The vibro-acoustic response of complex structures with uncertain properties is a problem of great concern for modern industries. In recent years, much research has been devoted to the prediction of this response in the mid-frequency range where, because neither finite element analysis nor statistical energy analysis are appropriate, a hybrid deterministic-statistical approach becomes a suitable solution. Despite its potential, the existence of systems with active components that are too complex to be modelled numerically can limit the application of the method. However, it may still be possible to measure the dynamical response of these structures experimentally. This paper is hence concerned with the possibility of integrating experimental data into a hybrid deterministic-statistical method. To explain the new methodology, two similar case studies, consisting of a deterministic source structure that is coupled to a statistical plate receiver using passive isolators, are used. For each case, the vibratory excitation, characterised using in-situ blocked force measurements, the source structure mobility, and the isolators stiffness are experimentally determined and inserted in the proposed hybrid model of the system. The paper explains the techniques used for obtaining the considered experimental data and the theoretical model proposed for describing the systems. To validate the proposed approach, the predicted vibration response of the receiver plate is compared to the one obtained by experimentally randomising the plate in both case studies. The results show that a good agreement is obtained, both for the ensemble average response of the receiver structure and for the ensemble variance of this response. Moreover, the upper confidence bounds predicted by the hybrid method enclose well the ensemble of experimental results. The cause of some narrow-band differences observed between the predicted response and the experimental measurements is finally discussed. It is therefore concluded that the capabilities of the hybrid deterministic-statistical method can be clearly enhanced through the incorporation of experimental data prescribing active sub-systems.

1. Introduction

52
53
54
55
56
57
58

The analysis of the vibro-acoustic response of complex structures becomes especially challenging as the wavelength of the propagating waves decreases with the increase of the frequency of excitation. In this

1
2
3 4 situation, the use of Finite Element (FE) models becomes unsuitable due to two main reasons: firstly, the
4 5 number of degrees of freedom required to represent the system may be prohibitively large and secondly,
5 6 the response becomes more and more sensitive to small imperfections that add uncertainty to the predicted
6 7 response. Several alternatives that consider a smaller number of degrees of freedom than a FE formulation
7 8 (being therefore more computationally efficient) have been presented in literature. Examples include the
8 9 variational theory of complex rays [1] and the wave based method [2], both based on the the Trefftz approach.
9 10 Another proposed approach is the use of efficient FE formulations, such as the discontinuous Galerkin method
10 11 with plane waves and Lagrange multipliers [3]. At high-frequencies, both FE difficulties are successfully
11 12 overcome by the Statistical Energy Analysis (SEA) approach, which allows prediction of the mean [4] and
12 13 variance [4, 5] of an ensemble of nominally identical systems by solving a relatively simple power balance
13 14 equation. Additional difficulties arise in the commonly termed 'mid-frequency range', the frequencies where
14 15 neither FE analysis nor SEA are appropriate. Some authors have proposed methods that generalise the
15 16 SEA formulation by, for example, employing a more detailed description of the system, as in the case of
16 17 statistical modal energy distribution analysis (SmEdA) [6], or the vibrational conductivity approach [7]. A
17 18 general wave-based approach for coupling both theories in a single model has been proposed by Shorter
18 19 and Langley [8]. The approach, based on a diffuse field reciprocity result [9, 10], is briefly detailed in the
19 20 next section. This hybrid FE-SEA approach has since been numerically and experimentally validated [11],
20 21 demonstrating its use as a wide-band vibro-acoustic prediction tool. The method has been also extended
21 22 with the development of expressions for determining the variance of the predicted response [12] and, more
22 23 recently, with the inclusion of parametric uncertainties in the FE components of the system [13, 14]. Despite
23 24 the capabilities and potential of the hybrid FE-SEA method, its applicability can be limited in those cases
24 25 where the studied systems contain active structures that are too complex to be modelled numerically. In such
25 26 cases, however, the dynamical response of these subsystems can still be measured experimentally, leading
26 27 to the possibility of a combined experimental/numerical methodology.

27 28 The use of experimental data in SEA models has been considered by many researchers. Cimerman et
28 29 al. [15] reviewed the use of test-based or Experimental SEA (ESEA) methods, in which the prediction
29 30 rely on parameters experimentally determined. Bies and Hamid [16] proposed a power injection method to
30 31 determine the internal and coupling loss factors of two coupled plates. The instabilities of their method
31 32 were addressed by Lalor [17], who proposed an alternative ESEA formulation. Rosen and Borello [18] made
32 33 ESEA available for industrial applications, by developing the SEA-XP software. The accuracy of the ESEA
33 34 formulations has been also discussed by Hopkins [19], who tested methods to identify the wave conversion in
34 35 T-junctions. More recently, Guasch [20] proposed an alternative method to determine coupling loss factors
35 36 from energy transmissibility measurements. Despite its great interest, the experimental approach of ESEA
36 37 methods differs from the one proposed here.

37 38 The independent characterisation of vibratory sources has been of interest to those within the field of

1
2
3
4 39 structural dynamics for many decades. Of the available quantities, there exist two fundamental descriptors of
5 40 structural source activity. These are the blocked force and the free velocity [21]. In this work we are concerned
6 41 primarily with the blocked force, and its application in the construction of a hybrid experimental/numerical
7
8 42 model. The blocked force is defined as the force required to constrain the terminals of a vibration source
9
10 43 such that their kinematics are constrained to zero. Direct measurement of the blocked force is complicated
11
12 44 by the requirement of a sufficiently rigid termination which, in practice, can only be approximated over
13
14 45 a limited frequency range. Recent work by Moorhouse et al. [22] has shown that the blocked force may
15 46 instead be acquired in-situ (i.e. without removing the source from its intended installation) through an
16
17 47 inverse procedure. The in-situ blocked force has since emerged as the most promising method towards
18
19 48 the independent characterisation of structural sources and has found numerous applications within the
20
21 49 automotive [23–31], aerospace [32], domestic product [33] and building acoustics [34] sectors. Whilst the
22
23 50 in-situ blocked force approach has become well established, its experimental implementation is still an area
24
25 51 of active research and its limitations must be acknowledged.

26
27 52 This paper is concerned in the use of experimental data to extend and enhance the applicability of the
28
29 53 hybrid FE-SEA method. The paper presents two case studies where the excitation caused by a vibration
30
31 54 source and the dynamic response of several mechanical components are experimentally characterised in a
32
33 55 form that is suitable to be embedded in the hybrid method formulation. In Section 2, the general formulation
34
35 56 of the hybrid FE-SEA-eXperimental method is presented. The formulation is used in Section 3 to develop
36
37 57 a hybrid model for the case studies considered. Then, the responses predicted by the developed hybrid
38
39 58 models are compared with experimental results in Section 4. Finally, the main conclusions of this work are
40
41 59 summarised in Section 5.

42 60 **2. Theoretical development**

43
44 61 This section presents a brief outline of the theoretical background on which the development of a hybrid
45
46 62 FE-SEA-X model is based. The key aspects of the hybrid FE-SEA method and the expressions used for
47
48 63 predicting the mean and variance of the response of an ensemble of random systems are summarised in
49
50 64 Section 2.1. The section ends with a description of the modifications applied to the hybrid equations in
51
52 65 order to include systems with components that are experimentally characterised. Then, methodologies for
53
54 66 characterising vibratory sources and vibration isolators are described in Sections 2.2 and 2.3, respectively.

55 67 *2.1. The hybrid deterministic-statistical method*

56
57 68 This section presents a brief outline of the general hybrid FE-SEA method formulation, with the addition
58
59 69 of experimental terms. A detailed derivation of the presented expressions is given in [8] and [12].

1
2
3 70 *2.1.1. Method overview and main assumptions*
4

5 71 The hybrid FE-SEA formulation assumes that a built-up structure consists of a deterministic system
6 72 which is coupled to a set of statistical subsystems. Each statistical subsystem is assumed to have random
7
8 73 properties due to material or manufacturing imperfections. The deterministic system, modelled using the
9
10 74 FE approach, is described by a set of degrees of freedom (DoF) representing the detailed deformation of
11
12 75 the system; in contrast, each statistical subsystem is represented by only one DoF, its vibrational energy.
13
14 76 The finite element model of the deterministic system yields a dynamic stiffness matrix \mathbf{D}_d which must be
15
16 77 coupled to the statistical subsystems. This is done by representing the response of each subsystem as the
17
18 78 sum of a "direct field" and a "reverberant field". The direct field is associated with waves generated at the
19
20 79 connections to the FE model, and the coupling is accounted for through the addition of appropriate stiffness
21
22 80 matrices to \mathbf{D}_d . The reverberant (reflective) field is accounted for separately, as explained in Subsection
23
24 81 2.1.2.

25
26 82 As it will be detailed in the following subsections, the hybrid FE-SEA equations yield the mean and
27
28 83 variance of the response of all the components of the built-up structure. The main assumptions of the
29
30 84 method are:

- 31 85 • The response of each statistical subsystem (across its ensemble) constitutes a diffuse wavefield [9, 10].
- 32 86 • The subsystems are weakly coupled through the deterministic system. The hybrid method formulation
- 33 87 considers the junctions between different statistical subsystems to be components of the deterministic
- 34 88 system [8].
- 35 89 • The statistical subsystems are sufficiently random to ensure that the statistics of their isolated natural
- 36 90 frequencies and mode shapes conform to the Gaussian Orthogonal Ensemble (GOE) [35].

37
38
39
40 91 *2.1.2. Ensemble mean response*

41 92 The first step in the application of the hybrid FE-SEA method is the identification of which parts of the
42
43 93 vibro-acoustic system under consideration can be assumed to be deterministic and which ones are better
44
45 94 described as statistical subsystems. The deterministic part is then represented by a finite set of degrees
46
47 95 of freedom (DoF) \mathbf{q} and the statistical part is defined by a set of subsystems, with each subsystem having
48
49 96 a single degree of freedom (the vibrational energy E). As mentioned in the previous subsection, the wave
50
51 97 field generated in each of the statistical subsystems can be understood as the combination of two fields:
52
53 98 the response due to the initially generated waves (direct field), and the contribution from all the waves
54
55 99 generated by the reflections at the subsystem's unknown boundaries (reverberant field). This separation
56
57 100 can be used to define a direct field dynamic stiffness \mathbf{D}_{dir} for each subsystem. This matrix, which will be
58
59 101 only populated for those DoF that define the deterministic boundaries of the subsystem, can be computed
60
61 102 analytically for many simple cases or by a boundary element analysis in general. Then, the contribution of

1
2
3
4 103 the statistical subsystem k on \mathbf{q} is taken into account by, first, adding $\mathbf{D}_{\text{dir}}^{(k)}$ to the dynamic stiffness of the
5 104 deterministic part \mathbf{D}_d and, second, including the forces arising from the existence of the reverberant field in
6 105 each subsystem $\mathbf{f}_{\text{rev}}^{(k)}$. Then, for a given harmonic frequency ω , the governing equations of motion are [11]

$$7 \quad \mathbf{D}_{\text{tot}}(\omega)\mathbf{q}(\omega) = \mathbf{f}_{\text{ext}}(\omega) + \sum_k \mathbf{f}_{\text{rev}}^{(k)}(\omega), \quad (1)$$

$$8 \quad \mathbf{D}_{\text{tot}}(\omega) = \mathbf{D}_d(\omega) + \sum_k \mathbf{D}_{\text{dir}}^{(k)}(\omega), \quad (2)$$

9
10
11
12
13
14
15
16 106 where the ω dependence has been explicitly written for clarity, but will be later omitted for brevity, and
17 107 where \mathbf{D}_{tot} is the dynamic stiffness matrix of the deterministic part augmented by the direct field stiffness
18 108 matrices of the considered subsystems. The force term \mathbf{f}_{ext} is used to prescribe external forces to the
19 109 deterministic part of the system, and that the reverberant force term $\mathbf{f}_{\text{rev}}^{(k)}$ describes, physically, the blocking
20 110 force required to constrain the interface DoF of subsystem k in the presence of the reverberant field.

21
22
23
24 111 The key result to develop the hybrid FE-SEA method equations from Equations (1) and (2) is a reci-
25 112 procity identity derived by Shorter and Langley [8] that relates the cross-spectral matrix of the reverberant
26 113 forces of a subsystem k , denoted as $\mathbf{S}_{ff,\text{rev}}^{(k)}$, with its energy E_k and with its direct field dynamic stiffness
27 114 matrix $\mathbf{D}_{\text{dir}}^{(k)}$. This relationship, valid when the ensemble response constitutes a diffuse random wavefield
28 115 [10], can be expressed as

$$29 \quad \mathbf{S}_{ff,\text{rev}}^{(k)} = \text{E}[\mathbf{f}_{\text{rev}}^{(k)}\mathbf{f}_{\text{rev}}^{(k)*T}] = \left(\frac{4E_k}{\pi\omega n_k} \right) \text{Im}\{\mathbf{D}_{\text{dir}}^{(k)}\}, \quad (3)$$

30
31
32
33
34
35 116 where $\text{E}[\]$ denotes the ensemble average and E_k and n_k are, respectively, the ensemble and time averaged
36 117 vibrational energy and the ensemble averaged modal density of the subsystem.

37
38 118 An analysis of the energy flow in subsystem j leads to a power balance equation of the form [13]

$$39 \quad \omega(\eta_j + \eta_{d,j})E_j + \sum_k \omega\eta_{jk}n_j \left(\frac{E_j}{n_j} - \frac{E_k}{n_k} \right) = P_j + P_{\text{in},j}^{\text{ext}}, \quad (4)$$

40
41
42
43
44 119 where P_j and $P_{\text{in},j}^{\text{ext}}$ are the power inputs from external sources applied, respectively, on the subsystem and
45 120 on the deterministic system, η_j is the loss factor of the subsystem, η_{jk} is a coupling loss factor and $\eta_{d,j}$ is
46 121 the loss factor term associated with the deterministic system. The detailed expressions for these items are
47 122 [13]

$$48 \quad \omega\eta_{d,j} = \frac{2a_j}{\pi n_j} \sum_{r,s} \text{Im}\{D_{d,rs}^{(j)}\} \left(\mathbf{D}_{\text{tot}}^{-1} \text{Im}\{\mathbf{D}_{\text{dir}}^{(j)}\} \mathbf{D}_{\text{tot}}^{-1*T} \right)_{rs}, \quad (5)$$

$$49 \quad \omega\eta_{jk}n_j = \frac{2a_j}{\pi} \sum_{r,s} \text{Im}\{D_{\text{dir},rs}^{(j)}\} \left(\mathbf{D}_{\text{tot}}^{-1} \text{Im}\{\mathbf{D}_{\text{dir}}^{(k)}\} \mathbf{D}_{\text{tot}}^{-1*T} \right)_{rs}, \quad (6)$$

$$P_{\text{in},j}^{\text{ext}} = \frac{\omega}{2} \sum_{r,s} \text{Im}\{D_{\text{dir},rs}^{(j)}\} \left(\mathbf{D}_{\text{tot}}^{-1} \mathbf{S}_{ff} \mathbf{D}_{\text{tot}}^{-1*T} \right)_{rs}, \quad (7)$$

where the term a_j is included to take into account local concentrations in the wavefield [12, 36] and where \mathbf{S}_{ff} is the cross-spectral matrix of external forces. In Equations (5)-(7) the subscripts rs are used to identify the r sth components of each matrix.

The hybrid FE-SEA method also yields the cross-spectral matrix of the response \mathbf{q} , which can be expressed as

$$\mathbf{S}_{qq} = \text{E}[\mathbf{q}\mathbf{q}^{*T}] = \mathbf{D}_{\text{tot}}^{-1} \left[\mathbf{S}_{ff} + \sum_k \left(\frac{4a_k E_k}{\pi\omega n_k} \right) \text{Im}\{\mathbf{D}_{\text{dir}}^{(k)}\} \right] \mathbf{D}_{\text{tot}}^{-1*T}. \quad (8)$$

The set of equations obtained by writing Equation (4) for each subsystem can be expressed in matrix form:

$$\mathbf{C}_0 \hat{\mathbf{E}} = \mathbf{P} + \mathbf{P}_{\text{in}}^{\text{ext}}, \quad (9)$$

where $\hat{E}_j = E_j/n_j$ is the ensemble averaged modal energy (i.e. the energy per mode) for subsystem j . Equation (9), which has exactly the same form of the SEA equations [4], relates the power inputs applied from external forces \mathbf{P} and $\mathbf{P}_{\text{in}}^{\text{ext}}$ with the subsystem modal energies $\hat{\mathbf{E}}$. The entries of the matrix \mathbf{C}_0 can be computed using Equations (5) and (6). Equation (9) can be solved to obtain the subsystem energies, and these energies can then be substituted in Equation (8) to obtain the deterministic response.

2.1.3. Ensemble variance response

It is shown by Langley and Cotoni [12] that an expression in the form of Equation (9) can be written for each member of the random ensemble as

$$\mathbf{C}\bar{\mathbf{E}} = \bar{\mathbf{P}} + \bar{\mathbf{P}}_{\text{in}}^{\text{ext}}, \quad (10)$$

where \bar{E}_j is the modal energy of subsystem j (so that $\hat{\mathbf{E}} = E[\bar{\mathbf{E}}]$) and where the overbar on a quantity indicates that it is referred to one member of the ensemble, instead of being an ensemble average. It follows from a first order expansion in \mathbf{C} [12] that $\mathbf{C}_0 = E[\mathbf{C}]$. Therefore, $\bar{\mathbf{P}}$, $\bar{\mathbf{P}}_{\text{in}}^{\text{ext}}$ and \mathbf{C} vary randomly across the ensemble but, their mean values can be computed from Equations (4)-(7).

Then, the ensemble covariance of the subsystem modal energies \bar{E}_i and \bar{E}_j is obtained by considering a first order perturbation expansion of Equation (10). It has been shown in [12] that this covariance can be expressed as

$$\begin{aligned}
\text{Cov}[\bar{E}_i, \bar{E}_j] &= \sum_k \sum_s C_{0,ik}^{-1} C_{0,js}^{-1} \text{Cov}[\bar{P}_k + \bar{P}_{\text{in},k}^{\text{ext}}, \bar{P}_s + \bar{P}_{\text{in},s}^{\text{ext}}] \\
&+ \sum_k \sum_s \sum_{r \neq k} [(C_{0,ik}^{-1} - C_{0,ir}^{-1}) C_{0,js}^{-1} + (C_{0,jk}^{-1} - C_{0,jr}^{-1}) C_{0,is}^{-1}] \hat{E}_r \text{Cov}[C_{kr}, \bar{P}_s + \bar{P}_{\text{in},s}^{\text{ext}}] \\
&+ \sum_k \sum_p \sum_{s \neq k} \sum_{r \neq p} (C_{0,ik}^{-1} - C_{0,is}^{-1}) (C_{0,jp}^{-1} - C_{0,jr}^{-1}) \hat{E}_s \hat{E}_r \text{Cov}[C_{ks}, C_{pr}],
\end{aligned} \tag{11}$$

where the $C_{0,jk}^{-1}$ represents the jk th component of \mathbf{C}_0^{-1} . The covariance terms on the right-hand side of Equation (11) can be derived by using random matrix theory and Equation (3). A detailed derivation of these terms can be found in [12] and, for the sake of brevity, general expressions for these terms will not be repeated here. However, the particular expressions used for the case studies considered in this work will be presented in Subsection 3.6. It is important to mention that, once the hybrid mean equations have been solved, all the right-hand side terms of Equation (11) are known quantities.

The randomness in the subsystems leads to randomness in the response of the deterministic system. Langley and Cotoni [12] have shown that the ensemble variance of \mathbf{S}_{qq} is given by

$$\begin{aligned}
\text{Var}[(\mathbf{S}_{qq})_{ij}] &= 2(\mathbf{D}_{\text{tot}}^{-1} \mathbf{S}_{ff} \mathbf{D}_{\text{tot}}^{-1*T})_{ij} \sum_k \hat{E}_k G_{ij}^{(k)} \\
&+ \sum_{k,s} \{2\text{Cov}[\bar{E}_k, \bar{E}_s] + \hat{E}_k \hat{E}_s\} G_{ij}^{(k)} G_{ij}^{(s)},
\end{aligned} \tag{12}$$

where

$$\mathbf{G}^{(k)} = \left(\frac{4a_k}{\omega\pi} \right) \mathbf{D}_{\text{tot}}^{-1} \text{Im}\{\mathbf{D}_{\text{dir}}^{(k)}\} \mathbf{D}_{\text{tot}}^{-1*T}. \tag{13}$$

As in the case of the ensemble average response, once Equation (11) has been solved to obtain the subsystem covariances $\text{Cov}[\bar{E}_i, \bar{E}_j]$, these can be substituted in Equation (12) to determine the deterministic system variance $\text{Var}[(\mathbf{S}_{qq})_{ij}]$.

2.1.4. Hybrid FE-SEA-X method

The hybrid FE-SEA method can be enhanced by considering that some of the deterministic components of the system are modelled using experimental data instead of using a FE or an analytical approach. This experimental data can be characterising either a passive quantity or an active quantity of the structure. More precisely, the dynamic stiffness matrix of the deterministic part of the system, \mathbf{D}_d , can be assumed to be composed as a combination of a numerically/analytically determined dynamic stiffness matrix $\mathbf{D}_{d,\text{FE}}$ and one or more experimentally determined dynamic stiffness matrices $\mathbf{D}_{d,\text{exp}}^{(j)}$. Then

$$\mathbf{D}_d = \mathbf{D}_{d,\text{FE}} + \sum_j \mathbf{D}_{d,\text{exp}}^{(j)}, \tag{14}$$

1
2
3
4 164 where, the summation represents the assembly of the various matrices in the conventional fashion.

5 165 A similar decomposition can be considered for the cross-spectral matrix of external forces, which can be
6
7 166 expressed as

$$\mathbf{S}_{ff} = \mathbf{S}_{ff,FE} + \sum_j \mathbf{S}_{ff,exp}^{(j)}, \quad (15)$$

8
9
10
11
12 167 where $\mathbf{S}_{ff,exp}^{(j)}$ is an experimentally determined cross-spectral blocked force matrix.

13
14 168 The procedures necessary for experimentally determining $\mathbf{D}_{d,exp}^{(j)}$ and $\mathbf{S}_{ff,exp}^{(j)}$ will be discussed in the
15
16 169 following.

17 18 170 *2.2. Characterisation of structure-borne sound sources*

19
20 171 A vibratory source is an active sub-system that generates a disturbance as a result of some internal, often
21
22 172 inaccessible, mechanism. Unlike passive sub-systems, a vibratory source is characterised by two parameters.
23
24 173 The first, a passive quantity describing the source's ability to transfer energy, and the second, an active
25
26 174 quantity describing the operational behaviour of the source. In the context of the hybrid FE-SEA-X method
27
28 175 discussed above, these quantities are characterised, *independently*, by the sub-system's free interface dynamic
29
30 176 stiffness matrix, $\mathbf{D}_{d,exp}$, and blocked force, $\bar{\mathbf{f}}$, respectively.

31 177 *2.2.1. Free interface dynamic stiffness matrix*

32 178 The free interface dynamic stiffness matrix, $\mathbf{D}_{d,exp}^{(S)}$, of an experimental sub-system S describes the force
33
34 179 on each DoF when another DoF is displaced, whilst all others are fixed. This constraint makes the direct
35
36 180 measurement of $\mathbf{D}_{d,exp}^{(S)}$ impractical. Instead, it may be determined through its inverse relationship with
37
38 181 some measurable frequency response function (FRF) matrix, for example, the free mobility.

39 182 The free mobility of a sub-system with M interface DoF, $\mathbf{Y}_S \in \mathbb{C}^{M \times M}$, is an independent characterisation
40
41 183 of its passive properties and is defined by the velocity/force ratios at and between its interface DoF whilst
42
43 184 uncoupled and freely suspended. Analogous quantities include the free accelerance and the free receptance,
44
45 185 which are related to the free mobility through integration and differentiation, respectively.

46
47 186 Experimentally, a close approximation to the free mobility is achieved by resiliently suspending the
48
49 187 sub-system and measuring its interface dynamics directly. However, if the sub-system is very large, or too
50
51 188 lightweight, resilient suspension may not be practical or yield a suitable free boundary condition. In this
52
53 189 case decoupling procedures may be required [37, 38]. Alternatively, the source mobility may be obtained, in
54
55 190 theory, from a numerical model.

56
57 191 Once acquired, the free mobility may be used to determine the free interface dynamic stiffness matrix
58
59 192 required by the hybrid method,

$$\mathbf{D}_{d,exp}^{(S)} = i\omega \mathbf{Y}_S^{-1}. \quad (16)$$

1
2
3
4 193 It is important to note that the inversion of measured FRF matrices is an important source of errors in
5 194 experimental sub-structuring [39]. Care should therefore be taken to ensure that a reliable \mathbf{Y}_S is obtained.
6

7
8 195 *2.2.2. In-situ blocked force*

9 196 The blocked force is a fundamental descriptor of structural source activity and is defined as the force
10
11 197 required to block the terminals of a vibration source such that their velocity is zero (see Figure 1a) [21]. It
12
13 198 was shown by Moorhouse et al. [22] that the blocked force may be determined ‘in-situ’ through an inverse
14
15 199 procedure. The relation of note is given by,

$$\mathbf{v}_{C_b} = \mathbf{Y}_{C_{bc}} \bar{\mathbf{f}}_{S_c}, \quad (17)$$

16
17
18
19 200 where $\mathbf{Y}_{C_{bc}} \in \mathbb{C}^{N \times M}$ is the measured mobility matrix of the coupled assembly in which the source is
20
21 201 installed, $\mathbf{v}_{C_b} \in \mathbb{C}^N$ is a measured operational velocity vector, and $\bar{\mathbf{f}}_{S_c} \in \mathbb{C}^M$ is the vector of unknown
22
23 202 blocked forces. Here, subscripts b and c represent remote receiver and coupling interface DoFs, respectively.
24
25 203 For $N = M$, providing that the measured mobility matrix is of full rank, a unique solution is found through
26
27 204 the inverse mobility matrix $\mathbf{Y}_{C_{bc}}^{-1}$. For $N > M$, the Moore-Penrose pseudo inverse [40] may be used in place
28
29 205 of the classical matrix inverse, leading to a least squares solution of the problem. The remote DoFs b are
30
31 206 collocated with the DoFs c when measurements are performed solely at the coupling interface. In such a case
32
33 207 over-determination may be achieved by including an additional set of remote DoFs, such that the interface
34
35 208 DoFs are a subset of those used to determine the blocked forces.

36
37 209 The experimental implementation of Equation (17) requires a two part measurement procedure. In part
38
39 210 one, the source is turned on and the operational velocity, \mathbf{v}_{C_b} , is measured. In the other, the source is turned
40
41 211 off and the mobility matrix, $\mathbf{Y}_{C_{bc}}$, is measured.

42
43 212 Once the blocked forces related to a vibratory source are determined, they can be used to compute the
44
45 213 associated experimental cross-spectral blocked force matrix as follows

$$\mathbf{S}_{ff,\text{exp}}^{(j)} = \bar{\mathbf{f}}_{S_c} \bar{\mathbf{f}}_{S_c}^{*T}. \quad (18)$$

46
47 214 This cross-spectral matrix can then be used to compute the cross-spectral matrix of external forces \mathbf{S}_{ff}
48
49 215 using Equation (15).

Figure 1: Diagrams for blocked force and isolator characterization.

2.3. Characterisation of vibration isolators

It is typical to place vibratory sources on resilient foundations or footings so as to reduce the severity of their transmitted vibration. It is important therefore to be able to correctly characterise the properties of such elements in a way that they may be included in a hybrid model.

The preferred quantity for the characterisation of a resilient element is the dynamic transfer stiffness [41], defined as the ratio of the applied displacement at one interface to the blocked force at the other (see Figure 1b). The dynamic transfer stiffness is an independent property of the element and therefore invariant to changes in the dynamics of source and receiver sub-systems (neglecting compressional effects such as pre-load). Whilst there exist standardised methods for the determination of dynamic transfer stiffness [42], they require elements to be removed from their intended installation and installed within specialized test rigs. This is not only inconvenient but arguably places the coupling element under a non-representative mounting condition. An alternative procedure was recently proposed by Meggitt et al. [43], where a coupling interface mobility matrix \mathbf{Y}_C is measured and subsequently inverted, yielding a pair of independent transfer impedances, $\mathbf{Z}_{I_{c1c2}}$ and $\mathbf{Z}_{I_{c2c1}}$,

$$\begin{bmatrix} \mathbf{Z}_{C_{c1c1}} & \mathbf{Z}_{I_{c1c2}} \\ \mathbf{Z}_{I_{c2c1}} & \mathbf{Z}_{C_{c2c2}} \end{bmatrix} = \begin{bmatrix} \mathbf{Y}_{C_{c1c1}} & \mathbf{Y}_{C_{c1c2}} \\ \mathbf{Y}_{C_{c2c1}} & \mathbf{Y}_{C_{c2c2}} \end{bmatrix}^{-1}. \quad (19)$$

Once acquired, the transfer impedance may be related to the dynamic transfer stiffness through,

$$\mathbf{K}_{I_{c1c2}} = i\omega\mathbf{Z}_{I_{c1c2}}. \quad (20)$$

1
2
3
4 231 This approach has been validated and shown to provide an independent and broad-band characterisation
5 232 suitable for the hybrid method [43, 44]. Note that the in-situ method discussed above is related to a more
6
7 233 general class of characterisation techniques referred to as inverse sub-structuring.

8 234 Having determined the dynamic transfer stiffness of the element, an appropriate stiffness matrix $\mathbf{D}_{d,\text{exp}}^{(I)}$
9
10 235 must be formulated for use within the hybrid model. Assuming simple spring like behavior $\mathbf{D}_{d,\text{exp}}^{(I)}$ may be
11 236 approximated as,

$$\mathbf{D}_{d,\text{exp}}^{(I)} = \begin{bmatrix} -\mathbf{K}_{I_{c1c2}} & \mathbf{K}_{I_{c1c2}} \\ \mathbf{K}_{I_{c1c2}} & -\mathbf{K}_{I_{c1c2}} \end{bmatrix}. \quad (21)$$

16 237 The above construction is only valid whilst force is conserved across the element, i.e. below its first internal
17
18 238 resonance. If the coupling element possesses significant internal dynamics and/or requires rotational DoFs
19 239 an alternative construction of $\mathbf{D}_{d,\text{exp}}^{(I)}$ may be required.

22 240 3. Hybrid model for a case study

24
25 241 As a means of illustrating the construction of a hybrid model, two case study structures are considered
26 242 in this paper. Both structures consist of a vibration source coupled resiliently to a large thin plate. In
27
28 243 this section, a brief description of these case studies is followed by the definition of the deterministic and
29 244 random parts of the hybrid model developed to represent them. Then, expressions for the matrices \mathbf{D}_d , \mathbf{S}_{ff}
30
31 245 and \mathbf{D}_{dir} are detailed and, finally, the energy mean and energy variance expressions required for these case
32
33 246 studies are presented.

35 247 3.1. Description of the case studies considered

37 248 Figures 2a and 2b show the two case studies considered in this work. In both cases the vibration source is
38
39 249 connected to a large thin receiver plate using four resilient elements. In the first study, the source subsystem
40 250 is an electric pump that does not allow a direct access to the coupling interface, adding difficulties to its
41
42 251 experimental characterisation. In the second, the source consists of a servomotor bolted to a small aluminium
43 252 plate, and this small plate is bolted to four steel feet which have been designed to facilitate the placement
44
45 253 of sensors in the coupling interface between the vibration source and the resilient elements. In each case
46 254 study, resilient elements of an appropriate size are used. Figure 2b also shows the positions of the set of
47
48 255 accelerometers used to measure the response and some of the additional small masses used to randomise
49
50 256 the large thin plate to produce an ensemble of systems. Additional information regarding the experimental
51
52 257 setup can be found in Section 4.

53 258 The hybrid model of the case studies is developed by determining, for each of them, the matrices \mathbf{D}_d
54
55 259 and \mathbf{S}_{ff} experimentally. Therefore, the model does not contain any FE component and only the second
56 260 right-hand side term in Equations (14) and (15) is considered.

(a) Source-isolators-plate setup for the first case study

(b) Experimental setup for the second case study, with the added masses and the measuring accelerometers on the large thin plate.

Figure 2: Case studies considered

3.2. Definition of the deterministic and statistical parts of the case studies

The case studies are modelled using the hybrid method by considering the vibration source and the four isolators to compose the deterministic part of the structure, and the large receiver plate, to be the (only) statistical subsystem. In order to compute the ensemble mean response of the statistical subsystem it is necessary to derive expressions for the matrices that appear in Equations (5) and (7) (Equation (6) is not computed in a hybrid model that has only one statistical subsystem). The size of these matrices depends on how many DoFs are considered for the deterministic part of the hybrid model.

The aim of the present work is to characterise the dynamical properties of the deterministic subsystem (as represented by \mathbf{D}_d), using experimentally determined properties. Therefore, the response at the DoF considered should be easily (directly or indirectly) measured. It has been assumed that, due to the type of coupling that exists between the different components of the system, it is sufficient to consider the vertical response at points situated at the top and base of the four isolator feet in order to model the system. Then, DoF q_1 to q_4 are defined at the contact between the source system and the top of the isolators, and DoF q_5 to q_8 are defined at the contact between the bottom of the isolators and the large receiver thin plate. A scheme with the position and number of each one of these eight DoF for the second case study is presented in Figure 3. The same positions and numbering are considered for the first case study.

Figure 3: Scheme of the hybrid model used in both case studies, with the considered degrees of freedom and the external forces depicted.

3.3. Determination of \mathbf{D}_d from experimental measurements

The dynamic stiffness matrix of the deterministic part of the system can be expressed as a combination of the experimental dynamic stiffness matrices of the vibration source $\mathbf{D}_{d,\text{exp}}^{(S)}$ and of the experimental dynamic stiffness matrices of each one of the four isolators $\mathbf{D}_{d,\text{exp}}^{(I_k)}$ ($k = 1, \dots, 4$). With the DoF considered $\mathbf{D}_{d,\text{exp}}^{(S)}$ is a 4×4 matrix obtained from Equation (16), and each $\mathbf{D}_{d,\text{exp}}^{(I_k)}$ is a 2×2 matrix obtained from Equation (21). The experimental and numerical procedures performed to obtain both matrices have been described in Sections 2.2.1 and 2.3.

Once the frequency response functions of the deterministic components have been experimentally determined, they are combined to obtain the experimental \mathbf{D}_d . This matrix can be written as

$$\mathbf{D}_d = \begin{bmatrix} d_{11}^{(S)} + d_{11}^{(I_1)} & d_{12}^{(S)} & d_{13}^{(S)} & d_{14}^{(S)} & d_{15}^{(I_1)} & 0 & 0 & 0 \\ d_{21}^{(S)} & d_{22}^{(S)} + d_{22}^{(I_2)} & d_{23}^{(S)} & d_{24}^{(S)} & 0 & d_{26}^{(I_2)} & 0 & 0 \\ d_{31}^{(S)} & d_{32}^{(S)} & d_{33}^{(S)} + d_{33}^{(I_3)} & d_{34}^{(S)} & 0 & 0 & d_{37}^{(I_3)} & 0 \\ d_{41}^{(S)} & d_{42}^{(S)} & d_{43}^{(S)} & d_{44}^{(S)} + d_{44}^{(I_4)} & 0 & 0 & 0 & d_{48}^{(I_4)} \\ d_{51}^{(I_1)} & 0 & 0 & 0 & d_{55}^{(I_1)} & 0 & 0 & 0 \\ 0 & d_{62}^{(I_2)} & 0 & 0 & 0 & d_{66}^{(I_2)} & 0 & 0 \\ 0 & 0 & d_{73}^{(I_3)} & 0 & 0 & 0 & d_{77}^{(I_3)} & 0 \\ 0 & 0 & 0 & d_{84}^{(I_4)} & 0 & 0 & 0 & d_{88}^{(I_4)} \end{bmatrix}, \quad (22)$$

where $d_{ij}^{(S)}$ represents the ij th component of \mathbf{D}_S , and $d_{ij}^{(I_k)}$ represents the ij th component of \mathbf{D}_{I_k} .

3.4. Determination of \mathbf{S}_{ff} from experimental measurements

The cross-spectral matrix of external forces $\mathbf{S}_{ff} = \mathbf{f}\mathbf{f}^{*T}$ is computed using the set of forces acting on the eight DoF considered. In order to do that, the blocked forces that characterise the operational behaviour of the vibration source are experimentally obtained using the in-situ procedure described in Section 2.2.2. This characterisation, which requires measurement at the coupling interface between the source and receiver

parts of the structure, has been performed considering that this coupling interface is defined by the DoF q_1 to q_4 . Therefore, the force vector acting on both case studies is

$$\mathbf{f} = \left(\bar{f}_1 \quad \bar{f}_2 \quad \bar{f}_3 \quad \bar{f}_4 \quad 0 \quad 0 \quad 0 \quad 0 \right)^T, \quad (23)$$

where, for each case study and for each type of excitation considered, the blocked forces \bar{f}_i are determined using Equation (17).

3.5. Determination of \mathbf{D}_{dir} for the case studies

The direct field dynamic stiffness matrix for a set of point contacts on a statistical thin plate can be computed using analytical techniques. As the deterministic boundaries for the case study considered are simply the DoF q_5 to q_8 , \mathbf{D}_{dir} can be easily computed using the analytical expression of the transverse response of an infinite thin plate to a vertical point load (due to the type of coupling that exists between the plate and the isolators, it has been assumed that the effect of the in-plane forces and bending moments can be neglected). The response at a position i due to a point load applied at a position j can be expressed as [45]

$$H_{ij} = H(r_{ij}) = \frac{H_0^{(2)}(k_B r_{ij}) - 2i/\pi K_0(k_B r_{ij})}{8i\omega\sqrt{D\rho h}}, \quad (24)$$

where r_{ij} is the distance between both positions, $H_0^{(2)}$ is the Hankel function of the second kind and zeroth order, K_0 is the modified Bessel function of the second kind and zeroth order, D is the flexural rigidity of the plate, ρ is its mass density, h is its thickness and $k_B = (\rho h \omega^2 / D)^{1/4}$ is the plate bending wavenumber.

Equation (24) can be used to build a 4×4 matrix of plate receptances \mathbf{H} that defines the response at the boundary DoF q_5 to q_8 . The matrix \mathbf{D}_{dir} can then be simply obtained by inverting \mathbf{H} and inflating the resulting matrix to the eight DoF considered. This yields

$$\mathbf{D}_{\text{dir}} = \begin{bmatrix} \mathbf{0}_{4 \times 4} & \mathbf{0}_{4 \times 4} \\ \mathbf{0}_{4 \times 4} & \mathbf{H}^{-1} \end{bmatrix}, \quad (25)$$

where $\mathbf{0}_{4 \times 4}$ denotes a 4×4 matrix of zeros.

3.6. Energy mean and variance expressions for the case studies

In both case studies the structure is modelled considering only one statistical subsystem, and external forces are only applied on the deterministic part of the system. Therefore, Equation (4) reduces to

$$\omega(\eta + \eta_d)E = P_{\text{in}}^{\text{ext}}, \quad (26)$$

1
2
3
4 314 where the subsystem subscripts have been omitted, and where $\omega\eta_d$ and $P_{\text{in}}^{\text{ext}}$ are computed using Equations
5 315 (5) and (7). Furthermore, the covariance expression defined by Equation (11) is reduced to the variance of
6
7 316 the subsystem modal energy, which can be written as

$$\text{Var}[\bar{E}] = C_0^{-2} \text{Var}[\bar{P}_{\text{in}}^{\text{ext}}] = C_0^{-2} \text{Relvar}[\bar{P}_{\text{in}}^{\text{ext}}] \mathbb{E}[\bar{P}_{\text{in}}^{\text{ext}}]^2. \quad (27)$$

11
12 317 In this case, the matrix \mathbf{C}_0 defined in Equation (9) is reduced to $C_0 = \omega(\eta + \eta_d)n$, and the value of
13 318 $\mathbb{E}[\bar{P}_{\text{in}}^{\text{ext}}]$ can be again computed using Equation (7). The relative variance of the power input $\text{Relvar}[\bar{P}_{\text{in}}^{\text{ext}}]$
14
15 319 is computed using the general expression for the relative covariance of the power inputs applied to different
16
17 320 subsystems presented in [12]. For a system composed of only one statistical subsystem, this expression is
18 321 reduced to

$$\text{Relvar}[\bar{P}_{\text{in}}^{\text{ext}}] = \frac{a}{\pi m'} \left[\frac{\mathbf{q}^{(0),*T} \mathbf{J} \mathbf{q}^{(0)}}{\mathbf{q}^{(0),*T} \text{Im}\{\mathbf{D}_{\text{dir}}\} \mathbf{q}^{(0)}} \right]. \quad (28)$$

23
24 322 In Equation (28), $\mathbf{q}^{(0)} = \mathbf{D}_{\text{tot}}^{-1} \mathbf{f}$ is the zeroth order term in the perturbation expansion used in [12] to
25 323 obtain an approximate solution of the equation of motion of the master system. In the considered case
26
27 324 studies, the vector of external forces \mathbf{f} is the vector of blocked forces defined in Equation (23). Additionally,
28 325 $m' = \omega\eta'n$ is the effective modal overlap of the subsystem, with $\eta' = 1/(\omega n C_0^{-1})$ being the effective in-situ
29
30 326 loss factor [4]. As before, the parameter a takes into account local concentrations in the wavefield [12, 36].
31
32 327 Finally, for a single subsystem the Hermitian matrix \mathbf{J} takes the following form

$$\begin{aligned} \mathbf{J} = & 4\text{Im}\{\mathbf{D}_{\text{dir}}\} \mathbf{D}_{\text{tot}}^{-1} \text{Im}\{\mathbf{D}_{\text{dir}}\} \mathbf{D}_{\text{tot}}^{-1*T} \text{Im}\{\mathbf{D}_{\text{dir}}\} + \text{Im}\{\mathbf{D}_{\text{dir}}\} \\ & - 2i\text{Im}\{\mathbf{D}_{\text{dir}}\} \mathbf{D}_{\text{tot}}^{-1} \text{Im}\{\mathbf{D}_{\text{dir}}\} + 2i\text{Im}\{\mathbf{D}_{\text{dir}}\} \mathbf{D}_{\text{tot}}^{-1*T} \text{Im}\{\mathbf{D}_{\text{dir}}\}. \end{aligned} \quad (29)$$

33 34 35 36 37 38 39 40 328 **4. Comparison with experimental results**

41 42 329 *4.1. Case study I: electric pump/isolators/damped plate*

43 44 330 *4.1.1. The test system and the experimental setup*

45
46 331 The first case study considered in this work, shown in Figure 2a, consisted of an electric pump connected
47 332 to a receiver large thin plate using four resilient elements. This type of vibration source is a realistic source
48
49 333 likely encountered in practice. The construction of a hybrid model for this assembly required to characterise
50
51 334 experimentally the source mobility, the blocked forces acting on the source-isolators interface (for each type
52
53 335 of excitation considered) and the dynamic stiffness of the isolators.

54
55 336 For the measurement of its free mobility \mathbf{Y}_S , the source was suspended on soft elastic bungees. Each
56
57 337 foot was instrumented with a single accelerometer, located directly above the coupling interface. Due to

1
2
3
4 338 restricted interface access, excitations were applied from beneath. A spaced pair of excitations were applied
5 339 at each interface DoF. Appropriate averaging and sign corrections returned the free source mobility.

6 340 In the characterisation of its blocked force the source was resiliently coupled to a second assembly. With
7
8 341 access to the coupling interface restricted the blocked force was determined using remote receiver DoFs b
9
10 342 only. A two fold over-determination was achieved using eight remote DoFs. The transfer mobility between
11 343 the coupling interface and each remote DoF b_i was measured reciprocally. The operational velocities at b
12
13 344 were measured for both operational and artificial excitation conditions. For repeatability the operational
14
15 345 velocities due to the artificial excitation were normalised to the input force. The blocked forces were
16 346 subsequently calculated as per Section 2.2.2.

17 347 The four resilient elements used in this case study (type: Fibet 1413vv10-60) were assumed to have
18 348 nominally identical stiffness values. As such only a single element was characterised. This was done using
19 349 the in-situ approach presented in Section 2.3. The resilient element was placed in a mass-isolator-mass
20
21 350 assembly, as illustrated in Figure 1b, for characterization prior to constructing the main assembly. A spaced
22
23 351 pair of accelerometers were mounted above and below the coupling element and excitations performed at
24
25 352 each. The resulting mobilities were averaged appropriately to yield the coupling interface mobility matrix,
26
27 353 $\mathbf{Y}_C \in \mathbb{C}^{2 \times 2}$. The element's transfer stiffness was then determined as per Equations (19) and (20). The
28
29 354 resilient elements were characterised only in the vertical translational DoFs, i.e. in-plane and rotational
30
31 355 components were neglected. This was justified based on previous success when using the same source and
32
33 356 coupling elements in an experimental sub-structuring prediction [46]. Similarly, for the resilient elements
34
35 357 used in case study two experimental evidence in [47] justified this approximation. Furthermore, inspection
36
37 358 of the transfer stiffness obtained (for both case studies) revealed that there were no significant dynamics
38
39 359 (i.e. internal mount resonances) in the frequency range considered, thus enabling the use of Equation (21)
40
41 360 to approximate the element stiffness matrix.

42 361 The receiver subsystem was a large aluminium rectangular thin plate of dimensions $L_1 = 1$ m, $L_2 = 0.8$
43 362 m and thickness $h = 3$ mm. The mechanical parameters considered for the aluminium were density $\rho = 2700$
44 363 $\text{kg}\cdot\text{m}^{-3}$, Young modulus $E = 70$ GPa, and Poisson ratio $\nu = 0.33$. The modal density was computed using
45 364 the asymptotic expression for the bending modes of a thin plate [4] $n = L_1 L_2 / 4\pi \sqrt{\rho h / D}$, giving $n = 0.013$
46 365 modes/(rad/s). The edges of the plate were supported on an external structure and the damping of the
47
48 366 structure was increased by gluing viscoelastic damping patches to the plate structure. The loss factor of the
49
50 367 plate was experimentally determined from its response without the deterministic subsystem, i.e. the source
51
52 368 and the four isolators, placed on it. The loss factor was slightly frequency dependent, with an average value
53
54 369 of $\eta = 2.3\%$ in the frequency range studied (1-1250 Hz). With these values, the modal overlap factor of the
55
56 370 plate at 1000 Hz is $m = \omega n \eta = 1.87$.

57 371 In order to create an ensemble of subsystems, the plate response was randomised experimentally by
58
59 372 adding seven small masses at randomly chosen locations. The total mass added was 650 g, approximately

1
2
3
4 373 10% of the initial mass of the plate.

5 374 As a first step in the performed comparisons, the experimental response of the receiver plate was studied
6
7 375 prior to attach the electric pump and the isolators on it. After that, two types of excitations were studied
8
9 376 with the source subsystem coupled to the receiver plate: an impact excitation applied on the source structure
10
11 377 using an instrumented hammer and the excitation caused by the electric pump operating at constant speed.
12
13 378 A summary of the results presented for this case study (and for the one described in Section 4.2) can be
14
15 379 found in Table 1.

31
32
33
34 380 *4.1.2. Receiver plate ensemble average and variance comparison*

35 381 To study the experimental response of the receiver plate, an impact excitation was applied on it using
36
37 382 an instrumented hammer and, in order to have a space average of the plate vibration, the response was
38
39 383 measured at four different positions. The responses per unit force were computed dividing the measured
40
41 384 acceleration spectra by the measured force spectrum. The response of an ensemble of subsystems was
42
43 385 obtained by performing the test 20 times with different mass locations each time.

44 386 The vibration energy of the plate has been estimated from the experimental results by averaging the
45
46 387 response of each test over the four accelerometers to give $\langle |v|^2 \rangle_a$, and then noting that $E = m_p \langle |v|^2 \rangle_a / 2$.
47
48 388 With this approach, an ensemble of 20 experimental estimations of the plate energy has been obtained.

49 389 The response of the plate has been predicted by considering a hybrid FE-SEA model of the system. The
50
51 390 model consists of a trivial deterministic system with a single DoF, the position where the hammer impacts
52
53 391 were applied, and one statistical subsystem, the whole plate. The predicted response per unit force has
54
55 392 been obtained by considering a vertical unitary force at the only DoF of the system. The matrices that
56
57 393 appear in Equations (5) and (7) are then scalars with the following expressions: $D_d = 0$, $S_{ff} = 1$ and
58
59 394 $D_{dir} = 8i\omega\sqrt{D\rho h}$.

Figure 4: (a) Energy of the plate due to a unit point force excitation. Gray: response of the 20 members of the ensemble; red: experimental ensemble mean response; thick blue: hybrid method prediction; dashed black: 95% CI upper bound; dotted black: 99% CI upper bound. (b) Relative variance of the energy. Red: experimental ensemble variance; thick blue: hybrid method prediction.

In general, there is a good agreement between the measured plate ensemble average response and the response predicted by the hybrid model. The hybrid prediction seems to slightly overestimate the low-frequency response of the system and also the response in the range 450-700 Hz, a result that can be explained by the effect that the damping treatment has on the plate response. A good agreement has been also found in the relative variance results, with differences that are only significant at very low frequencies, where the ensemble of systems may not be random enough. The agreement in the average response could be slightly improved by using a frequency-dependent subsystem loss factor. However, as the differences observed

1
2
3
4 411 are acceptable, the authors have opted to use the frequency averaged constant loss factor previously defined
5 412 for the comparisons presented in Sections 4.1.3 and 4.1.4.
6

7
8 413 *4.1.3. Coupled system. Results for an impact excitation*

9 414 The response of the coupled electric pump-isolators-plate system to an impact excitation is considered
10 415 in this section. The excitation was applied, using an instrumented hammer, on the electric pump structure,
11 416 and the response was measured at three different locations of the receiver plate. As before, the responses
12 417 per unit force were computed dividing the measured acceleration spectra by the measured force spectrum.
13
14 418 The response of an ensemble of experimental subsystems was obtained by performing the test 20 times (with
15
16 419 different mass locations).
17

18
19 420 Figure 5(a) presents the response per unit force of the receiver plate to the impact excitations. The
20 421 responses of the three measuring accelerometers for all the 20 tests have been used to create an ensemble of
21
22 422 60 experimental realisations. The ensemble mean of the experimental modulus squared of the velocity has
23 423 been compared with the predicted response of the hybrid method. This prediction has been computed using
24 424 Equation (26) and the relation $E[|v|^2] = 2E[E]/m_p$, where m_p has been considered to be the mass of the
25 425 receiver plate with the additional point masses. In this case, the set of blocked forces required by Equation
26 426 (23) and determined following the experimental procedure described in Section 2.2.2, are blocked forces per
27 427 unit of input force. Again, the upper CI for a 95% CL, and for a 99% CL have been computed assuming
28 428 that the statistical distribution of the plate energy is lognormal. In this case, the CLs are computed using
29
30 429 the relative variance of the energy density at a point (ε say), which is approximately related to the relative
31 430 variance of the total subsystem energy as follows [48]
32
33
34
35
36

$$\text{Relvar}[|v|^2] = \text{Relvar}[\varepsilon] = 1 + 2\text{Relvar}[E]. \quad (30)$$

37
38
39
40 431 The relative variance predicted by the hybrid method, computed using Equations (26) and (27), has been
41 432 compared to the experimental relative variance of the response in Figure 5(b), and these values have been
42
43 433 used to produce the confidence intervals in Figure 5(a).

Figure 5: (a) Modulus squared of the velocity of the receiver plate due to a unit point force excitation in the first case study. Gray: response of the 60 members of the ensemble; red: experimental ensemble mean response; thick blue: hybrid method prediction; dashed black: 95% CI upper bound; dotted black: 99% CI upper bound. (b) Relative variance of the modulus squared of the velocity. Red: experimental ensemble variance; thick blue: hybrid method prediction.

In general, there is a good agreement between the measured plate ensemble average response and the response predicted by the hybrid model developed in this work. Significant discrepancies are only observed between 400 and 550 Hz and at 600 Hz, where the model predicts increases in the response that are not observed in the experimental results. These two peaks are mainly caused by an unexpectedly high amplitude of the characterised blocked forces and, as explained in the Appendix, these incorrect values are caused by consistency problems in the measurements. Solutions for overcoming this problem are currently being studied by the authors [47].

The relative variance of the experimental modulus squared velocity only differs significantly from the predicted result at very low frequencies. Moreover, it can be seen in Figure 5(a) that the predicted upper CIs satisfactorily enclose the ensemble of experimental results for those frequencies where the blocked force measurements do not show consistency problems. This agreement shows that the assumption of a lognormal distribution for the statistics of the subsystem response is reasonable. As mentioned previously, this is an expected result for the type of experiment performed [49].

4.1.4. Coupled system. Results for the operational excitation forces

This section considers the response of the receiver plate to the excitation generated by the electric pump operating. Again, the response of the plate subsystem was measured at three different locations and, in

order to build the ensemble of experimental subsystems, the test was performed for 20 randomisations of the point masses. The locations of the three accelerometers and the seven masses for each randomisation were the same as the ones used for the impact excitation.

Figure 6(a) presents the response of the receiver plate to the operational excitation forces. As before, an ensemble of 60 experimental realisations has been created combining the responses of the three accelerometers. An expanded view of a section of the Figure is shown in Figure 6(b). In this case, the blocked force contains a large number of strong harmonics, and these harmonics are propagated to the predicted response. Even in Figure 6(b), the comparison between the hybrid prediction and the experimental results is confused by the high degree of fluctuations in the curves.

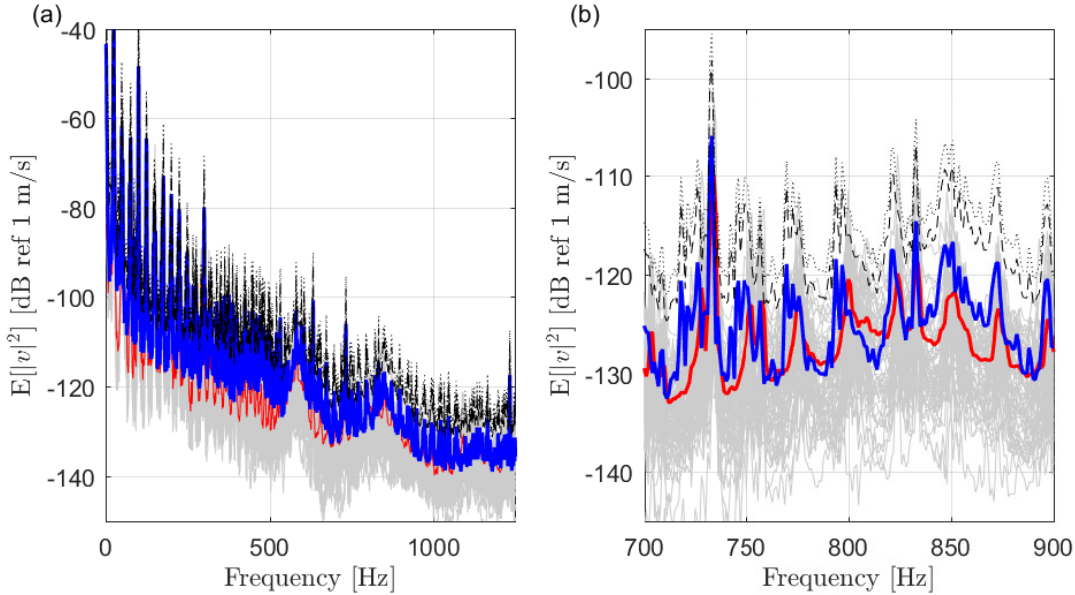

Figure 6: (a) Modulus squared of the velocity of the receiver plate for the running engine excitation (smoothed) in the first case study. Gray: response of the 20 members of the ensemble; red: experimental ensemble mean response; thick blue: hybrid method prediction; dashed black: 95% CI upper bound; dotted black: 99% CI upper bound. (b) Zoomed view of the results presented in (a).

An alternative comparison is presented in Figure 7 where, for clarity, the results have been smoothed by applying a running band average of width $\Delta f = 40$ Hz. As in the impact excitation case, there is a fairly good agreement between the experimental response of the plate and the response predicted by the hybrid model. In this case, significant differences are mainly observed between 150 and 250 Hz, and between 400 and 550 Hz. Again, the cause of these differences, which is discussed in more detail in the Appendix, is an overprediction of the characterised blocked forces. Figure 7(b) shows that a good agreement is also observed between the measured and the predicted relative variance of the response.

Figure 7: (a) Modulus squared of the velocity of the receiver plate for the running engine excitation (smoothed) in the first case study. Gray: response of the 20 members of the ensemble; red: experimental ensemble mean response; thick blue: hybrid method prediction. (b) Relative variance of the modulus squared of the velocity. Red: experimental ensemble variance; thick blue: hybrid method prediction.

4.2. Case study II: motor on a small plate/isolators/large thin plate

4.2.1. The test system and the experimental setup

The vibration source used in this case study, shown in Figure 2b, consisted of a servo motor bolted to a small aluminium plate, itself attached to four steel feet. Each foot was instrumented with two single axis accelerometers, spaced approx. 2.5cm apart. The source subsystem was again connected to a receiver large thin plate using four resilient elements. The construction of a hybrid model for this second assembly again required to characterise experimentally the source mobility, the blocked forces acting on the source-isolators interface and the dynamic stiffness of the isolators.

In the characterisation of its free mobility, the source was suspended on soft elastic bungees and each foot excited in four positions. Appropriate averaging of the spaced excitation and response measurements returned the free source mobility, $\mathbf{Y}_S \in \mathbb{C}^{4 \times 4}$.

In the characterisation of its blocked force the source was resiliently coupled to the intended installation and the coupled source mobility measured as per the above procedure. Note that the blocked force need not be characterised on the assembly in which predictions are made. This was done to avoid any variation in the excitation mechanism between the characterisation and validation phases.¹ The characterisation was

¹In the first case study the source was characterised on a separate assembly, and the blocked forces were ‘transferred’ into the intended installation.

1
2
3
4 481 performed using only the coupling interface DoFs, i.e. $b = c$, thus no over-determination was performed.
5 482 Operational velocities were measured for both operational and artificially excited conditions. For repeata-
6 483 bility the operational velocities due to the artificial excitation were normalised to the input force. Having
7
8 484 averaged the spaced velocities appropriately, the blocked forces were found as per Section 2.2.2.

9
10 485 In this case each of the four resilient elements (type: Fibet 2525VV18-45) used in this study were
11 486 characterised using the in-situ approach presented in Section 2.3. Each element was used to construct a
12
13 487 mass-isolator-mass assembly, as illustrated in Figure 1b. A spaced pair of accelerometers were mounted
14 488 above and below the coupling element and excitations performed at each. The resulting mobilities were
15
16 489 averaged appropriately to yield the coupling interface mobility matrix, $\mathbf{Y}_C \in \mathbb{C}^{2 \times 2}$. The transfer stiffness
17
18 490 of each element was then determined as per Equations (19) and (20).

19 491 The receiver subsystem was the same aluminium plate considered in the first case study, but no damping
20
21 492 treatment was applied in this case. The loss factor of the plate was again experimentally determined from
22
23 493 its response without the deterministic subsystem, i.e. the source structure and the four isolators, placed on
24 494 it. The loss factor was found to be approximately constant in the frequency range of interest (1-1250 Hz),
25
26 495 with a value $\eta = 0.7\%$. With this value, the modal overlap factor at 1000 Hz is $m = \omega n \eta = 0.57$.

27 496 In order to create an ensemble of subsystems, the plate response was randomised experimentally by
28
29 497 adding 10 small masses at randomly chosen locations. The total mass added was 600 g, approximately 10%
30
31 498 of the initial mass of the plate.

32 499 Two types of excitations were studied with the source subsystem considered in this case study: an impact
33
34 500 excitation applied on the source structure using an instrumented hammer and the excitation caused by the
35
36 501 servomotor running at a constant speed of 2800 rpm. A summary of the results presented for this case study
37
38 502 can be seen in Table 1.

39 503 *4.2.2. Results for an impact excitation*

40
41 504 Figure 8(a) presents the response of the receiver plate for the case where an impact excitation was
42
43 505 applied on the source subsystem using an instrumented hammer. The impacts were applied on the small
44
45 506 plate structure and the responses per unit force were computed dividing the measured acceleration spectra
46
47 507 by the measured force spectrum. The plate response was measured at six different locations and the test
48
49 508 was performed for 20 randomisations of the point masses.

50
51 509 The responses of the six measuring accelerometers for all the 20 tests have been used to create an ensemble
52
53 510 of 120 experimental realisations. The ensemble mean of the experimental modulus squared of the velocity
54
55 511 has been compared with the predicted response of the hybrid method. As in the previous case study, the
56
57 512 upper CI for a 95% CL and for a 99% CL have been computed assuming that the statistical distribution
58
59 513 of the plate energy is lognormal. The relative variance predicted by the hybrid method, computed using
60
61 514 Equations (26) and (27), has been compared to the experimental relative variance of the response in Figure

515 8(b). Again, this relative variance has been used to produce the confidence intervals shown in Figure 8(a).

Figure 8: (a) Modulus squared of the velocity of the receiver plate due to a unit point force excitation in the second case study. Gray: response of the 120 members of the ensemble; red: experimental ensemble mean response; thick blue: hybrid method prediction; dashed black: 95% CI upper bound; dotted black: 99% CI upper bound. (b) Relative variance of the modulus squared of the velocity. Red: experimental ensemble variance; thick blue: hybrid method prediction.

The results show that there is a good agreement between the measured plate ensemble average response and the response predicted by the hybrid model of this second case study. Significant discrepancies are only observed at very low frequencies, and around 180 and 250 Hz, where the model predicts two sharp peaks that are not observed in the experimental measures. Again, these peaks are caused by the consistency problems that arise in the experimental determination of the blocked forces, as explained in the Appendix.

The good agreement between the experimental results and the predicted response can be also observed in the relative variance results. The relative variance of the experimental modulus squared velocity only differs significantly from the predicted result at very low frequencies. Moreover, it can be seen in Figure 8(a) that the predicted upper CIs are satisfactorily enclosing the ensemble of experimental results, showing once more that the experimental results support the assumption of a lognormal distribution for the statistics of the subsystem response [49].

An ensemble of 20 experimental estimations of the plate energy has been obtained from the experimental results using that $E = m_p \langle |v|^2 \rangle_a / 2$. A comparison between the mean and relative variance of the experimental energy, and the responses predicted by the hybrid model, computed again using Equations (26) and (27), is shown in Figure 9. As before, the upper CI for a 95% and a 99% CLs have been included in the

531 energy comparison.

Figure 9: (a) Energy of the receiver plate due to a unit point force excitation in the first case study. Gray: response of the 20 members of the ensemble; red: experimental ensemble mean response; thick blue: hybrid method prediction; dashed black: 95% CI upper bound; dotted black: 99% CI upper bound. (b) Relative variance of the energy. Red: experimental ensemble variance; thick blue: hybrid method prediction.

Again, there is a good agreement between the mean and variance of the energy predicted by the hybrid method and the experimental results. The main discrepancies observed are again the significant differences at low frequencies and the two peaks at 180 and 250 Hz. The space average performed in the experimental results has reduced significantly the variability of the ensemble responses and this effect has been properly caught by the hybrid model, which predicts a lower relative variance and, due to this, lower upper CIs. It should be mentioned that the experimental energy has been estimated by performing a space average of the response at only six positions and it is reasonable to expect that taking measurements at a larger number of positions would reduce the fluctuations in the experimental relative variance.

4.3. Results for a running motor

Figure 10(a) presents the response of the receiver plate for the case where the servomotor of the source subsystem was running at a constant speed of 2800 rpm. As in the previous excitation case, the response of the plate subsystem was measured at six different locations and the test was performed for 20 randomisations of the point masses. The locations of the six accelerometers and the 10 masses for each randomisation were the same as the ones used for the impact excitation. For clarity, the results have been smoothed by applying a frequency running average with a bandwidth $\Delta f = 40$ Hz.

Figure 10: (a) Modulus squared of the velocity of the receiver plate for the running engine excitation (smoothed). Gray: response of the 120 members of the ensemble; red: experimental ensemble mean response; thick blue: hybrid method prediction. (b) Relative variance of the modulus squared of the velocity. Red: experimental ensemble variance; thick blue: hybrid method prediction.

As in the impact excitation case, there is a good agreement between the experimental response of the plate and the response predicted by the hybrid model. A good agreement is also observed for the relative variance, as shown in Figure 10(b).

The mean and relative variance of the vibrational energy of the plate predicted by the hybrid method are compared with their corresponding experimental values in Figure 11. The results again show that the predicted mean response agrees very well with the experimental results, but the hybrid model slightly underpredicts the relative variance of the structure. As in the impact excitation case, it is reasonable to assume that the differences observed would be reduced if a larger number of accelerometers were used to estimate the plate energy.

Figure 11: (a) Energy of the receiver plate for the running engine excitation (smoothed). Gray: response of the 20 members of the ensemble; red: experimental ensemble mean response; thick blue: hybrid method prediction. (b) Relative variance of the energy. Red: experimental ensemble variance; thick blue: hybrid method prediction.

5. Conclusion

This paper has presented a hybrid FE-SEA-experimental methodology for predicting the mid-frequency response of random dynamic systems. The proposed methodology combines the use of experimentally characterised structures with a previously developed hybrid FE-SEA numerical formulation [8, 12]. The methodology has been successfully applied to two case studies consisting of a vibration source coupled with isolators to a large thin receiver plate. These case studies show that both active (e.g., motors) and passive (e.g., vibration isolators) experimentally determined subsystems can be included in the new formulation.

The proposed approach yields predictions for the ensemble mean and variance of the response of a random system, and confidence bands on this response can also be established. The method implicitly assumes that GOE statistics can be used to model the uncertainty in the SEA subsystems (in the case studies, a random plate) and this avoids the need for detailed information regarding the nature of the uncertainty, and also the need for Monte Carlo simulations. The approach has been shown to yield to good agreement with benchmark experimental results for randomised systems. One issue that has been found with the experimental characterisation of the vibration sources is that the use of the measured blocked forces can on rare occasions lead to unexpected sharp peaks in the predicted response. It has been shown that these peaks can be explained by the sensitivity of the determined blocked forces to experimental errors. Care is needed to try to identify these false peaks in the modelling process. This issue is left as further work.

1
2
3
4 573 It can be concluded that the approach can be used to extend the existing FE-SEA method [8, 12] to
5 574 systems which contain components that cannot be modelled analytically, and therefore require experimental
6 575 characterisation. The result is an efficient methodology which reduce modelling effort by employing SEA
7
8 576 and experimental results, and which yields a detailed statistical description of the response.

17 18 580 **Appendix A. Sensitivity of the blocked force determination**

19
20
21 581 The sensitivity of the determined blocked force to experimental errors is studied in this appendix using
22 582 a simple hybrid FE-SEA model. The considered system, shown in Figure A.1, consists of three point
23
24 583 masses (m_1 , m_2 and m_3) connected in series with two spring elements (with stiffness constants k_1 and k_2 ,
25
26 584 respectively). The lower mass, m_3 , is considered to be perfectly attached to a large thin plate and the whole
27 585 system is excited by a vertical unitary harmonic point load, $f_{\text{ext}} = 1$, applied on the upper mass m_1 .
28

29 586 The deterministic part of the system is assumed to consist of three-DoF (q_1 - q_3) representing the vertical
30 587 response of the three point masses. The response of q_2 , q_3 and of the receiver plate (defined by its vibrational
31
32 588 energy E) to the external excitation is equivalent to that obtained by considering the following blocked force
33 589 applied at q_2
34

$$35 \quad \bar{f}_2 = \frac{1}{1 - m_1 \omega^2 / k_1}. \quad (\text{A.1})$$

Figure A.1: Analytical 3DoF-plate model with the external excitation considered (left) and its corresponding blocked force excitation at q_2 (right).

The matrices required to compute the hybrid mean and variance equations for the analytical model are

$$\mathbf{D}_d = \begin{bmatrix} k_1 - m_1\omega^2 & -k_1 & 0 \\ -k_1 & k_1 + k_2 - m_2\omega^2 & -k_2 \\ 0 & -k_2 & k_2 - m_3\omega^2 \end{bmatrix}, \quad (\text{A.2})$$

$$\mathbf{D}_{\text{dir}} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 8i\omega\sqrt{D\rho h} \end{bmatrix}, \quad (\text{A.3})$$

$$\mathbf{S}_{ff} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & \bar{f}_2\bar{f}_2^* & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad (\text{A.4})$$

where it has been assumed that the applied excitation is the blocked force defined by Equation (A.1).

The blocked force can also be expressed in terms of the free mobilities of the subsystem $m_1 - k_1 - m_2$ as follows

$$\bar{f}_2 = Y_{22}^{-1}v_{2,fs} = Y_{22}^{-1}Y_{21}, \quad (\text{A.5})$$

where $v_{2,fs}$ is the free velocity of q_2 and where

$$Y_{22} = (k_1 - m_1\omega^2)\Delta, \quad Y_{21} = k_1\Delta, \quad (\text{A.6})$$

597 with $\Delta = \frac{i\omega}{(k_1 - m_1\omega^2)(k_1 - m_2\omega^2) - k_1^2}$.
598

599 The effect of adding an artificial numerical error to the measured mobilities can be assessed by considering
600 measured mobilities $Y_{21}^m = Y_{21} + \epsilon_1$ and $Y_{22}^m = Y_{22} + \epsilon_2$, where ϵ_i are small errors added to the measurement.
601 The effect that adding this small artificial errors has on the response of the system is shown in Figure A.2.
602 The results have been computed considering $m_1 = 2$ kg, $m_2 = 2.5$ kg, $m_3 = 0.25$ kg, $k_1 = 10^6$ N/m, $k_2 =$
603 10^5 N/m. Structural damping has been added considering a complex valued stiffness $k_i^c = k_i(1 + i\eta)$, with
604 $\eta = 0.01$. For each computed frequency, the error quantities ϵ_i have been considered to have a constant
605 amplitude and a random phase. These amplitudes have been considered to be equal to 0.2% of the maximum
606 amplitude of the mobilities in the range of frequencies studied (50-200 Hz).

607 The results highlight how sensitive is the blocked force determination to measuring errors at antireso-
608 nances of Y_{22} . As can be seen in Figures A.2(c) and (d), this error may cause an incorrect characterisation
609 of the blocked force, which results in an incorrect prediction of the receiver plate energy. A general descrip-
610 tion of this experimental inconsistency, not limited to the type of hybrid models presented in this work,
611 can be found in [47]. It is worth noting that similar errors are often encountered in experimental dynamic
612 sub-structuring, although in this case they stem from inconsistencies in measured FRF matrices [39], as
613 opposed to blocked forces.

Figure A.2: Results for the simple 3 DoF-plate model with (solid line) and without (dashed line) a numerical error. (a) Mobility Y_{21} . (b) Mobility Y_{22} . (c) Magnitude of the blocked force applied on q_2 . (d) Energy of the receiver plate.
