium biogeography in herbaceous-dominated systems.

## INTRODUCTION

Sodium is an essential nutrient for herbivores (Michell 1989; Snell-Rood *et al.* 2014) that can determine animal foraging preferences and movement patterns in space and time (McNaughton 1988; Prather *et al.* 2018). In contrast, sodium is not used for physiological function in most plants, and at high concentrations sodium can be toxic for plants (Mäser *et al.* 2002; Pardo & Quintero 2002; Marschner 2011; Maathuis 2014). Because of this key difference in the mineral nutrition of herbivores and the plants they eat, herbivores must use natural salt licks and seek out and efficiently use the sodium present in plants to meet physiological demands for sodium (Michell 1989). In spite of the essential role of plant sodium content for wild herbivores (Seastedt & D. A. Crossley 1981), there is little understanding of the relative importance of the many factors that may control foliar sodium in plants.

1  
2  
3 64 For example, abiotic factors including soil sodium content, soil fertility, or climate may determine  
4  
5 65 sodium availability, whereas biotic constraints such as plant species phylogeny and lifeform or  
6  
7 66 palatability to herbivores may determine the capacity for sodium exclusion and whole tissue losses that  
8  
9  
10 67 may occur with preferential herbivory. Further, these factors may interact and operate globally or  
11  
12 68 regionally to influence foliar sodium, and context may determine whether foliar sodium is likely to  
13  
14 69 interact with herbivory to determine the composition of plant communities in future environments.  
15  
16  
17 70 Plants access sodium through leaf uptake from atmospheric deposition (Benes *et al.* 1996) or root  
18  
19 71 uptake from soil water (Epstein 1973). Because of the similarity of sodium to the potassium ion that is  
20  
21 72 physiologically critical for plants, cation transporters of roots will transport both sodium and potassium  
22  
23 73 across cell membranes (Pardo & Quintero 2002; Maathuis 2014). Although a relatively small group of  
24  
25 74 plants – mostly C<sub>4</sub> grasses – requires sodium (Brownell & Crossland 1972; Furumoto *et al.* 2011), the  
26  
27 75 sodium cation is present in the foliage of many species and can be used for a variety of critical plant  
28  
29 76 functions, including stomatal opening and closing, particularly when potassium is in short supply  
30  
31 77 (Subbarao *et al.* 2003). However, terrestrial sodium is geographically variable (Kaspari *et al.* 2008;  
32  
33 78 Kaspari *et al.* 2009; Wicke *et al.* 2011; Vet *et al.* 2014; Doughty *et al.* 2016) because of mineral  
34  
35 79 acquisition from sources such as ocean spray, terrestrial salinization, or road salting practices  
36  
37 80 (Ramakrishna & Viraraghavan 2005; Vet *et al.* 2014), urine (Kaspari *et al.* 2017), loss from leaching  
38  
39 81 (Vitousek & Sanford 1986), and climatic influences, particularly aridity (Raheja 1966). In spite of these  
40  
41 82 general associations, it remains unclear whether foliar sodium varies predictably among plant taxonomic  
42  
43 83 lineages or biogeographically with e.g., distance to coast or site aridity and whether there are site or  
44  
45 84 plant species characteristics that effectively predict the foliar sodium content of the most abundant  
46  
47 85 plants.  
48  
49  
50  
51  
52  
53 86 Although plant sodium is often assumed to simply track soil sodium supply, at biogeographic scales, a  
54  
55 87 growing body of evidence suggests that plant sodium content may not be determined solely via soil  
56  
57  
58  
59  
60

1  
2  
3 88 sodium supply. Like other soil cations, sodium uptake by plants can be reduced in high pH soils (Tyler &  
4  
5 89 Olsson 2001; Bolan & Brennan 2011), and aridity can lead to increased soil pH (Slessarev *et al.* 2016),  
6  
7 90 suggesting that aridity may either increase foliar sodium via increased soil sodium or reduce it via  
8  
9 91 increased soil pH. Evidence also is accumulating that the supply of macronutrients such as nitrogen can  
10  
11 92 reduce the availability of mineral cations to plants (Lucas *et al.* 2011). Thus, anthropogenic activities that  
12  
13 93 are altering soil pH or increasing macronutrient supply to ecosystems (Franklin *et al.* 2016) may  
14  
15 94 interactively alter the sodium content of foliage and quality of foliage for herbivores (Kaspari *et al.*  
16  
17 95 2017). Furthermore, herbivores may themselves alter the sodium concentration in plant tissue either by  
18  
19 96 promoting the availability of sodium through recycling (McNaughton *et al.* 1997; Doughty *et al.* 2016),  
20  
21 97 by promoting saline soil conditions (McLaren & Jefferies 2004), or selectively consuming plant species  
22  
23 98 with elevated salt levels in their foliage (Seastedt & D. A. Crossley 1981; Welte *et al.* 2019). These  
24  
25 99 conditions may, alternatively, promote plant species with relatively high foliar sodium that have traits,  
26  
27 100 such rapid regrowth, basal meristems, or use of sodium to modify osmotic potential under drought, that  
28  
29 101 are beneficial under both saline soil conditions and high grazing intensity (Coughenour 1985; Veldhuis *et*  
30  
31 102 *al.* 2014; Griffith *et al.* 2017).

32  
33 103 Here, we use existing and experimentally-created environmental gradients to address the following  
34  
35 104 questions (1) *Patterns of foliar sodium*: Which site ( $10^4$  m<sup>2</sup>), plot ( $10^0$  m<sup>2</sup>), and species characteristics  
36  
37 105 predict foliar sodium content? For example, does foliar sodium vary predictably among plant taxa, with  
38  
39 106 distance to coast, or along a gradient of soil pH or site aridity? (2) *Responses of foliar sodium to a*  
40  
41 107 *changing environment*: Do selective herbivory or elevated nutrient supply reduce foliar sodium at the  
42  
43 108 local (plot) scale? (3) *Effects of foliar sodium on grassland species composition*: Does a grassland species'  
44  
45 109 foliar sodium content predict changes in the species' relative abundance in response to herbivory or  
46  
47 110 elevated nutrients?  
48

## 112 METHODS

113 Experimental design and locations. Samples for this study were collected at 26 sites that are part of a  
114 long-term, nutrient-addition and herbivore-fencing experiment being performed in herbaceous-  
115 dominated sites around the world, the Nutrient Network distributed experiment (NutNet,  
116 [www.nutnet.org](http://www.nutnet.org)). The subset of the NutNet sites that were able to collect tissue samples that comprise  
117 the data used in this study spanned Africa, Australia, Europe, and North America (SI Table 1).

118 Each site had three experimental blocks composed of 10 – 5 x 5 m plots, each assigned randomly to one  
119 of 10 unique treatment combinations. Treatments included a factorial addition of N (10 g N m<sup>-2</sup> yr<sup>-1</sup> as  
120 timed-release urea [(NH<sub>2</sub>)<sub>2</sub>CO]), P (10 g P m<sup>-2</sup> yr<sup>-1</sup> as triple-super phosphate [Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub>]), and K  
121 (10 g K m<sup>-2</sup> yr<sup>-1</sup> as potassium sulphate [K<sub>2</sub>SO<sub>4</sub>]) plus micronutrients ( $\mu$ , a mix of Fe (15%), S (14%), Mg  
122 (1.5%), Mn (2.5%), Cu (1%), Zn (1%), B (0.2%) and Mo [0.05%]), for a total of 8 plots/block. Importantly,  
123 no sodium (Na) was added in any treatment. N, P, and K were applied annually at each site for 2-4 years  
124 (SI Table 1); the micronutrient mix,  $\mu$ , was applied once in the first experimental year to avoid toxicity.

125 For the focal fence and fertilization experiment, fence treatments were crossed with the control and the  
126 all nutrient treatment (N+P+K $\mu$ ), adding two fenced plots to each block. Fences were built to exclude  
127 medium and large mammals and had been in place for 2-4 years at the time of sampling. Fences were  
128 230 cm tall with four strands of barbless wire suspended at equal vertical distances above the lower  
129 90 cm which was surrounded by 1-cm woven wire mesh with a 30-cm outward-facing flange stapled to  
130 the ground. At some sites, logistical considerations required slight modifications of the fence design  
131 (Fence exceptions table, SI Table 2). All sampling plots were separated by at least 1 m wide walkways to  
132 reduce the impact of treatments on adjacent plots. For additional methods details, see (Borer *et al.*  
133 2014).

1  
2  
3 134 Pre-treatment soil collection. Before applying the experimental treatments, three 2.5 x 10cm soil cores  
4  
5 135 were collected from each experimental plot, combined, homogenized into a single sample for each 5 x 5  
6  
7 136 m plot (roughly 500 g of soil), and dried. Percent soil C and N from each plot were analyzed in a single  
8  
9 137 analytical laboratory using a Costech ECS 4010 CHNSO Analyzer on pulverized soil (Knops lab, University  
10  
11 138 of Nebraska, USA). Extractable soil P, K, and micronutrients, including Na, and pH for every soil sample  
12  
13 139 also were quantified in a single analytical laboratory using standard methods (Borer *et al.* 2014) (A&L  
14  
15 140 Laboratories, Memphis, Tennessee, USA). Across our study sites, plot-level soil sodium ranged from 21  
16  
17 141 ppm (at Val Mustair in Switzerland) to 150 ppm (at Elliott Chaparral, USA).

18  
19  
20  
21 142 Plant abundance and biomass estimation. To determine the most abundant plant species in each plot  
22  
23 143 and the change in cover of species in response to the experimental treatments, the percent areal cover  
24  
25 144 of each species was estimated to the nearest 1 percent for each species within a permanently marked 1-  
26  
27 145 m<sup>2</sup> subplot of each treatment unit.

28  
29  
30  
31 146 A metric of site-level net herbivore impact was estimated as the average difference in live mass inside  
32  
33 147 and outside of fences within a block during the first year of the treatment. To estimate this, we clipped  
34  
35 148 the aboveground biomass of all plants rooted within a 0.2 m<sup>2</sup> area of each fenced and control plot. Each  
36  
37 149 sample was divided into growth from the current year and litter from previous years. We used the first  
38  
39 150 year of treatment to estimate herbivore impact on vegetation mass, prior to species-level selection and  
40  
41 151 turnover in response to long-term herbivore exclusion.

42  
43  
44  
45 152 Foliar sampling & sodium analysis. Within each plot, the most abundant species were determined as a  
46  
47 153 function of percent cover, and a single healthy leaf was collected from five unique individuals of the  
48  
49 154 species with the greatest cover at the site. Most sites had three to five dominant species present in most  
50  
51 155 plots; however, one site collected 8 different species (Val Mustair), because there were not clearly  
52  
53 156 dominant species. All leaves were transported in a cooler, and then dried at 60°C for 48 hours (Firn *et al.*

1  
2  
3 157 2019). The collected species represented 5.3% (Val Mustair, Switzerland, a high elevation, highly diverse  
4  
5 158 (25 species/plot) site; this is the site that sampled 8 species) to 52.1% (Saline, KS, USA) of the total plot  
6  
7 159 cover with an average representation of 26% of the total cover across all plots and sites (SI Table 1). All  
8  
9  
10 160 leaves were then sent to Queensland University of Technology (Dr. J. Firn) for sodium analysis. Dried  
11  
12 161 leaves were ground to a fine powder, then analyzed for sodium content with an Agilent 8800 Laser  
13  
14 162 Ablation Inductively Coupled Plasma Mass Spectrometer (LA-ICP-MS), following Duodu *et al.* (Duodu *et*  
15  
16 163 *al.* 2015) with two exceptions: C, the most abundant naturally occurring element, was used as a  
17  
18 164 standard, and no additional pulverizing was performed beyond that required for C analysis. The  
19  
20 165 reference material for sodium was NIST SRM 1570a Trace elements in spinach leaves (USA National  
21  
22 166 Institute of Standards and Technology 2014). Elemental quantification followed the method of Longerich  
23  
24 167 *et al.* (1996), using lolite, a data reduction software (Paton *et al.* 2010).

25  
26  
27  
28 168 Climate data. The WorldClim database provided comparable long-term climate data for all sites (version  
29  
30 169 1.4; <http://www.worldclim.org/bioclimate>). These global climate data were interpolated at high-resolution  
31  
32 170 from data stations with 10 to 30 years of data (Hijmans *et al.* 2005). We used these data to test whether  
33  
34 171 foliar sodium in the most abundant taxa declined with mean annual precipitation (MAP in mm per year)  
35  
36 172 or increased with a site-level index of aridity (MAP divided by potential evapotranspiration in mm per  
37  
38 173 year)(Barrow 1992). Site-level MAP ranged from 14 at Sheep Station, USA to 1898 mm of annual  
39  
40 174 precipitation at HJ Andrews LTER; Lookout, USA and the index of aridity ranged from 0.2 at Mount  
41  
42 175 Caroline, Western Australia to 2.4 mm at Val Mustair, Switzerland (SI Table 1).

43  
44  
45  
46  
47 176 Analyses. We explored the relative importance and interactions among the many factors that we  
48  
49 177 hypothesized to constrain foliar sodium. Many of these factors could covary (e.g., annual precipitation,  
50  
51 178 distance to coast, and soil pH), and it was possible that there could be multiple models that were  
52  
53 179 similarly informative (i.e., had similar AICc values). For this reason, we used a multi-model approach,  
54  
55 180 which does not try to identify a single best model (Grueber *et al.* 2011). This information theoretic

1  
2  
3 181 approach starts by calculating all possible subsets of the parameters in the full model, and then uses  
4  
5 182 Akaike's information criterion (AICc) to determine the subset of models sharing similarly high levels of  
6  
7 183 parsimony (Grueber *et al.* 2011). In our case, we included in our high parsimony set all models that fell  
8  
9 184 within 4 AICc units of the model with the lowest AICc value (Grueber *et al.* 2011). Parameter estimates  
10  
11 185 and significance are based on a weighted average of the set of high parsimony models. We present the  
12  
13 186 weighted average parameter value estimate, significance, and the summed AIC weights for all models in  
14  
15 187 which the parameter is included, or *importance*. We used the *dredge* function in the MuMIn R library to  
16  
17 188 calculate the AICc of all possible models and the *model.avg* function in the MuMIn R library to calculate  
18  
19 189 the weighted parameter and statistics.

20  
21  
22  
23  
24 190 All models used a random effect structure with site and species within site treated as random intercepts  
25  
26 191 to account for the hierarchical nature of the sampling. To examine biogeographic predictors of foliar  
27  
28 192 sodium, we examined only control plot values, but for the effects of environmental change, we used  
29  
30 193 data from all experimental plots. Experimental treatments were retained in all models. Because of  
31  
32 194 missing soil data, one site (Mt. Caroline) is excluded from experimental analyses. In addition, to avoid  
33  
34 195 bias from having rare species that were found only in one treatment driving the results, for the analysis  
35  
36 196 of the fence and fertilization experiment (shown in Fig 4), we include species that are present in Control  
37  
38 197 plots and at least two other treatments (e.g., Control, Fence, and Fertilized or Control, Fence, and Fence  
39  
40 198 + Fertilized). Similarly, for analysis of the factorial nutrient experiment (SI Figure 1), we include only  
41  
42 199 species present in Control plots and at least 5 other treatments. Finally, in analyses of abiotic factors  
43  
44 200 associated with foliar sodium, we tested the leverage of two outlier sites. In particular, we examined the  
45  
46 201 role of a single site (Sheep Station, USA) in driving the association of foliar sodium with soil pH and  
47  
48 202 another site (Lancaster, UK) in determining the importance of distance from the coast in foliar sodium  
49  
50 203 content.  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 204 In addition to assessing foliar sodium, we also used multi-model inference to examine the cover  
4  
5 205 response of each plant for which sodium was measured in each plot as a function of the sodium  
6  
7 206 concentration of that species. For assessing the effects of foliar sodium on plant cover in response to the  
8  
9  
10 207 experimental treatments, species with less than 0.1% cover in a plot were removed (23 out of 1,828  
11  
12 208 records or 1.3%).

13  
14  
15 209 All analyses were performed in R (version 3.3; R Foundation for Statistical Computing).  
16  
17

## 18 210 RESULTS

### 21 211 *Patterns of foliar sodium*

22  
23  
24 212 Foliar sodium in 201 of the most abundant grassland plant species from 26 sites on four continents,  
25  
26 213 including representatives of 32 plant families, varied across five orders of magnitude among sites and  
27  
28 214 the most abundant plant taxa in unmanipulated plots. Foliar sodium ranged from 0.5 ppm in *Phleum*  
29  
30 215 *pratense* (Poaceae) to 28,271 ppm in *Epiltes australis* (Asteraceae, SI Table 1), and average site-level  
31  
32 216 plant sodium across the most abundant species ranged from 2.7 ppm (at Konza Prairie in the North  
33  
34 217 American Great Plains) to 9,715 ppm (at Burrawan in southeastern Australia). Foliar sodium of the most  
35  
36 218 abundant species in control plots was similar across grasses with C<sub>4</sub> (463 ± 201 ppm) and C<sub>3</sub> (624 ± 159  
37  
38 219 ppm) photosynthetic pathways ( $P = 0.10$ ). However, across all taxa in unmanipulated (control) plots,  
39  
40 220 foliar sodium varied spatially both within and among sites (Fig. 1); mean foliar sodium content also  
41  
42 221 varied substantially among plant families (Fig. 1,  $P < 0.001$ , SI Table 3).  
43  
44  
45

46  
47 222 We found that among sites, mean site-scale foliar sodium in control plots increased with soil sodium  
48  
49 223 (Fig. 2,  $P = 0.015$ ;  $t = 2.68$ ), whereas within sites, foliar sodium did not co-vary with plot-scale soil sodium  
50  
51 224 ( $P = 0.51$ ;  $t = 0.64$ ). In a model that included multiple candidate predictors (site aridity, distance from  
52  
53 225 coast, soil pH, photosynthetic pathway, and soil sodium), foliar sodium declined with increasing site-  
54  
55 226 level water availability (increasing AI;  $P = 0.001$ ) and soil pH (Fig. 3,  $P = 0.04$ , SI Table 4). However, our  
56  
57  
58  
59  
60

1  
2  
3 227 model selection criteria did not retain soil sodium or photosynthetic pathway in final models. The  
4  
5 228 decline in foliar sodium was similar across both coastal and inland sites except for a single site in the UK  
6  
7 229 with high precipitation and exceptionally high sodium ion deposition relative to most locations on Earth  
8  
9 230 (Vet *et al.* 2014) (Fig 3b, Lancaster, UK). In contrast, for sites with neutral to acidic soils (all except one in  
10  
11 231 this study, Sheep Station, USA), there was no relationship between foliar sodium and soil pH (Fig. 3).  
12  
13  
14 232 Thus, the biogeographic variation in foliar sodium content is explained, in part, by a combination of local  
15  
16 233 conditions, including soil sodium availability and aridity.  
17  
18

#### 19 234 *Responses of foliar sodium to a changing environment*

20  
21  
22 235 Nutrients and herbivory interacted to determine the foliar sodium of the most abundant plants, and the  
23  
24 236 strength of this effect depended on aridity but not soil pH (SI Table 5). In particular, at mesic sites, when  
25  
26 237 herbivores were present, nutrient addition favored abundant plants with high foliar sodium compared  
27  
28 238 to plants in ambient (control) plots (Fig. 4a, SI Table 5). As a result, the addition of the full suite of  
29  
30 239 nutrients (N+P+K $\mu$ , but not Na) outside of fences weakened the negative effect of increasing water  
31  
32 240 availability (increasing AI) on foliar sodium content (Fig. 4b). The factorial nutrient addition experiment  
33  
34 241 clarified that the interaction between aridity and nutrient supply was primarily driven by the effects of  
35  
36 242 potassium and micronutrients (K $\mu$ ) and to a lesser extent the effects of nitrogen and phosphorus  
37  
38 243 addition (SI Table 6, SI Fig. 1).  
39  
40  
41  
42

43 244 We examined the subset of species that were sampled multiple times among plots and sites to explore  
44  
45 245 the role of intraspecific variability of sodium content in determining these observed responses. Of the  
46  
47 246 201 species in this experiment, 41 were among the most abundant (and therefore sampled) in plots at  
48  
49 247 more than one site, and 94 were sampled in both control and treatment plots within sites. Models of  
50  
51 248 the subset of species present among sites and in both control and treatment plots were qualitatively  
52  
53  
54 249 similar to models of the larger dataset for both experiments (SI Tables 7 and 8), suggesting that some of  
55  
56  
57  
58  
59  
60

1  
2  
3 250 the observed variation in foliar chemistry is attributable to intraspecific change in foliar sodium content  
4  
5 251 in response to the biotic and abiotic environment.

7  
8 252 *Effects of foliar sodium on grassland species composition*  
9

10  
11 253 The sodium content of foliage and plot-scale nutrient supply contributed to the effects of herbivores on  
12  
13 254 changes in the relative abundance of grassland plant species. Fertilization (with NPK $\mu$ ) increased the  
14  
15 255 cover of the most abundant species, and in the presence of herbivores, the abundance of species low in  
16  
17 256 foliar sodium increased in response to fertilization, whereas high sodium species became less abundant  
18  
19 257 when fertilized (Fig. 5). However, in the absence of herbivores, fertilization had no consistent effects on  
20  
21 258 species abundances in relation to their foliar sodium concentration (SI Table 9, SI Fig. 2). These effects  
22  
23 259 on foliar sodium were independent of the intensity of herbivory among sites (measured as the site-level  
24  
25 260 log ratio of live biomass inside and outside of herbivore exclusion fences ( $P > 0.57$  for all main effects  
26  
27 261 and interactions; importance  $< 0.40$  [model not shown]). The factorial nutrient addition experiment  
28  
29 262 clarified that, in the presence of herbivores, the addition of any elemental nutrient caused dominant  
30  
31 263 plant species with relatively high foliar sodium content to decline more than species with lower foliar  
32  
33 264 sodium (SI Table 10); this effect was greatest in response to fertilization with P (SI Table 10). These  
34  
35 265 results point to selective consumption by herbivores of high nutrient, high sodium plants.  
36  
37  
38  
39  
40

41 266 DISCUSSION  
42  
43

44 267 This multi-continent, biogeographic study demonstrated that foliar sodium in dominant grassland plants  
45  
46 268 is highly variable among sites and even plots within a site, and there also is significant variation in foliar  
47  
48 269 sodium among families and taxa within families, regardless of geographic location. These patterns likely  
49  
50 270 reflect variation in long-term environmental conditions (e.g., aridity, grazing) that have selected for  
51  
52 271 species with differing strategies for environmental sodium uptake. While there is evidence for  
53  
54 272 phylogenetic conservation of cation transport proteins that can influence sodium uptake (Schachtman &  
55  
56  
57  
58  
59  
60

1  
2  
3 273 Liu 1999) with predictable differences across photosynthetic pathways (Brownell & Crossland 1972),  
4  
5 274 photosynthetic pathway was not a predictor of foliar sodium in grasses. Nonetheless, the very highest  
6  
7 275 foliar sodium content recorded in this study was 9% (91,818 ppm) in *Eragrostis curvula* (Poaceae,  
8  
9 276 commonly called African Lovegrass) found at Burrawan, Australia. This species has a C<sub>4</sub> photosynthetic  
10  
11 277 pathway, indicating a physiological requirement for sodium, and this site is among the more arid sites in  
12  
13 278 the experiment, suggesting that both photosynthetic pathway (Brownell & Crossland 1972; Furumoto *et*  
14  
15 279 *al.* 2011) and aridity (Raheja 1966) can be strongly associated with foliar sodium, in some cases.  
16  
17 280 However, while individual species supported this hypothesis, as a group, C<sub>4</sub> grasses were not  
18  
19 281 consistently high in foliar sodium.  
20  
21  
22  
23  
24 282 The results of this globally-extensive study demonstrate that the relative abundance of plant species in  
25  
26 283 grasslands is altered by herbivores as a function of sodium content and elemental nutrient supply. In  
27  
28 284 particular, herbivores in grasslands spanning four continents with a variety of herbivore types and  
29  
30 285 densities consistently reduced the cover of plants with high foliar sodium only in high nutrient  
31  
32 286 conditions. The reduction in abundance of sodium-rich plants in fertilized plots is evidence of targeted  
33  
34 287 herbivory of high sodium, protein-rich plants. In particular, herbivores are attracted to plots with  
35  
36 288 elevated nutrients (Mattson 1980), and selective consumption reduces the abundance those species  
37  
38 289 with the highest sodium. These plants are not likely extirpated from the community, since the same  
39  
40 290 species are generally found at higher abundance inside herbivore exclosures, rather they are likely to be  
41  
42 291 in a constant state of regrowth from having their aboveground foliage selectively consumed. Such  
43  
44 292 selective foraging is common in many ecosystems (Belovsky 1981; Jefferies *et al.* 1994; Wallis de Vries &  
45  
46 293 Schippers 1994; Bartolome *et al.* 1998; Doughty *et al.* 2016). Related to this, the impact of herbivores on  
47  
48 294 sodium content of the most abundant plant species was contingent on aridity, with foliar sodium  
49  
50 295 content high and indistinguishable among experimental treatments at arid sites, but declining with  
51  
52 296 increasing water availability. Our arid region results are consistent with previous work that found  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 297 positive feedbacks generating and maintaining high sodium content grazing lawns because of high  
4  
5 298 evaporation rates under the cropped vegetation (McNaughton 1988). By examining herbivore impacts  
6  
7 299 across a much broader precipitation gradient, we demonstrate that both aridity and herbivory  
8  
9 300 determine foliar sodium biogeography across the world's grasslands, with declining sodium content  
10  
11 301 under increased precipitation and preferential feeding by herbivores.  
12  
13  
14

15 302 Our experimental work also demonstrated that the sodium content of locally abundant plants increases  
16  
17 303 with soil sodium at the site-scale; however, when included in models, site aridity was a much more  
18  
19 304 effective predictor of biogeographic variation in foliar sodium than soil sodium. At broad spatial scales,  
20  
21 305 foliar sodium is positively related to soil sodium as has been observed in previous work (Sutcliffe 1959;  
22  
23 306 Epstein 1973; Pardo & Quintero 2002; Maathuis 2014), but foliar sodium was not strongly predicted by  
24  
25 307 distance to coast, a common surrogate for sodium ion deposition (Vet *et al.* 2014). However, because  
26  
27 308 arid regions are characterized by high evapotranspiration relative to precipitation, these sites tend to  
28  
29 309 accumulate salts over time (Raheja 1966). In contrast, coastal sites may have both high ion input and  
30  
31 310 high precipitation (Vet *et al.* 2014), reducing the environmental pools of ions, including sodium, and  
32  
33 311 causing a mismatch between salt deposition and the location of sodic soils (Wicke *et al.* 2011). In this  
34  
35 312 study, the coastal site with exceptionally high foliar sodium relative to site-scale precipitation (Lancaster,  
36  
37 313 UK) is also situated in a location on Earth with an exceptionally high rate of sodium ion input (Vet *et al.*  
38  
39 314 2014), suggesting that site aridity combined with direct measures of site-level sodium ion input rate will  
40  
41 315 likely provide even better predictions of site-level foliar sodium in the most abundant plant taxa. In  
42  
43 316 addition, although we found a decline in foliar sodium with increasing soil pH, this pattern was driven  
44  
45 317 by a single, arid site in the intermountain west of the USA. While this pattern is consistent with  
46  
47 318 expectations of reduced cation uptake in higher pH soils (Tyler & Olsson 2001; Bolan & Brennan 2011),  
48  
49 319 we have only a single site with a pH above neutral. Because soil pH is intimately associated with  
50  
51 320 aridity (Slessarev *et al.* 2016), disentangling the roles of soil pH and aridity in determining grassland  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 321 plant sodium biogeography will require more thorough sampling, particularly at sites with basic soils  
4  
5 322 spanning a range of aridity. Nonetheless, the strong spatial variation in foliar sodium suggests that  
6  
7 323 environmental context is key in determining foliar sodium which, by extension, implies that future  
8  
9 324 environmental changes may alter foliar sodium for herbivores. Given the importance of dietary sodium  
10  
11 325 for herbivores (Seastedt & D. A. Crossley 1981; McNaughton 1988; McNaughton *et al.* 1997; Kaspari *et*  
12  
13 326 *al.* 2008; Doughty *et al.* 2016), biogeographic patterns of foliar sodium in abundant grassland plants may  
14  
15 327 arise from interactions with wild herbivores, and likely have significant implications for the distribution  
16  
17 328 and impacts of consumers in grassland ecosystems.

18  
19 329 The strong difference in the physiological importance of sodium to grassland plants and wild herbivores  
20  
21 330 has gained increasing attention in ecology, with recent calls for a greater understanding of the  
22  
23 331 biogeography of sodium (Kaspari *et al.* 2008). The current study of both patterns and responses to  
24  
25 332 experimental manipulation, performed at 26 sites spanning wide biotic and abiotic gradients,  
26  
27 333 demonstrates that aridity, soil acidity, nutrient supply, and herbivory, interact to influence  
28  
29 334 biogeographic patterns of foliar sodium and its effect on plant abundance. In future environments,  
30  
31 335 climate change is expected to impact global patterns of soil salinity via changes in precipitation and  
32  
33 336 evapotranspiration (Schofield & Kirkby 2003). The current results suggest that the impact of these  
34  
35 337 changes on grassland plant composition will depend on the interactive effects of large-scale changes in  
36  
37 338 aridity and elemental nutrient (N, P) supply and the resulting nutritional value for consumers.

#### 339 ACKNOWLEDGMENTS

340 This work was generated using data from the Nutrient Network experiment (<http://www.nutnet.org>),  
341 funded at the site-scale by individual researchers. Coordination and data management have been  
342 supported by funding to E. Borer and E. Seabloom from the National Science Foundation Research  
343 Coordination Network (NSF-DEB-1042132) and Long Term Ecological Research (NSF-DEB-1234162 to  
344 Cedar Creek LTER) programs, and the Institute on the Environment (DG-0001-13). We also thank the

521

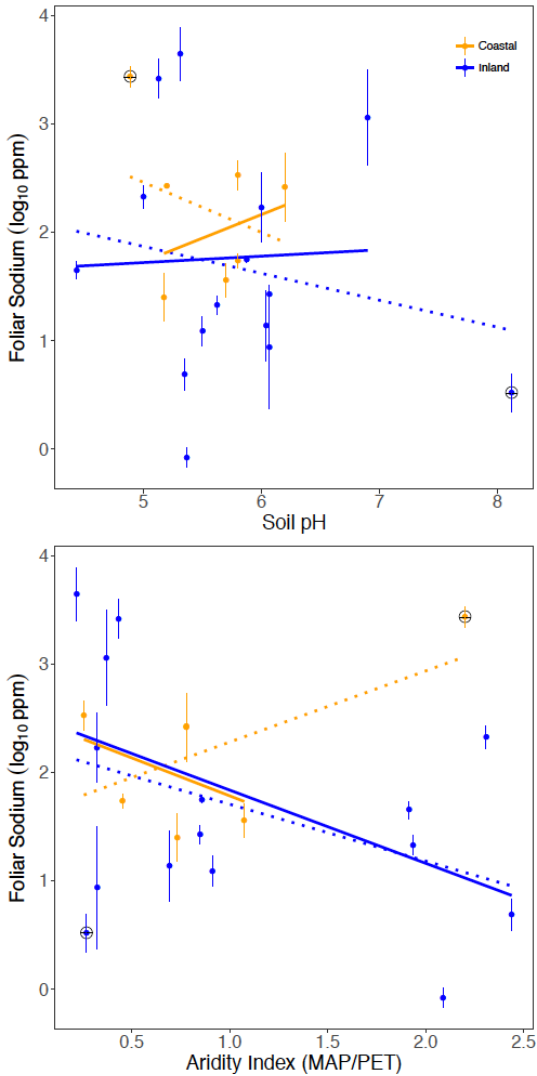

522 **Fig. 1.** *Foliar Na variation across taxonomic and spatial scales:* Variance components analysis of foliar  
523 sodium in the 85 locally-abundant plant taxa from control plots at 26 sites across nested taxonomic and  
524 spatial scales. Foliar sodium for 41 species was measured at two or more sites. Variation in foliar sodium  
525 associated with plant location is shown in orange; variation associated with taxonomic groups is shown  
526 in blue. Variance explained by genus is extremely small, but non-zero ( $<3 \times 10^{-6}$ ), thus is barely visible in  
527 this graph. SI Table 3 provides the full statistical model associated with this figure.

528

529

530 **Fig. 2. Foliar Na and soil Na:** Foliar sodium increases with soil sodium in 85 locally-abundant plant taxa  
531 from control plots control plots among sites but not among plots or species within sites. Sites have  
532 different colors; site means are shown as large points and small points are species data. Site-level  
533 regression is shown as a black line.

534

535 **Fig. 3. Predictors of foliar Na:** The foliar sodium of the most abundant plant species declined across a  
 536 gradient of plot-scale pH ( $z=2.03$ ,  $P=0.04$ ) and site-scale water availability (MAP/PET;  $z=3.24$ ,  $P=0.001$ ).

537 Data include the 85 taxa across 22 sites that were growing in control plots. Coastal (orange) and Inland

538 (blue) are divided at 100km from a coast. The dashed yellow line shows the model with all sites

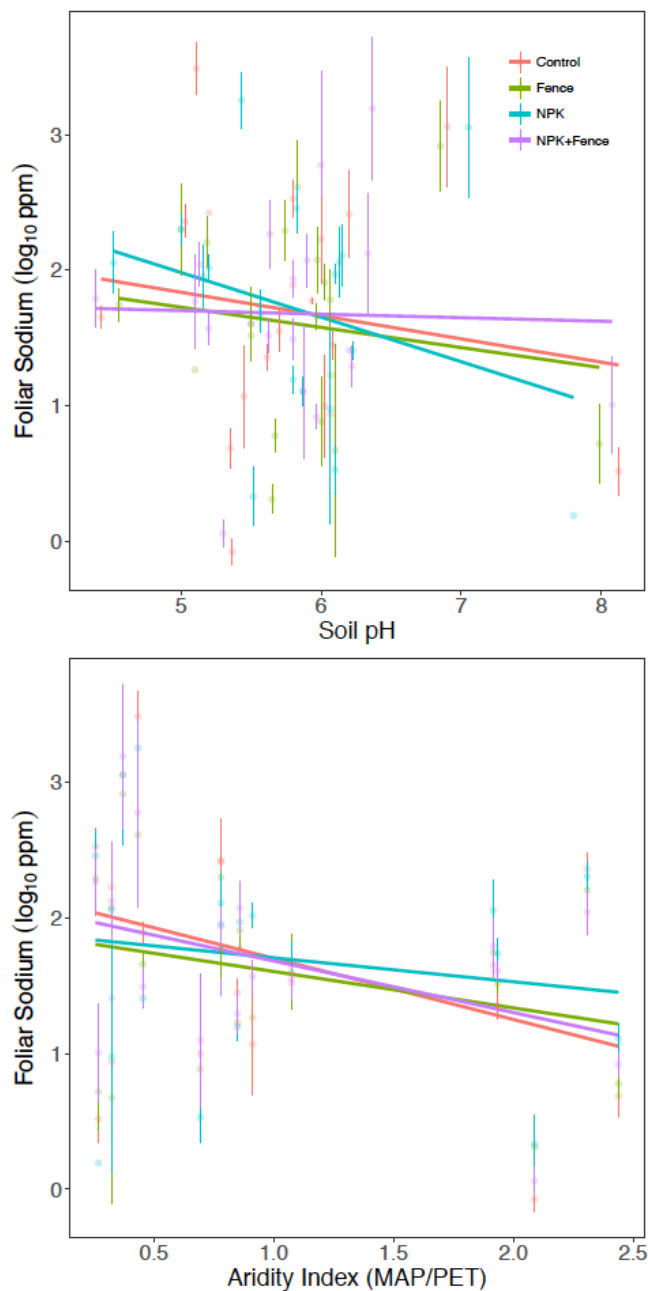

539 included; the solid yellow line shows these relationships without a single site in the UK (Lancaster,

540 orange circled site) with high precipitation and coastal salt input. Similarly, the dashed blue line shows

541 the model with all sites included; the solid blue line shows the relationships without the only site with

542 basic soil pH found in US Intermountain West (Sheep Station, blue circled site). Error bars represent

543  $\pm$ SE. SI Table 4 provides the full statistical model associated with the solid lines shown in this figure.

544

545 **Fig. 4.** Responses of foliar sodium to changes in herbivory and nutrient supply: Response of foliar Na in  
 546 153 locally abundant plants to a factorial combination of fencing to reduce vertebrate herbivory and  
 547 fertilization by a suite of micro- and macronutrients (not including Na<sup>+</sup>) (a) across a gradient in plot-scale  
 548 pH and (b) across a gradient in site-scale water availability. Foliar sodium is higher than expected from  
 549 control plots where precipitation is relatively high and nutrients are added ( $z=3.49$ ,  $P=0.0005$ ). Error bars  
 550 represent  $\pm$ SE. SI Table 5 provides details of the full statistical model.

551

552 **Fig. 5.** *Effects of foliar sodium on grassland species composition:* Response of plant abundance to a  
 553 factorial combination of fencing to reduce vertebrate herbivory and fertilization by a suite macro- and  
 554 micronutrients (not including Na<sup>+</sup>) as function of foliar sodium in 153 grassland plant species. SI Table 9  
 555 shows the final model describing species abundance as a function of treatments and foliar sodium  
 556 content.

557 **SI: DATA AND MODEL TABLES UNDERLYING RESULTS TEXT**

558 **SI Table 1.** Sites, locations, mean annual precipitation (MAP), index of aridity, modeled nitrogen deposition (N Dep.), measured plot-scale soil  
 559 pH, and measured foliar sodium in each of the most abundant species at the site (leaf Na (ppm)).

| Site name                 | Continent     | Country | Latitude   | Longitude  | MAP  | AI     | Leaf Na (ppm) | Soil pH | Soil Na (ppm) |

591

592 **SI Tables 5 & 6. Responses of foliar sodium to a changing environment:**

593 **SI Table 5.** Response of foliar sodium in 153 dominant grassland plant species growing in plots with experimental manipulation of herbivores and  
 594 nutrients. Regression table shows conditional average model results without Lancaster; when this site is included, the results are qualitatively

596 similar but the effect of nutrient addition across the water availability gradient is somewhat weaker due to the extreme outlier. The regression  
 597 table shows the conditional average values across models in which parameters were included, the number of models in which parameters were  
 598 included, and their importance in the models.

599

For Review Only

For Review Only

645  
 646 **SI Figure 1.** Response of foliar sodium in locally abundant plants to a factorial combination of nitrogen, phosphorus, and potassium plus  
 647 micronutrients (not including Na<sup>+</sup>). Plot-scale soil pH and site-scale water availability are significant biogeographic drivers of foliar Na that  
 648 improve model fit, so are included in all models. This analysis includes 179 species from the factorial nutrient addition experimental plots.  
 649

650

651 **SI Figure 2.** Response of plant abundance to a factorial combination of nitrogen, phosphorus, and potassium plus micronutrients (not including

652 Na<sup>+</sup>) as a function of foliar sodium. This analysis includes 179 species from the factorial nutrient addition experimental plots.

653

654

655 **SI Tables 7 and 8. Responses of foliar sodium to a changing environment:**

656 **SI Table 7.** Response of foliar sodium to experimental manipulation of herbivores and nutrients for the subset of 60 species present in control  
657 plots and at least 3 experimentally treated plots of the fence x fertilization experiment. The regression table shows the conditional average  
658 values across models, relative importance values are shown below the table.

**SI Table 12.** All data contributors listed by site; site names match those in SI Table 1. Their effort in providing samples was key to this work.

| <b>Site PI</b>  | <b>Site name(s) from which trait data were contributed</b>  |
|-----------------|---|
| Peter Adler     | Sheep Experimental Station  |
| Jonathan Bakker | Smith Prairie   |
| Lori Biederman  | Chichaqua Bottoms   |
| Dana Blumenthal | Shortgrass Steppe LTER  |
| Elizabeth Borer | Mclaughlin UCNRS, Bunchgrass (Andrews LTER), Sierra Foothills REC, Hopland REC, Lookout<br>(Andrews LTER) |

754  
 755 **SI Figure 3.** Site-level soil pH declines as a function of site-level water availability (MAP/PET); this relationship does not vary as a function of  
 756 distance from coast. Coastal and Inland are divided at 100km from a coast. The Lancaster site in the UK, shown with a black circle and cross-hairs  
 757 in this figure, falls along this line, but has very high coastal sodium influence in its precipitation, leading to exceptionally high site-level sodium  
 758 (see main text).
