Summary

Neurotransmitter-gated ion-channels are allosteric proteins that switch on and off in response to agonist binding. Most studies have focused on the agonist-bound, activated channel whilst assigning a lesser role to the apo or resting state. Here, we show that nanoscale mobility of resting AMPA-type ionotropic glutamate receptors (AMPARs) predetermines responsiveness to neurotransmitter, allosteric anions and auxiliary TARP subunits. Mobility at rest is regulated by alternative splicing of the flip/flop cassette of the ligand-binding domain which controls motions in the distant AMPAR amino-terminal domain (NTD). Flip variants promote moderate NTD movement which establishes slower channel desensitization and robust regulation by anions and auxiliary subunits. In contrast, greater NTD mobility imparted by the flop cassette acts as a master-switch to override allosteric regulation. In AMPAR heteromers, TARP stoichiometry further modifies these actions of the flip/flop cassette generating two functionally-distinct classes of partially- and fully-TARPed receptors typical of cerebellar stellate and Purkinje cells.

Introduction

α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type ionotropic glutamate receptors (iGluRs) mediate most fast-excitatory neurotransmission in the mammalian brain (Dingledine et al., 1999; Traynelis et al., 2010). They form the hardwiring of glutamatergic circuits but also strengthen or weaken synaptic transmission during periods of sustained patterned activity or altered homeostasis (Herring and Nicoll, 2016; Turrigiano, 2017). AMPA receptors (AMPARs) are also implicated in numerous CNS disorders and thus are targeted for the development of clinically-relevant compounds (Bowie, 2008). Consequently, there has been a concerted effort to provide a full understanding of the structural and functional aspects of AMPAR signaling.

AMPARs assemble as tetramers in either a homomeric (Sobolevsky et al., 2009) or heteromeric (Herguedas et al., 2016; Herguedas et al., 2019) subunit arrangement that may additionally include accessory subunits such as the transmembrane AMPA receptor regulatory proteins (TARPs) and cornichon families (Greger et al., 2017; Jackson and Nicoll, 2011) (Fig. 1A). The AMPAR subunit is composed of four functional domains that include: (i) a cytoplasmic C-terminal domain (CTD, not shown in Fig. 1A) that directs receptor trafficking and synaptic anchoring (Shepherd and Huganir, 2007), (ii) a transmembrane domain (TMD) which forms a central ion channel pore that rapidly transports Na^+ and Ca^{2+} ions in response to binding of the neurotransmitter, L-glutamate (L-Glu) (Dingledine et al., 1999; Traynelis et al., 2010), (iii) a clamshell-like ligand-binding domain (LBD, Fig. 1B) (Mayer and Armstrong, 2004) and (iv) an amino-terminal domain (NTD) which directs subunit assembly and receptor clustering at

synapses (Garcia-Nafria et al., 2016).

In addition to these four distinct regions of the overall tetrameric structure, the LBD dimer interface has been shown to be critical in determining the time course of AMPAR gating (Dawe et al., 2015). Specifically, recent work from our lab has identified a novel cation binding pocket that promotes channel activation by the formation of a network of electrostatic interactions at the apex of both the AMPAR (Dawe et al., 2016) and kainate receptor (KAR) (Dawe et al., 2013) LBD dimer interfaces. Interestingly, anions have also been shown to control the time course of AMPAR gating (Bowie, 2002); however, the structural basis of this mechanism has yet to be understood. Another unresolved issue related to AMPAR gating is the possible role of the NTD in channel gating. Recent work has highlighted the dynamic motions in the NTD of both AMPA- and kainate-type iGluRs (Dürr et al., 2014; Dutta et al., 2015; Matsuda et al., 2016; Meyerson et al., 2014; Nakagawa et al., 2005) and interactions with auxiliary proteins (Cais et al., 2014; Moykkynen et al., 2014; Shaikh et al., 2016) that may facilitate trans-synaptic contact formation (Garcia-Nafria et al., 2016) and permit AMPAR trafficking during synapse strengthening (Diaz-Alonso et al., 2017; Watson et al., 2017). Since structural re-arrangements of the NTD accompany receptor desensitization (Dürr et al., 2014; Meyerson et al., 2014; Nakagawa et al., 2005; Twomey et al., 2017a), it has been assumed that the underlying movement is triggered by agonist binding. However, it is also possible that the intrinsic thermodynamic mobility of the resting AMPAR determines NTD movement and its responsiveness to agonist.

Here, we have designed experiments to distinguish between these two possibilities. Our data identify a novel allosteric anion binding pocket at the alternatively spliced flip/flop cassette that

modifies NTD motions in the resting state prior to agonist binding and regulates channel gating in the presence and absence of auxiliary subunits. Ser775 of the GluA2flip isoform (GluA2$_i$) renders AMPARs sensitive to anion modulation whereas Asn775 of the GluA2flop isoform (GluA2$_o$) almost eliminates the effects of anions on the NTD and channel gating. Imaging by atomic force microscopy (AFM) reveals that the NTDs of GluA2$_o$ receptors are more mobile than those of GluA2$_i$ receptors, indicating differences in the intrinsic conformational flexibility of their resting states. This behavior is interchangeable via a single amino acid, the Ser775 residue, that operates as a molecular switch between flip and flop isoforms. TARP stoichiometry further modifies these actions of the flip/flop cassette on AMPAR heteromers generating two distinct classes of partially- and fully-TARPed GluA1/A2 receptors that match the functional profile of native AMPARs expressed by cerebellar stellate and Purkinje cells, respectively.

Results

Anions modulate AMPAR desensitization

Although the structural and functional bases of anion and cation modulation of KARs have been studied extensively (Bowie, 2002, 2010; Dawe et al., 2013; Wong et al., 2006), much less is known about the effect of external ions on AMPARs. Recent work identified the structural mechanism of cation regulation (Fig. 1B) (Dawe et al., 2016); however, the nature of anion modulation of AMPARs (Bowie, 2002) remains unknown. The effect of external anions on AMPAR deactivation and desensitization was studied by recording agonist-evoked membrane currents in outside-out membrane patches excised from HEK293 cells expressing GluA2$_i$(Q) (Fig. 1C-H, see Methods). As observed previously for GluA1$_i$ receptors (Bowie, 2002), the time course of entry into desensitization for GluA2$_i$ was sensitive to external halides, accelerating 1.7- and 4.6-fold in bromide (τ = 4.3 ± 0.2 ms; n = 7) and iodide (τ = 1.6 ± 0.1 ms; n = 7), respectively, compared to chloride (τ = 7.3 ± 0.3 ms; n = 15) (Fig. 1C and F, Table S1). In contrast, deactivation rates were almost identical for all anions tested on GluA2$_i$ (Fig. 1D and G, Table S1). In keeping with this, recovery rates out of desensitization were also anion-dependent with GluA2$_i$ recovering from desensitization in external iodide ($\tau_{recovery}$ = 62.5 ± 3.0 ms; n = 6) about 3-fold more slowly than in external chloride ($\tau_{recovery}$ = 24.1 ± 1.5 ms; n = 13) (Fig. 1E and H, Table S1). Interestingly, rates into and out of desensitization have a predictive relationship with the ionic radius of the external anion (Fig. 1F and H), with faster desensitization rates observed with anions of a larger radius. The relationship between ionic radius and channel desensitization is consistent with the existence of a specific anion binding pocket. Previous work has located cation binding pockets critical to AMPAR and KAR gating to the interface of

LBD dimers (Dawe et al., 2013; Dawe et al., 2016) (Fig. 1B); consequently, we reasoned that anions may bind to this region too. Moreover, previous work has demonstrated the important role of the LBD dimer interface in regulating AMPAR gating, including desensitization (Dawe et al., 2015; Horning and Mayer, 2004; Sun et al., 2002).

To determine the location of the anion binding pocket, two soluble constructs of the GluA2-LBD were crystallized in the presence of bromide ions (Fig. 2). Since bromide ions give anomalous scattering, we used this property to identify the position of the bound bromide ions in the structure and to distinguish them from other ions and water molecules in the X-ray diffraction data (Fig. 2A-D), as also previously done for localization of the anion binding site in kainate receptors (Plested and Mayer, 2007). Two X-ray structures were determined which correspond to the flop isoform (GluA2$_o$-LBD; PDB code, 6GL4) and the flip-like mutant GluA2$_o$-LBD N775S (PDB code, 6GIV). The structures are shown in Figs. 2 and S1 along with statistics of data collection and refinement in Table S2. The anomalous scattering data clearly indicate the location of two bromide ions near the base of the D1-D1 dimer interface in both structures (Fig. 2C and D, Fig. S1A-C). More specifically, these anion binding sites are in a hydrophobic space, surrounded by Pro515 and Leu772 from one subunit, Ile502, Leu504 and Pro515 from the partner subunit, and capped by Lys514 (Fig. 2E and F, Fig. S1D and E, Fig. S2A and B). There are also several water molecules surrounding each bromide, separating the ion from Ser775 (Fig. 2C-F). Interestingly, we also determined a structure of GluA2$_o$-LBD in the presence of a high concentration of chloride ions and the electron density indicated that chloride ions bind to the same location as bromide in the LBD dimer interface (data not shown).

Ser775 is notable for interacting with positive modulators of AMPARs (Fig. S1F) such as cyclothiazide (CTZ) (Partin et al., 1996), as well as being one of the residues that forms the alternatively spliced flip/flop cassette (Sommer et al., 1990). Given the high affinity for CTZ, we hypothesized that it would displace bromide ions from their bound positions. In agreement with this, electrophysiological responses observed in different external anions were non-decaying in each case (Fig. S1G and H) consistent with the idea that CTZ out competes external anions for binding. Likewise, mutation of Leu504 to an Ala or Cys residue either reversed or eliminated anion regulation of GluA2$_i$ receptor decay kinetics, respectively (Fig. S2C-F), further validating the location of anion binding pocket as being at the LBD dimer interface. Taken together, these results identify an anion binding pocket which, when occupied by halide ions, may be responsible for regulating the rates of entry into and exit from AMPAR desensitization.

Ser/Asn residue regulates anion effects

To establish a causal relationship between the anion binding pocket and the functional effects of external anions on GluA2, we focused on position 775 which, as mentioned previously, is modified by alternative splicing and is also involved in all regulatory effects of the flip/flop cassette (see below). The flip isoform of the AMPAR contains a serine (Ser) at position 775 whereas the flop isoform contains an asparagine (Asn) (Fig. 3A and B) (Sommer et al., 1990), which we hypothesized may differentially affect anion modulation of AMPARs.

To test this, we first compared the effect of external anions on desensitization rates of $GluA2_i$ and $GluA2_o$ receptors whose amino acid sequences differ at nine residues (Fig. 3A) (Sommer et al., 1990). As anticipated, $GluA2_i$ and $GluA2_o$ receptors differed in their sensitivity to modulation by external ions (Fig. 3C and D), though the trend of faster desensitization in the presence of larger anions persisted (Fig. 3F). For example in $GluA2_o$ receptors, iodide accelerated rates into desensitization about 1.6-fold ($\tau = 0.8 \pm 0.05$ ms; n = 6) compared to chloride ($\tau = 1.3 \pm 0.06$ ms; n = 12) which was substantially less than the 4.6-fold difference observed on $GluA2_i$ receptors (Fig. 3C, D and F, Table S1). To examine whether this difference was due to residue 775, which is in close proximity to the bromide binding site (Fig. 2E), we repeated these experiments on the Ser775Asn $GluA2_i$ receptor (Fig. 3E and F, Table S1). As anticipated, the $GluA2_i$ S775N receptor was much less sensitive to modulation by external anions. For example, iodide ($\tau = 3.6 \pm 0.5$ ms; n = 6) accelerated desensitization compared to chloride ($\tau = 5.2 \pm 0.4$ ms; n = 12) by only 1.4-fold (Fig. 3E and F, Table S1). In contrast, mutation of the two more apical dimer interface residues that contribute to fast $GluA2_o$ desensitization (Fig. 3B) (Quirk et al., 2004) produced a receptor (T765N/P766A) that still exhibited robust anion sensitivity (Fig. S3). As a result, the near loss of anion modulation from flip- to flop-type GluA2 AMPARs can be primarily attributed to Asn775, consistent with our structural data placing bromide ions in the lower D1-D1 LBD dimer interface. Interestingly, anion modulation of recovery from desensitization was still present in $GluA2_i$ S775N receptors (Fig. 3G and H) demonstrating that anion effects on rates into and out of desensitization have different mechanisms.

Anions control resting and active AMPARs

Anions may affect AMPARs by controlling the receptor's resting and/or activated state(s). To delineate between these possibilities, we investigated whether external halides elicited global, conformational changes in protein structure in the absence and/or presence of agonist. Specifically, we measured protein height as an indicator of conformation using atomic force microscopy (AFM) since AMPAR activation and desensitization involve compression in the quaternary structure (Dürr et al., 2014; Herguedas et al., 2016; Meyerson et al., 2014; Twomey et al., 2017a, b) as in NMDA-type iGluRs (Balasuriya et al., 2014; Suzuki et al., 2013). To image the receptor, we purified and reconstituted individual AMPAR complexes into lipid bilayers (Fig. 4 and Fig. S4, see Methods).

The addition of L-Glu to NaCl-based external solution prompted a 0.69 ± 0.11 nm (n = 11) reversible reduction in GluA2$_i$ receptor height (Fig. 4A and C, Fig. S5) which was prevented by the competitive antagonist, CNQX, and the positive allosteric modulator, CTZ (Table S3, Fig. S5). AFM experiments were also repeated to determine if height changes could be induced by different anions (Fig. 4B and D, Fig. S5, Table S3). Unexpectedly, merely changing the main external anion species from NaCl to NaBr (0.74 ± 0.06 nm; n = 12) or NaI (0.87 ± 0.11 nm; n = 13) produced a substantial and reversible vertical compression of individual GluA2$_i$ receptors (Fig. 4D and S5) comparable to L-Glu-evoked responses (Fig. 4C). Interestingly, much less additional compression (~ 0.2 nm) was observed when L-Glu (10 mM) was added to NaBr or NaI solutions (Fig. 4C), suggesting the principal role of anions is to prime the receptor. Since the

action of L-Glu, however, was not entirely occluded, the structural rearrangements observed with anion substitution must differ from those elicited by agonist binding.

To establish a relationship between anion-induced height changes (Fig. 4D) and their effect on desensitization (Fig. 1C and F), we repeated AFM measurements on $GluA2_o$ whose gating properties are relatively anion-insensitive. Remarkably, anion-induced height compression was almost completely absent from the $GluA2_o$ receptor when external solution containing NaCl was switched to either NaBr (0.03 ± 0.06 nm; n = 14) or NaI (0.08 ± 0.06 nm; n = 14) (Fig. 4D, Table S3). Importantly, agonist binding continued to elicit reductions in the height of all anion species (Fig. 4C) reaffirming that anion and agonist effects are different. In agreement with our electrophysiology data, iodide anions did not affect the AFM-reported height changes of $GluA2_i$ receptors containing the single S775N point mutation (Fig. 4D, Table S3), establishing a critical role for the Ser/Asn residue and causal relationship between the effects of anions on channel gating and height changes. Finally, AFM-reported height changes elicited by switches in external anions were absent from the $GluA2_i$ L504A receptor, whereas L-Glu persisted in reducing height in all anion species tested (Fig. S2G and H, Table S3).

Taken together, these data indicate two important points. First, external anions prime the receptor prior to activation. Whether priming then determines the rate of AMPAR desensitization prior to agonist binding is investigated below. Second, anion modulation reveals a coupling between the LBD dimer interface and the NTD. This latter possibility was examined in additional AFM experiments on GluA2 lacking the NTD (i.e. GluA2 ΔNTD).

Flip/flop cassette controls NTD motions

Anion- and agonist-induced height changes were repeated using the truncated GluA2$_i$ ΔNTD receptor (Fig. 4E-G and Fig. S6). Contrary to wildtype behavior, virtually no height changes could be induced in the GluA2$_i$ ΔNTD receptor by replacing NaCl with NaI (-0.05 ± 0.08 nm; n = 15) or by agonist application (in NaCl, 0.03 ± 0.06 nm; n = 13) (Fig. 4E, Table S3), demonstrating that receptor compression requires the NTD. To explore this further, we re-engineered GluA2$_i$ and GluA2$_o$ receptors, replacing each NTD with an eGFP molecule (Fig. 4F and G). Importantly, the expressed GluA2 ΔNTD-eGFP constructs exhibited similar functional behavior in terms of anion sensitivity and responsiveness to agonist (data not shown). We reasoned that although anions and agonists bind to the LBD, the energy of binding may induce a conformational change that is more prominently observed in distant regions of the protein, even if the NTD is replaced by eGFP. Consistent with this, compression induced by external anions (NaCl to NaI, 0.32 ± 0.09 nm; n = 18) and agonist application (in NaCl 0.28 ± 0.04 nm; n = 10) was restored in the GluA2$_i$ ΔNTD-eGFP construct, demonstrating that binding events in the LBD are transferred to the NTD. Since the GluA2$_i$ ΔNTD-eGFP construct retained the original linker sequences, we reasoned that the linkers might exert a similar downward pulling force on whatever is attached above. Since eGFP has a different size and likely does not form inter-subunit dimers, these distinctions may explain why height changes were about 2-fold less with GluA2$_i$ ΔNTD-eGFP. Finally, agonist but not anion binding induced compression of the GluA2$_o$ ΔNTD-eGFP construct (Fig. 4G) confirming that compression of the NTD is differentially controlled by the flip/flop cassette. Given this, we

next tested if the intrinsic motions in resting GluA2 AMPARs may be a critical factor in determining its anion and agonist responsiveness.

AMPARs have different resting states

AFM visualization of the NTD movements of the GluA2 AMPAR (Fig. 5) revealed that both isoforms exist as two distinct globular structures, which show mobility even in the resting state (Fig. 5A, Movies S1 and S2). Unexpectedly, NTD movements at rest, expressed as cumulative squared displacement (CSD), were almost 3-fold greater for GluA2$_o$ (resting CSD, 15.53 ± 2.54 nm^2, n=7) compared to GluA2$_i$ (resting CSD, 5.58 ± 0.92 nm^2, n=5) (Fig. 5B and D, Table S4) revealing that NTD motions are controlled by the flip/flop cassette. Bath application of a saturating concentration of L-Glu (10 mM) increased the NTD mobility of the GluA2$_i$ AMPAR (CSD, 13.90 ± 2.11 nm^2, n=9) but not that of GluA2$_o$ (CSD, 17.12 ± 0.59 nm^2, n=5) (Fig. 5C and D, Movies S3 and S4). As expected, the NTD mobility in the presence of L-Glu was reduced by CNQX for both GluA2$_i$ (5.33 ± 0.82 nm^2, n=4) and GluA2$_o$ (9.50 ± 1.95 nm^2, n=3) (Fig. 5D, Table S4) demonstrating a direct relationship between NTD mobility and agonist binding. NTD movement of GluA2$_i$ was agonist-concentration dependent (Fig. 5E, Table S4), whereas the mobility of GluA2$_o$ was not. Most importantly, the NTD mobility of the GluA2$_i$ S775N mutant (resting CSD, 14.00 ± 1.70, n=9) was also greater than that of wildtype GluA2$_i$, but not of GluA2$_o$ (Fig. 5B, Table S4). This observation is important as it establishes a causal link between the effects of anions on channel gating (Figs. 1 and 3) and height changes (Fig. 4) with the resting state of the AMPAR.

Given this, we reasoned that the lower conformational mobility of the GluA2$_i$ receptor at rest would favor more stable interactions in regions of the protein, such as the LBD dimer interface (Dawe et al., 2015; Dawe et al., 2016), that stabilize the activated state of the receptor. A more stable AMPAR structure would also favor anion binding to the LBD dimer interface and account for the greater effect of external halide ions on GluA2$_i$ receptors. Conversely, the higher mobility of the GluA2$_o$ receptor would disfavor anion binding (and its regulation) and destabilize the open state of the receptor, explaining its much more rapid desensitization kinetics and weaker anion sensitivity. Given this, we concluded that the flop cassette of the AMPAR receptor acts as a master-switch that overrides allosteric mechanisms, such as anion regulation that impacts the time AMPARs remain in the open state. We therefore hypothesized that GluA2$_o$ should also be similarly insensitive to regulation by auxiliary proteins, such as the prototypical TARP, stargazin (γ2).

To test this hypothesis, we compared the electrophysiological responses of GluA2$_i$, GluA2$_o$ and GluA2$_i$ S775N receptors expressed with γ2 (Fig. 6A-D). As noted previously (Dawe et al., 2016), co-assembly of GluA2$_i$ receptors with γ2 slowed desensitization rates (τ_{des}, ms) and reduced equilibrium desensitization ($I_{equilibrium}$, %) by about 4-fold and 22-fold, respectively (Fig. 6A, C, and D, Table S1). Desensitization rates and equilibrium desensitization were also anion-sensitive, exhibiting a similar rank order of potency as described for GluA2$_i$ receptors alone (Fig. 6B-D, Table S1). In contrast, co-assembly of GluA2$_o$ receptors with γ2 almost eliminated the effect of the TARP on desensitization rates, equilibrium desensitization and anion regulation (Fig. 6A-D, Table S1) in agreement with the hypothesis that the flop cassette overrides TARP

regulation. Importantly, $\gamma2$ also had a greatly attenuated effect on GluA2$_i$ S775N receptors, further demonstrating the pivotal role of the 775 residue as a molecular switch (Fig. 6A-E, Table S1).

Native AMPARs are also sensitive to anion regulation

To examine how these actions of the flip/flop cassette impact native receptors, we studied the gating properties of AMPARs in outside-out and nucleated patches excised from cerebellar Purkinje and stellate cells, respectively (Fig. 7, Table S5). Previous work has shown that AMPARs expressed by both cell types are regulated by $\gamma2$ but that their gating properties are distinct (Barbour et al., 1994; Bats et al., 2012; Yamazaki et al., 2015). In keeping with this, rapid application (250 ms) of 10 mM L-Glu to excised patches from Purkinje cells elicited AMPAR responses that decayed at a slower rate and to a lesser extent than responses from stellate cells (Fig. 7A). There was a 6-fold difference in equilibrium desensitization between Purkinje and stellate cells corresponding to steady-state/peak values of 8.3 ± 0.6 % (n=21) and 1.4 ± 0.1 % (n=29), respectively (Fig. 7B). Similarly, the decay kinetics of the responses from Purkinje cells were best fit with a weighted time constant of 7.5 ± 0.4 ms (n=20) compared to 2.9 ± 0.1 ms (n=30) for responses from stellate cells (Fig. 7C). These distinctions in decay kinetics and the degree of equilibrium desensitization of Purkinje and stellate cells are reminiscent of the functional differences between GluA2$_i$/$\gamma2$ and GluA2$_o$/$\gamma2$ receptors, respectively (Fig. 6A-D). However, two subsequent observations suggested that a more complicated explanation was required to account for the properties of AMPARs expressed by Purkinje and stellate cells.

First, the positive allosteric modulator CTZ (100 μM) eliminated macroscopic desensitization of AMPAR-mediated responses of Purkinje and stellate cells (Fig. 7A, insets) confirming that both cell types express flip-dominant AMPARs (Partin et al., 1995; Partin et al., 1994; Penn et al., 2012). Flop-dominant AMPARs continue to desensitize in the presence of CTZ, albeit at a reduced rate (Partin et al., 1995; Partin et al., 1994), which is distinct from the responses observed in patches from Purkinje and stellate cells. Second, although AMPAR responses exhibited by Purkinje and stellate cells were sensitive to external anion modulation (Fig. 7D and E), their effect on decay kinetics were intermediate between GluA2$_i$/γ2 and GluA2$_o$/γ2 receptor responses (Fig. 6D, Table S1). AMPAR decay kinetics in both cell types slowed by about 2- to 3-fold upon exchange of external Br$^-$ (Purkinje, τ = 3.9 ± 0.5 ms, n=5; stellate, τ = 2.0 ± 0.2 ms, n=8) with F$^-$ (Purkinje, τ = 10.6 ± 0.9 ms, n=6; stellate, τ = 5.0 ± 0.6 ms, n=5). These apparently inconsistent observations may be reconciled if Purkinje and/or stellate cells express AMPAR tetramers that contain both flip and flop variants. Consistent with this suggestion, previous work has shown that CTZ eliminates macroscopic desensitization of recombinant GluA1$_i$/A2$_o$ or GluA1$_o$/A2$_i$ heteromers (Partin et al., 1994), matching the responses from patches of Purkinje and stellate cells. Since the functional impact of the flip/flop cassette on GluA1/A2 heteromers has yet to be studied in terms of their modulation by TARP γ2 and sensitivity to external anions, we performed additional experiments to better understand this relationship.

TARP stoichiometry shapes the functional behavior of AMPAR heteromers

To examine how alternative splicing impacts the function of GluA1/A2 heteromers, we initially focused on fully TARPed receptors by tethering the γ2 auxiliary subunit to flip/flop variants of

GluA1(Q) and GluA2(R) subunits. GluA1/A2 heteromerization was confirmed in each recording by testing for the loss of cytoplasmic polyamine block (Fig. S7, see Methods), as described previously (Partin et al., 1995).

The flip/flop cassette had a profound and concomitant effect on the decay kinetics and equilibrium desensitization of fully-TARPed GluA1/A2 heteromers (Fig. 8A). Flip-only heteromers (A1$_i$/γ2 + A2$_i$/γ2) decayed with a slower rate (τ = 10.6 ± 0.3 ms, n=6) and to a lesser extent (ss/peak = 18.5 ± 1.4 %, n=6) in response to agonist stimulation than flop-only receptors (A1$_o$/γ2 + A2$_o$/γ2), which had faster decay kinetics (τ = 3.0 ± 0.2 ms, n=7) and more complete equilibrium desensitization (ss/peak = 3.5 ± 0.8 %, n=7) (Fig. 8B-D, Table S5). Although, GluA1/A2 heteromers containing both flip/flop variants had intermediate behavior, as might be expected, alternative splicing of GluA2 had the more dominant impact on channel gating. For example, GluA1$_i$/A2$_o$ receptors (A1$_i$/γ2 + A2$_o$/γ2) exhibited faster (τ = 3.3 ± 0.3 ms, n=7) and more complete desensitization (ss/peak = 7.1 ± 0.7 %, n=7) than GluA1$_o$/A2$_i$ receptors (A1$_o$/γ2 + A2$_i$/γ2, τ = 8.9 ± 0.5 ms, n=8; ss/peak = 14.3 ± 1.5 %, n=8) (Fig. 8B-D, Table S5). Analysis of anion effects on fully-TARPed GluA1/A2 heteromers revealed a similar relationship, where flip-only heteromers were more sensitive to anion-regulation than flop-only heteromers and alternative splicing of GluA2 had the more dominant effect (Fig. 8E, Table S5). Interestingly, the decay kinetics and equilibrium desensitization of fully-TARPed GluA1/A2 heteromers exhibited a linear relationship across all external anion conditions (Fig. 8F). Given this, we reasoned that this relationship could be used to interrogate TARP γ2 stoichiometry of native AMPARs with the data already obtained from cerebellar Purkinje and stellate cells.

In keeping with this, anion modulation of native AMPARs of cerebellar Purkinje cells was well fit by a linear relationship that was statistically indistinguishable from fully-TARPed recombinant GluA1/A2 heteromers (p = 0.10, ANOVA, Fig. 8F, red). The data taken from stellate cells, however, did not match the relationship: even though the stellate cell data were well fit by linear regression, the relationship had a different slope (Fig. 8G, cyan). Unlike fully-TARPed receptors and AMPARs from Purkinje cells, equilibrium responses elicited by AMPARs from stellate cells were only weakly sensitive to anion modulation (Fig. 7, Table S5). Given this, we reasoned that the response profile of AMPARs from stellate cells may be more consistent with a partially-TARPed receptor.

To test this, we examined the functional behavior of flip/flop variants of GluA1/A2 heteromers where $\gamma 2$ was tethered to either the GluA1 or GluA2 subunit so that any GluA1/A2 tetramer combination would possess only two $\gamma 2$ auxiliary subunits. As anticipated, the relationship between decay kinetics and equilibrium desensitization of partially-TARPed GluA1/A2 receptors was different from that of fully-TARPed heteromers (Fig. 8G). For example, although flip-containing heteromers exhibited slower desensitization kinetics (e.g. $A1_i/\gamma 2 + A2_i$, $\tau = 8.2 \pm 0.8$ ms, n=10) than heteromers containing both flip and flop (e.g. $A1_i/\gamma 2 + A2_o$, $\tau = 3.4 \pm 0.3$ ms, n=8), the degree of equilibrium desensitization was similar in each case ($A1_i/\gamma 2 + A2_i$, ss/peak = 3.7 ± 0.9 %, n=10 versus $A1_i/\gamma 2 + A2_o$, ss/peak = 1.5 ± 0.5 %, n=8) (Fig. 8B-C, Table S5). Although partially-TARPed heteromers containing both flip/flop variants had intermediate behavior, alternative splicing of GluA2 had the more dominant impact on desensitization kinetics. For

example, GluA1$_i$/A2$_o$ receptors exhibited faster desensitization kinetics (A1$_i$/γ2 + A2$_o$, τ = 3.4 ± 0.3 ms, n=8) than GluA1$_o$/A2$_i$ receptors (A1$_o$/γ2 + A2$_i$, τ = 7.0 ± 0.4 ms, n=6) (Fig. 8B-C, Table S5). Thus, the decay kinetics of partially-TARPed AMPARs varied according to subunit composition and the external anion type whereas equilibrium desensitization was relatively unchanged (Fig. 8G, Table S5), much like the behavior of AMPARs from stellate cells (Fig. 7). In fact, linear regression plots of data from partially-TARPed AMPARs and stellate cells were statistically indistinguishable (p = 0.20, ANOVA, Fig. 8G), suggesting that stellate cells express partially-TARPed AMPARs. Taken together, these data provide compelling evidence for the important role of TARP stoichiometry in dictating the functional behavior of recombinant and native AMPAR heteromers. Our results also provide a proof-of-principle approach for future enquiry interrogating the auxiliary subunit composition of native receptors.

Discussion

The present study advances our understanding of a major neurotransmitter receptor in several important ways. First, it underlines the central importance of the apo state in priming the receptor prior to activation and dictating its responsiveness to channel activators, allosteric modulators and auxiliary proteins. Second, it uncovers an unappreciated and new role of alternative splicing of the flip/flop cassette which shapes AMPAR signaling by regulating the nature of the apo state. Third, it reveals the additional role of TARP stoichiometry in also dictating the functional behavior of AMPAR heteromers and its potential value in explaining the responsiveness of native AMPARs. Finally, it establishes that the LBD of AMPARs exerts a long-range allosteric control on motions in the NTD. As discussed below, differences in the nanoscale mobility of the NTD may affect the trafficking and/or synapse strengthening of different subtypes of native AMPARs at glutamatergic synapses.

The dynamic nature of the apo or resting state

For decades, it has been assumed that the work performed by signaling proteins, such as ion channels, is initiated by the binding energy derived from a plethora of soluble activators, such as neurotransmitters. As a result, the role of the apo or resting state has been largely overlooked. However, some observations, particularly on nicotinic acetylcholine receptors (nAChRs), have challenged this orthodoxy. For example, nAChRs expressed by skeletal muscle can access the open or activated state of the channel in the absence of receptor agonists (Jackson, 1984, 1986) suggesting an underlying dynamic nature to the apo state. The probability that wildtype, unbound nAChRs enter into the open state is small, however many mutations

throughout the protein can increase this probability almost as much as agonist binding (Jadey et al., 2011; Purohit and Auerbach, 2009). In keeping with this, some nAChR mutations associated with congenital myasthenic syndromes can be linked to selective changes in the apo state rather than the activated state (Engel et al., 2010; Jadey et al., 2011), highlighting the importance of the resting state in the context of human disease.

The *lurcher* mutation (A654T) of the delta2 (δ2) iGluR subunit gives rise to cerebellar ataxia (Zuo et al., 1997) and was also concluded to reflect changes in the apo state since wildtype δ2 iGluRs are unresponsive to neurotransmitter (Hansen et al., 2009; Kohda et al., 2000; Taverna et al., 2000). The homologous mutation is also found in *de novo* missense mutations of GluA1 and GluA3 AMPAR subunits where it is associated with severe neurodevelopmental delay and autism (Geisheker et al., 2017). It was initially proposed that the *lurcher* mutation in GluA1 channels also gives rise to constitutively active channels (Kohda et al., 2000; Schwarz et al., 2001; Taverna et al., 2000); however, a more recent assessment concluded that the mutation has little or no effect on the apo state but rather increases sensitivity to the neurotransmitter L-Glu (Klein and Howe, 2004). The present study uncovers the existence of functionally-distinct apo states of the AMPAR that are regulated through alternative splicing of the LBD. Rather than facilitating entry into the main open state, the flip/flop cassette establishes the mobility of the apo state and, in doing so, fine tunes the responsiveness of AMPARs to neurotransmitter, allosteric anions and auxiliary proteins. As explained below, the complex expression pattern of flip and flop isoforms in the vertebrate brain suggests that the apo or resting state plays a critical role in neuronal signaling of developing and adult neuronal circuits.

A unifying role for the AMPA receptor flip/flop cassette

We identify an entirely new and unifying role for the AMPAR flip/flop cassette through its regulation of the apo or resting state of AMPARs. Previous studies have linked the flip/flop cassette to several important and apparently disparate properties of AMPARs that include determining the rates into AMPAR desensitization (Koike et al., 2000; Mosbacher et al., 1994; Quirk et al., 2004), regulation by positive allosteric modulators, such as CTZ, aniracetam, CX614 and PEPA (4-[2-(Phenylsulfonylamino)ethylthio]-2,6-Difluoro-Phenoxyacetamide) (Jin et al., 2005; Partin et al., 1995; Partin et al., 1994; Sekiguchi et al., 1997; Sun et al., 2002) as well as controlling AMPAR secretion from the endoplasmic reticulum (ER) (Coleman et al., 2006; Penn et al., 2008) (Fig. 6E).

Markov models describing the effect of alternative splicing on AMPAR channel gating and its regulation by allosteric modulators have assumed that the flip/flop cassette impacts AMPARs only <u>after</u> agonist binding (Koike et al., 2000; Partin et al., 1996). Our data provides an alternative explanation whereby the key events that shape channel gating and allosteric modulation occur <u>before</u> agonist binding pre-determined by the intrinsic mobility of the apo state. In keeping with this, kinetic differences between flip/flop isoforms are controlled by three closely-positioned residues in the flip/flop cassette (Fig. 3B and 6E), including Ser775Asn (Quirk et al., 2004). As this same residue regulates the apo state, it establishes a causal link between the mobility of the apo state with channel gating and allosteric modulation.

The effect of alternative splicing on AMPAR secretion from the ER has also been associated with motions triggered by agonist-bound AMPARs, primarily through the Val/Leu779 residue in coordination with Ser/Asn775 (Coleman et al., 2006; Penn et al., 2012) (Fig. 6E). Interestingly, mutating the Thr765 and Pro766 residues of the flip cassette to Asn and Ala in the flop isoform (Fig. 3A and B) has no effect on AMPAR secretion from the ER (Penn et al., 2008) but yet with Ser775Asn, they fully account for the kinetic differences between flip and flop isoforms (Quirk et al., 2004). This distinction reveals that some of the amino acid residues of the flip/flop cassette that govern differences in channel gating and ER exit of AMPARs are separable. Importantly, the Ser/Asn775 residue is implicated in all of these known regulatory effects of alternative splicing, which is in keeping with its central structural position at the kink between helices J and K of the flip/flop cassette (Fig. 6E) separating the 765/766 residues, that control channel gating, from the 779 residue, that controls ER exit. This structural arrangement has important ramifications for the developing and adult CNS since the expression of the flip/flop cassette in neurons is developmentally-regulated (Monyer et al., 1991), activity-dependent (Penn et al., 2012) and cell-type specific (Sommer et al., 1990). Consequently, our work establishes for the first time that fine-tuning nanoscale movements of apo or resting AMPARs may be a critical factor governing glutamatergic signaling in the mammalian brain. Finally, whether the nearby arginine of the R/G site, which fits directly into the LBD dimer interface (Greger et al., 2006), could influence LBD stability as well as anion and TARP sensitivity awaits to be studied.

TARP stoichiometry dictates the functional behavior of alternatively-spliced AMPA receptors

Our study establishes that TARP stoichiometry modifies the actions of the flip/flop cassette on recombinant AMPAR heteromers, generating two functionally-distinct classes that correspond to partially- and fully-TARPed AMPARs (Fig. 8F and G). Biochemical analysis of AMPARs native to the cerebellum has suggested that TARP stoichiometry is fixed (Kim et al., 2010), although it was not possible to determine whether the number of TARPs per AMPAR tetramer corresponded to partial (i.e. 1, 2 or 3 TARPs) or full occupancy (i.e. 4 TARPs). Cryo-EM structures and single-molecule imaging studies of AMPARs have shown that the make-up of AMPAR-TARP complexes can be quite variable, with assemblies containing 1 or 2 (Hastie et al., 2013; Twomey et al., 2016) or 4 (Hastie et al., 2013; Twomey et al., 2017a; Zhao et al., 2016) TARP auxiliary subunits per AMPAR tetramer complex (Chen and Gouaux, 2019). Our data from AMPARs expressed by cerebellar Purkinje and stellate cells suggest that TARP stoichiometry is variable and, most likely, fixed in each neuronal class, in agreement with a previous study comparing TARP stoichiometry between hippocampal granule and CA1 pyramidal cells (Shi et al., 2009). These conclusions are reliant on the similarity between the data from cerebellar neurons and recombinant GluA1/A2 heteromers. Whether a similar relationship can be extended to GluA2/A3 heteromers, another abundant AMPAR composition in the CNS (Bowie, 2012; Henley and Wilkinson, 2016; Jacobi and von Engelhardt, 2017), remains to be determined. Since data from Purkinje and stellate cells are consistent with AMPARs being fully-and partially-occupied by TARPs, respectively, it is possible that CNS neurons may regulate AMPAR responsiveness by varying the number of auxiliary subunits per tetramer. Since differences in the duration and amplitude of AMPAR-mediated excitatory postsynaptic potentials determines whether

postsynaptic neurons operate as integrators of synaptic activity or coincidence detectors (Konig et al., 1996; Shadlen and Newsome, 1994), it will be interesting in future studies to examine the role of TARP stoichiometry in shaping the complex behavior of neuronal circuits.

Long-range allosteric control of the amino-terminal domain by the flip/flop cassette

Several studies have reported dynamic motions in the NTD of both AMPA- and kainate-type iGluRs (Dürr et al., 2014; Dutta et al., 2015; Matsuda et al., 2016; Meyerson et al., 2014; Nakagawa et al., 2005) which have been assumed to be a consequence of agonist binding and receptor desensitization (Dürr et al., 2014; Meyerson et al., 2014; Nakagawa et al., 2005). Our data reveal unexpectedly that motions in the NTD occur in the apo state through long-range control exerted by the flip/flop cassette which primes the receptor prior to agonist binding (Fig. 4) and establishes its intrinsic mobility (Fig. 5). This mechanism is distinct from the allosteric coupling described for NMDA-type iGluRs where it is the NTD that dictates the behavior of the LBD of different GluN2-containing isoforms to determine agonist potency and channel kinetics (Gielen et al., 2009; Yuan et al., 2009). Flip variants promote moderate NTD movement and give rise to slower channel desensitization and robust regulation by anions and auxiliary subunits. The greater mobility imparted by the flop cassette overrides this allosteric regulation and acts as a master-switch presumably by rendering the LBD dimer interface less stable (Dawe et al., 2015). Removal of the NTD has only a modest slowing effect on AMPAR gating and allosteric regulation by anions (Table S1); consequently, it still unclear what role, if any, movements in the NTD may fulfill. An attractive possibility is that nanoscale mobility of the NTD controls trans-synaptic contact formation at glutamatergic synapses (Elegheert et al., 2016; Garcia-Nafria et

al., 2016), permitting AMPAR trafficking during synapse strengthening (Diaz-Alonso et al., 2017; Watson et al., 2017) as recently proposed for GluA1 and GluA2 subunits. Given that most native AMPARs are either GluA1/A2 or GluA2/A3 heteromers (Bowie, 2012; Henley and Wilkinson, 2016; Jacobi and von Engelhardt, 2017), it will be interesting in future studies to determine how the flip/flop cassette contributes to receptor trafficking and synapse strengthening.

On a broader perspective, the unappreciated role of the apo or resting state may have far reaching implications for our understanding of the inner workings of many types of signaling proteins, such as other ion channel families, G-protein coupled-receptors (GPCRs), transporters and kinases. For example, alternative splicing also dramatically impacts the signaling properties of other iGluRs (Regan et al., 2018), as well as many other ligand- and voltage-gated ion channels (Catterall et al., 2005; Kadowaki, 2015; Latorre et al., 2017; Lipscombe and Andrade, 2015; Soreq, 2015). Whether it can also explain the multiplicity of drug action on signaling proteins, such as GPCR biased agonism and modulation (Lane et al., 2017) also awaits future investigation.

Acknowledgments

Author contributions: In the Bowie lab, GBD, AMP, YY, RPDA and MA carried out the electrophysiology experiments, made figures and analyzed the data. GBD, AMP, YY and RPDA also contributed to the writing of the manuscript. MRPA generated the constructs for electrophysiology and AFM, made figures and contributed to the discussions of the manuscript. DB conceived of the study, coordinated the experiments between the different labs and wrote the manuscript. In the Edwardson and Barrera labs, MFK, CN, CF and EAS carried out the AFM experiments and analyzed data. NPB designed the AFM experiments and analyzed data. JME designed the AFM experiments, analyzed data and contributed to writing the manuscript. In the Kastrup lab, RV carried out crystallization of $GluA2_i$ and $GluA2_o$, collected diffraction data, refined structures, analyzed the structures, made figures, and contributed to writing of the manuscript. KF was involved in initial crystallization experiments, data collection and refinements of $GluA2_o$. JSK hypothesized the existence of an anion binding site in AMPARs, participated in data collections, performed the final refinements of the structures, analyzed the structures, made figures, participated in writing of the manuscript, and generally supervised the work.

Declaration of Interests: The authors declare no competing interests.

MAIN FIGURE TITLES AND LEGENDS

Figure 1. External anions selectively modulate AMPA receptor desensitization. (A) Cryo-EM structure of the GluA2-TARP γ2 (pale pink) receptor complex (PDB: 5KBU) in an antagonist-bound form. **(B)** Side view of the GluK2 (left, PDB: 3G3F) and GluA2 (right, PDB: 4IGT) LBD dimer, depicting the binding pockets for two Na^+ ions (purple) and one Cl^- ion (green) in GluK2 and two Li^+ ions (magenta) in GluA2. **(C-D)** Typical current responses of $GluA2_i$ receptors to a 250 ms (C, patch 140228p6) or 1 ms (D, patch 150825p10) application of 10 mM L-Glu in external NaCl (black), NaBr (grey), and NaF (light grey). Inset: responses scaled to compare decay kinetics. The uppermost trace (black) shows the junction current recorded after the experiment to monitor the solution exchange rate. **(E)** Recovery from desensitization for $GluA2_i$ receptors (patch 151201p9) in external NaCl (black) and NaI (orange). **(F-G)** Mean time constants of current decay after 250 ms (F, $\tau_{desensitization}$) or 1 ms (G, $\tau_{deactivation}$) L-Glu applications plotted against ionic radius. Data are mean ± SEM, from 7-15 (F) or 5-12 (G) independent patch experiments. **(H)** Recovery from desensitization experiments in different external anion solutions. Data are mean ± SEM, from 6 (NaI), 7 (NaBr), or 13 (NaCl) independent patch experiments. See also Table S1.

Figure 2. Detection of bromide ions in the GluA2-LBD dimer interface. (A-B) Side (A) and top (B) views of the $GluA2_o$-LBD N775S dimer. Bromide ions are shown in the dimer interface as brown spheres and glutamate with carbon atoms as green spheres. Nitrogen atoms are blue and oxygen atoms are red. **(C-D)** Anomalous difference electron density map (black; contoured at 7σ; before introduction of bromide ions in the structure) and Fo-Fc difference map (green; contoured at 3σ) from omitting Ser775/Asn775, bromide ions and water molecules within 4 Å of bromide from $GluA2_o$-LBD N775S (C) and $GluA2_o$-LBD (chain A) (D). **(E-F)** Magnified side (E) and top (F) views of the bromide binding sites in the $GluA2_o$-LBD N775S dimer interface. Water molecules are shown as grey spheres and amino acid residues surrounding the binding sites are orange or cyan sticks based on their subunit of origin. See also Figure S1 and Table S2.

Figure 3. Ser/Asn 775 residue of the flip/flop cassette governs anion modulation of AMPARs. (A) Sequence alignment of the GluA1 and GluA2 AMPAR flip/flop cassette, located toward the C-terminal end of the LBD. Positions that differ in both subunits are shaded grey, while residues are colored by chemical property (blue, positive charge; red, negative charge; pink, small polar; purple, large polar; green, hydrophobic). **(B)** $GluA2_o$-LBD dimer with residues Asn765, Ala766 and Asn775 shown as yellow spheres and the two bromide ions as brown spheres. The flip/flop cassette is orange in one subunit and cyan in the other subunit. **(C-E)** Typical current responses (250 ms, 10 mM L-Glu) of $GluA2_i$ (C, patch 151123p15), $GluA2_o$ (D, patch 160218p14), and $GluA2_i$ S775N (E, patch 160119p3) receptors in external NaCl (black) and NaI (colored trace). Inset: scaled responses in external NaI (colored trace), NaBr (grey), NaCl (black), and NaF (light grey). The uppermost trace (black) shows the junction current recorded after the experiment to monitor solution exchange rate. **(F)** Desensitization time constants for data shown in panels C-E, plotted against different halide ions. Data are mean ± SEM from 6-15 independent patch experiments. Prop refers to propionate. **(G)** Recovery from desensitization of $GluA2_i$ S775N

28

receptors (patch 160401p15) in external NaCl (black) and NaI (green). **(H)** Mean time constants of recovery from desensitization for $GluA2_i$ (orange), $GluA2_o$ (blue), and $GluA2_i$ S775N (green) in different external anions. Data are mean ± SEM from 5-32 independent patch experiments. See also Figures S2 and S3 and Table S1.

Figure 4. Anions control the resting and active quaternary structure of the AMPA receptor through the LBD. (A) Top: Representative AFM images of a bilayer containing $GluA2_i$ receptors before (left) and after (right) application of L-Glu (10 mM). Scale bar, 100 nm; color-height scale, 0-10 nm. Bottom: Sections through the receptor at the position indicated by the white line above. **(B)** Top: Representative AFM images of a bilayer containing $GluA2_i$ receptors before (left) and after (right) a switch from NaCl to NaI. Scale bar, 100 nm; color-height scale, 0-10 nm. Bottom: Sections through the receptor at the position indicated by the white line above. **(C)** Average height changes of $GluA2_i$, $GluA2_o$ and $GluA2_i$ S775N in response to L-Glu. Data are mean ± SEM for 10-14 receptors. **(D)** Average height changes of $GluA2_i$, $GluA2_o$ and $GluA2_i$ S775N in response to anion switches. Data are mean ± SEM for 12-14 receptors. **(E-G)** Mean height changes of $GluA2_i$ ΔNTD (E), $A2_i$ ΔNTD-eGFP (F), and $A2_o$ ΔNTD-eGFP (G) receptors in response to anion substitution as well as 10 mM L-Glu application in different external anions. Data are mean ± SEM for 10-22 receptors. Cartoon uses GFP (PDB: 1GFL) and AMPAR LBD (PDB: 1FTJ) structures for illustrative purpose only. See also Figures S4, S5 and S6 and Table S3.

Figure 5. Mobility of the resting state of GluA2 AMPARs is variable between flip and flop isoforms. (A) Galleries of zoomed (120 x 120 nm) AFM images of individual flip (left) and flop (right) AMPARs. Scale bar, 20 nm; color-height scale 0-8 nm. **(B)** Representative cumulative second-by-second (up to 28 s) mobility data for individual flip, flop and flip S775N AMPARs in the resting state. **(C)** Representative cumulative second-by-second (up to 28 s) mobility data for individual flip AMPARs in the resting state and in the presence of L-Glu (10 mM). **(D)** Combined mobility data (at 28 s) for flip and flop AMPARs in the resting state, in the presence of L-Glu and in the presence of L-Glu plus CNQX (0.5 mM). Asterisks indicate significant differences ($p < 0.05$) between groups (one-way ANOVA, Fisher test). NS, not significant. **(E)** Combined mobility data (at 28 s) for flip and flop AMPARs in the resting state and in the presence of different concentrations of L-Glu. Asterisks indicate significant differences ($p < 0.05$) between flip and flop receptors under equivalent conditions (Mann-Whitney U-test). CSD refers to cumulative squared displacement. See also Table S4 and Movies S1-S4.

Figure 6. The flop cassette acts as a master-switch to override regulation of AMPARs by TARP auxiliary subunits. (A) Typical current responses of $GluA2_i$ (patch 171120p1), $GluA2_o$ (patch 160324p7) and $GluA2_i$ S775N (patch 180813p9) receptors to a 250 ms application of 10 mM L-Glu when co-expressed with $\gamma2$ (colored trace). The AMPAR responses in the absence of $\gamma2$ were taken from patch numbers 180301p3 ($GluA2_i$), 160218p14 ($GluA2_o$) and 160119p3 ($GluA2_i$ S775N). The uppermost trace (black) shows the junction current recorded after the experiment to monitor solution exchange rate. **(B)** Typical current responses in different external anions of wildtype and mutant $GluA2_i$ AMPARs co-assembled with $\gamma2$. ($GluA2_i$, patch 151214p3; $GluA2_o$, patch 160324p7; $GluA2_i$ S775N, patch 180813p9). **(C)** Mean equilibrium current amplitude as a

percentage of the peak response. **(D)** Mean time constants of current decay in the continued presence of L-Glu. **(E)** GluA2 LBD dimer highlighting the flip/flop cassette in orange (front) and cyan (back). Although different residues are responsible for the functional differences between flip and flop GluA2 isoforms in terms of channel gating (residues 765, 766 and 775), allosteric regulation by anions and CTZ (residue 775) and ER exit (residues 775 and 779), the 775 residue is implicated in all of these regulatory functions. See also Table S1.

Figure 7. Native AMPARs are modulated by external anions. (A) Typical current responses of an excised Purkinje cell membrane patch (left, patch 190129p5) or stellate cell nucleated patch (right, patch 190205p4) to a 250 ms (black) or 1 ms (grey) application of 10 mM L-Glu. Insets show non-desensitizing responses in the presence of 100 µM CTZ (blue) (Purkinje, patch 190214p8; stellate, patch 190129p3). **(B)** Mean equilibrium current amplitude as a percentage of peak response ($I_{equilibrium}$). (***$p < 0.0001$, unpaired t-test) **(C)** Mean weighted time constants of current decay following 250 ms L-Glu application (τ_{des}). (***$p < 0.0001$, Mann-Whitney U test). **(D)** Normalized current responses to 250 ms application of L-Glu in NaCl (black), NaBr (dark grey) or NaF (light grey) in Purkinje (left, patch 190213p4) and stellate cell (right, patch 190205p4) patches. **(E)** Mean weighted τ_{des} across anion conditions in Purkinje (black squares) and stellate cell (black circles) patches. Data are presented as mean ± SEM. See also Table S5.

Figure 8. The functional behavior of AMPAR heteromers is shaped by TARP stoichiometry. (A) Typical current responses of heteromeric AMPARs to a 250 ms application of 5 mM L-Glu in tandem with TARP γ2 when indicated. Example traces are in the following sequence from left to right: GluA1$_i$/γ2+GluA2$_i$/γ2 (patch 190215p2), GluA1$_o$/γ2+GluA2$_i$/γ2 (patch 190215p13), GluA1$_i$/γ2+GluA2$_o$/γ2 (patch 190228p2), GluA1$_o$/γ2+GluA2$_o$/γ2 (patch 190301p2), GluA1$_o$/γ2+GluA2$_i$ (patch 190213p3), and GluA1$_o$+GluA2$_i$/γ2 (patch 190204p11). All GluA2$_{i/o}$ plasmids are Q/R edited. **(B)** Mean equilibrium current amplitude as a percentage of the peak response. **(C)** Mean time constants of current decay in the continued presence of L-Glu. Data are mean ± SEM with values of individual patches plotted as white circles. **(D)** Overlay of current responses of heteromeric AMPARs co-expressed with 4 TARPs (A, left) on a shorter time scale. **(E)** Left: typical current responses of GluA1$_i$/γ2+GluA2$_i$/γ2 (patch 190215p2) and GluA1$_o$/γ2+GluA2$_o$/γ2 (patch 190301p1) in external NaCl (black), NaBr (dark gray) or NaF (light grey). Right: summary of τ_{des} of GluA1$_i$/γ2+GluA2$_i$/γ2 (orange circles), GluA1$_o$/γ2+GluA2$_i$/γ2 (white circles), GluA1$_i$/γ2+GluA2$_o$/γ2 (white squares) and GluA1$_o$/γ2+GluA2$_o$/γ2 (blue squares) in external NaCl, NaBr and NaF. **(F-G)** Mean equilibrium current percentage plotted against mean time constants of desensitization. In (F), GluA1+GluA2 combinations in tandem with 4 TARPs (black circles) are included with pulled patches from cerebellar Purkinje cells (red circles). In (G), GluA1+GluA2 combinations in tandem with 2 TARPs (black circles) are included with pulled patches from cerebellar stellate cells (cyan circles). Data were fit by linear regression: (F) black, y = 1.76 - 0.30, r = 0.991; red, y = 1.70 - 2.23, r = 0.948; p = 0.10, one-way ANOVA; (G) black, y = 0.36 - 0.18, r = 0.738; cyan, y = 0.36 + 1.15, r = 0.614; p = 0.20, one-way ANOVA. See also Table S5.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

Cell Culture

Electrophysiology experiments: human embryonic kidney cells (HEK293T/17) were purchased from ATCC (CRL-11268). These cells constitutively express the simian virus 40 (SV40) large T-antigen and 17 refers to the clone number selected for its high transfectability. Cells were grown at 37°C under 5% CO_2 in Minimum Essential Medium with GlutaMAX (i.e. MEM GlutaMAX) supplemented with 10% fetal bovine serum. The sex of the cell line is not determined.

AFM experiments: tsA201 cells (a subclone of HEK293 cells stably expressing the SV40 large T-antigen, see (Suzuki et al., 2013)) were grown at 37°C under 5% CO_2 in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum, 100 μg/mL streptomycin and 100 units/mL penicillin. The sex of the cell line is not determined.

Mice

All experiments have been approved by the local authorities, were performed in accordance with the guidelines of the Canadian Council on Animal Care and were approved by the Animal Care Committee of McGill University. Wild-type mice with a C57BL/6J background were obtained from Jackson Laboratories (Bar Harbor, USA) and maintained as a breeding colony at McGill University. Both male and female wild-type mice were used for experiments and ranged from postnatal days 18 to 25.

METHOD DETAILS

Recombinant Electrophysiology

HEK293 cells were used to express recombinant GluA1 and/or GluA2 AMPAR subunits for outside-out patch recordings. For GluA2 homomers, the Q/R unedited flip and flop isoforms (GluA2Q$_i$ and GluA2Q$_o$) were used. For GluA1/A2 heteromers, the Q/R edited flip and flop isoforms of GluA2 (GluA2R$_i$ and GluA2R$_o$) were used. Residue numbering includes the signal peptide. Mutant receptors were generated using site-directed mutagenesis. External and internal recording solutions typically contained (in mM): 150 NaX (X = halide ion), 5 HEPES, 0.1 CaCl$_2$, 0.1 MgCl$_2$, and 2% phenol red at pH 7.4, and 115 NaCl, 10 NaF, 5 HEPES, 5 Na$_4$BAPTA, 0.5 CaCl$_2$, 1 MgCl$_2$, and 10 Na$_2$ATP at pH 7.4, respectively. For GluA1/A2 heteromer recordings, 30 µM spermine was included in the internal solution; data points were only included when the I/V plot was linear, typical of GluA2(R)-containing AMPARs (Partin et al., 1995) (see Fig. S7). Sucrose was supplemented to maintain the osmotic pressure at 300 mOsm. L-Glu was typically applied at 10 mM and CTZ at 100 µM, unless otherwise indicated.

Recording pipettes were composed of borosilicate glass (3-5 MΩ, King Precision Glass, Inc.) coated with dental wax. The reference electrode was connected to the bath via an agar bridge of 3 M KCl. Agonist solutions were applied using a piezo-stack driven perfusion system, and measured solution exchange time was under 400 µs. Series resistances (3-15 MΩ) were routinely compensated by 95%. All recordings were performed using an Axopatch 200B amplifier (Molecular Devices, LLC). Current records were low-pass filtered by an 8-pole Bessel filter at 10 kHz and sampled at 25-50 kHz. Data were acquired using pClamp9 software (Molecular Devices, LLC) and illustrated using Origin 7 (OriginLab Corp.).

Slice Electrophysiology

Slice preparation
Mice were anesthetized with isoflurane and immediately decapitated. A block of cerebellar vermis was rapidly dissected from the mouse head and submerged in ice-cold cutting solution perfused with carbogen gas (95% O$_2$, 5% CO$_2$). Cutting solution contains (in mM): 235 sucrose, 2.5 KCl, 1.25 NaH$_2$PO$_4$, 28 NaHCO$_3$, 0.5 CaCl$_2$, 7 MgCl$_2$, 28 D-glucose, 1 ascorbic acid, 3 sodium pyruvate (pH 7.4; 305–315 mOsmol/L). The block of vermis is then fastened to a platform, transferred to the slicing chamber and again submerged in ice-cold cutting solution, bubbled with carbogen throughout the remainder of the procedure. Thin slices of cerebellar vermis (300 µm) were obtained with a vibrating tissue sectioner (Leica VT1200; Leica Instruments, Nussloch, Germany). The slices were transferred to oxygenated artificial cerebrospinal fluid (aCSF) and held at room temperature (21°C-23°C) for at least 1 h before recordings were performed. aCSF contained the following (in mM): 125 NaCl, 2.5 KCl, 1.25 NaH$_2$PO$_4$, 26 NaHCO$_3$, 2 CaCl$_2$, 1 MgCl$_2$, 25 D-glucose (pH of 7.4; 305–315 mOsmol/L).

Acute slice electrophysiology

Slice experiments were performed on an Olympus BX51 upright microscope (Olympus, Southall, UK) equipped with differential interference contrast/infrared optics. Recordings were made from either visually-identified stellate or Purkinje cells in acute sagittal slices of cerebellar vermis. Patch pipettes were prepared from thick-walled borosilicate glass (GC150F-10, OD 1.5 mm, ID 0.86 mm; Harvard Apparatus Ltd, Kent, UK) and had open tip resistances of 3–6 MΩ when filled with an intracellular recording solution. Internal solution contained (in mM): 140 CsCl, 10 HEPES, 10 EGTA, 2 $MgCl_2$ and 60 µM spermine-HCl to examine rectification due to polyamine channel block (pH of 7.4; 295-305 mOsmol/L). Local agonist/antagonist applications were performed using a homemade flowpipe from theta tubing with a tip diameter of 300–400 µm. External solution was the same as described above with the addition of 10 µM D-APV to block NMDA receptors. Nucleated (stellate) or excised membrane (Purkinje) patches were placed near the mouth of a double-barreled flowpipe, which was rapidly jumped between control and solution containing 10 mM L-Glu (1 - 250 ms duration). Recordings were performed using a Multiclamp 700A amplifier (Molecular Devices, Sunnyvale, CA, USA). The bath was continuously perfused at room temperature (21–23 °C) with aCSF at a rate of 1–2 mL/min. Currents were filtered at 5 kHz with an eight-pole low-pass Bessel filter (Frequency Devices, Haverhill, MA, USA) and digitized at 25 kHz with a Digidata 1322A data acquisition board and Clampex 10.1 (pClamp) software.

Crystallization

Wildtype $GluA2_o$ and N775S (flip-like) mutant ligand binding domains (LBDs) were expressed and purified as described previously (Krintel et al., 2012). Crystallization was performed using the vapor diffusion hanging drop method at 6°C. The crystallization drop consisted of 1 µl $GluA2_o$-LBD solution (8 mg/ml) or $GluA2_o$-LBD N775S mutant (4 mg/ml) in a buffer containing 10 mM HEPES, 20 mM NaCl, 1 mM EDTA (pH 7.0), and 1 µl of reservoir solution. Before setting up the crystallization drops, the protein solution was mixed with L-Glu to a final concentration of 2 mM L-Glu and 300 mM NaBr ($GluA2_o$-LBD) or 4 mM L-Glu and 250 mM RbBr ($GluA2_o$-LBD N775S). Crystals used for diffraction data collections were obtained at conditions consisting of reservoir solution: 25% PEG4000, 0.2 M Na_2SO_4, and 0.1 M CH_3COONa, pH 5.5 ($GluA2_o$) or 22-24% PEG4000, 0.2-0.3 M Li_2SO_4 and 0.1 M cacodylate, pH 6.5 ($GluA2_o$-LBD N775S). Before data collection, the crystals were cryo-protected in reservoir solution containing 20% glycerol.

Data collection and structure determination

X-ray diffraction data on GluA2-LBD crystals were collected at the Max-Lab beamline I911-3 (Lund, Sweden) (Ursby et al., 2013) at 100 K. Diffraction images were processed in XDS (Kabsch, 2010). Data were scaled and merged using SCALA (Evans, 2006) within CCP4 (Winn et al., 2011) and the structures were solved by molecular replacement in Phaser (McCoy et al., 2007) using GluA2-LBD structures as search models (PDB: 3TDJ, molA for $GluA2_o$, (Krintel et al., 2012) and PDB: 4O3A, molA for $GluA2_o$-LBD N775S, (Krintel et al., 2014)). Initially, the structures were rebuilt in AutoBuild (Terwilliger et al., 2008) within Phenix (Adams et al., 2010). Structures were further improved using Coot (Emsley et al., 2010) and refinement in Phenix. Both structures displayed good quality indicators as calculated by MolProbity (Chen et al., 2010) within Phenix.

Figures were prepared with the PyMOL Molecular Graphics System (Version 1.7.4, Schrödinger, LLC). For statistics on data collection and refinements, see Table S2.

AMPA receptor purification and AFM imaging

The following constructs were used, all with an HA tag at the N-terminus and in the vector pRK5: rat $GluA2_i$ and $GluA2_o$ (Q/R site unedited), $GluA2_i$ with the point mutation S775N, ΔNTD-$GluA2_i$ (minus NTD), ΔNTD $GluA2_i$-GFP and ΔNTD $GluA2_o$-GFP. The HA tag contained the residues YPYDVPDYA, located after the first amino acid following the signal peptide (i.e. between residues 22 and 32).

Isolation of AMPARs

DNA (250 µg) was used to transfect 5 x 162 cm^2 flasks of tsA201 cells using polyethylenimine. After transfection, cells were incubated for 24-48 h at 37°C to allow expression of receptors. Proteins were isolated from transfected cells by immunoaffinity chromatography; all steps were carried out at 4°C. Cell pellets were resuspended in solubilization buffer [25 mM Tris-HCl, pH 7.5, 150 mM NaCl, 10 mM EDTA, 1% Triton X-100, 1 mM PMSF, and protease inhibitor cocktail (Roche), prepared in Biotechnology Performance Certified (BPC) water (Sigma)]. Precipitated DNA was removed by low-speed centrifugation, and the sample was then centrifuged in a 70 Ti rotor at 35,000 rpm for 1 h. Solubilized extracts were incubated with anti-HA-agarose beads (Sigma) for 3 h. The immunobeads bearing captured protein were then washed extensively with solubilization buffer containing 0.1% CHAPS (Sigma) instead of 1% (v/v) Triton X-100, and the bound protein was eluted with HA peptide (200 µg/mL). Protein purity was evaluated by silver staining and immunoblotting.

Integration of receptors into liposomes

Chloroform solutions of L-α-phosphatidylcholine (PC) and 1,2-dioleoyl-*sn*-glycero-3-phospho-L-serine (DOPS; Avanti Polar Lipids) were mixed at a molar ratio of 3:1. The chloroform was then evaporated under a stream of nitrogen gas, and the lipids were resuspended in HEPES-buffered saline (HBS; 150 mM NaCl, 20 mM HEPES, pH 7.6) containing CHAPS and mixed with purified receptor to give a final lipid concentration of 2 mg/mL and a final CHAPS concentration of 1% (w/v). The mixture was dialysed at 4°C against detergent-free buffer for 2 days, with several changes of buffer. To detect receptors, where appropriate, the dialysed sample was incubated for 12 h at 4°C with anti-HA antibody.

AFM imaging

A droplet (20 µL) of proteoliposome suspension was deposited onto the surface of a freshly cleaved mica disc (diameter, 1 cm), followed by incubation for 5 min at room temperature (20°C), during which time the proteoliposomes collapsed to form supported lipid bilayers containing integrated receptors. The mica surface was gently washed several times with HBS to remove unadsorbed proteoliposomes. AFM imaging under fluid was carried out at room temperature using a Bruker-AXS FastScan Dimension AFM instrument. The instrument was used in micro-volume fluid mode to facilitate the application of agonist, antagonist or ions directly while imaging. All images were collected in 'tapping' mode, using FastScan-D silicon probes

(Bruker). The cantilevers (with a typical spring constant of 0.25 N/m) were tuned to a resonance frequency of between 90 and 140 kHz. The microscope was engaged with a 2 μm x 2 μm scan area and a 5 nm target amplitude to allow for tuning. The amplitude setpoint was adjusted to the highest setting that allowed imaging with little noise, to minimize the force applied to the sample. To measure receptor heights, images were captured at a scan rate of 20 Hz (25 seconds/frame) with 512 scan lines per area. Individual particles were identified, and particles with heights between 5 and 10 nm were taken to represent AMPARs.

To follow the dynamics of the NTDs, sequential high-magnification (120 nm x 120 nm) images of receptor-containing bilayers were captured at a frequency of 1 frame/second with a fixed integral gain of 2.5 and a target amplitude of 1 nm. The target amplitude was kept at 1 nm to exert minimum force on the receptor. Individual particles were identified, and particles with heights between 7 and 10 nm were taken to represent AMPARs. N.B. The particles were slightly taller when using target amplitude 1 nm instead of the conventional target amplitude of 5 nm. Movement of the two globular structures relative to each other was followed under various conditions. The centers of the structures were identified by using Gaussian fitting (ImageJ plug-in, Adrian's FWHM), and NTD mobility was expressed as the cumulative squared displacement (CSD):

$$CSD(t) = \sum_{i=1}^{t} (x_{i+1} - x_i)^2$$

where x is the distance between the centers of the globular structures.

Data analysis

Image analysis was performed using the Nanoscope analysis 1.5 software and ImageJ (Schneider et al., 2012). Data analysis was carried out using Microsoft Excel, OriginPro 8.5 or SigmaPlot 12.5. Histograms were drawn with bin widths chosen according to Scott's equation:

$$h = 3.5\sigma / n^{1/3}$$

where h is the bin width, σ is an estimate of the standard deviation and n is the sample size.

QUANTIFICATION AND STATISTICAL ANALYSIS

Additional details of data analysis and statistical analysis can be found in the Method Details, main and supplemental figures, supplemental tables, and corresponding legends.

Electrophysiological data

Electrophysiological data were analyzed using Clampfit 10.5 (Molecular Devices, LLC). To measure deactivation and entry into desensitization, current decay rates were fitted using 1st or 2nd order exponential functions of the form $y = A_i*exp(-x/\tau_i)$. Where two exponential components were used, time constants are expressed as a weighted mean. To measure recovery from desensitization, a two-pulse protocol was delivered using variable interpulse intervals, and the peak amplitude of the second pulse was expressed as a fraction of the first peak. Recovery data were fitted with the Hodgkin-Huxley equation $y = N_0+(1-N_0)*(1-exp(-k_{rec}*x))^\wedge n$, where N_0 is the equilibrium response at the end of the first pulse, k_{rec} is the recovery rate, and n is an exponent that reflects the number of kinetic transitions contributing to the recovery time course. The value of n was set to 2 (see (Robert et al., 2005)). Distributions were first evaluated using Kolmogorov-Smirnova test. Non-normally distributed data were analyzed using non-parametric tests like the Mann-Whitney U test where indicated. Normally distributed data were compared using one-way ANOVA and unpaired two-tailed Student's t-test. Significance is defined as $p < 0.05$. Data are presented as mean ± SEM, with n referring to individual patches.

Atomic force microscopy data

Data are presented as mean ± SEM, with n referring to individual receptors. Heights of individual AMPARs before and after either the addition of L-Glu or an anion switch were compared using a Student's paired, two-tailed t-test. ATD mobility data for flip and flop AMPARs in the resting state, in the presence of L-Glu, and in the presence of L-Glu plus CNQX were compared using a one-way ANOVA, with a Fisher test. Combined ATD mobility data for flip and flop AMPARs in the resting state and in the presence of different concentrations of L-Glu were compared using a Mann-Whitney U test.

DATA AND SOFTWARE AVAILABILITY

The X-ray crystal structures of GluA2$_o$-LBD (PDB code, 6GL4) and the flip-like mutant GluA2$_o$-LBD N775S (PDB code, 6GIV) have been uploaded to the Protein Data Bank.

Supplemental Movie Titles

Videos showing NTD movements in individual receptors. Images were captured at 1 frame/s and are played back at 4 frames/s.

Movie S1. Flip receptor (resting state), Related to Figure 5.

Movie S2. Flop receptor (resting state), Related to Figure 5.

Movie S3. Flip receptor (10 mM L-Glu), Related to Figure 5.

Movie S4. Flop receptor (10 mM L-Glu), Related to Figure 5.

SUPPLEMENTAL FIGURES TITLES AND LEGENDS

Figure S1. Bromide ions in the GluA2-LBD dimer interface and sensitivity to cyclothiazide, Related to Figure 2. (A) Alignment of the GluA2$_o$ (magenta/blue) and "flip-like" GluA2$_o$-LBD N775S (cyan/orange) LBD dimers. Bromide ions at the dimer interface are shown as spheres (GluA2$_o$, grey; N775S, red). L-Glu is shown in green sticks representation. Nitrogen atoms are shown in blue and oxygen atoms in red. Left: side view; right: top view. Occupancy of bromide ions was refined to 0.4. **(B)** Anomalous difference electron density map (before introduction of bromide ions in the structure) from GluA2$_o$-LBD N775S, contoured at 7σ. Two bromide ions (1) were located in the vicinity of Pro515 at the dimer interface. **(C)** Anomalous difference electron density map from GluA2$_o$-LBD (chain A), contoured at 7σ. In addition to two bromide ions (1) located at the dimer interface, bromide ions lining the side chain of Arg506 in the glutamate binding site (2) and bromide ions involved in crystal packing (3) were observed in this structure. **(D)** Fo-Fc difference map (green; contoured at 3σ) from refining with water molecule instead of bromide ion in GluA2o-LBD N775S. A 2Fo-Fc electron density map (grey; contoured at 1σ) is shown for the bromide site and water molecules within 4 Å from the bromide site. **(E)** Fo-Fc difference map (green; contoured at 3σ) from refining with water molecule instead of bromide ion in GluA2o-LBD (chain A). A 2Fo-Fc electron density map (grey; contoured at 1σ) is shown for the bromide site and water molecules within 4 Å from the bromide site. **(F)** Top views of the GluA2$_o$-LBD N775S dimer (PDB: 3H6T; cyan/orange), showing two CTZ molecules (yellow sticks) bound in the dimer interface, aligned with bromide ions (brown spheres). **(G)** Response of GluA2$_i$ receptors to a sustained (250 ms) application of 10 mM L-Glu in different external halide ions, prior to (black) and during (blue) CTZ exposure. Responses in NaCl (patch 160516p4), NaBr (patch 160512p4), and NaI (patch 160510p4) were obtained from separate patch experiments. **(H)** Mean equilibrium current amplitude ($I_{equilibrium}$) of GluA2$_i$ receptors, as a percentage of the peak response (left axis, grey), in NaCl prior to CTZ application (Con.), or various halide ions in the presence of CTZ. The potentiation of the peak current response induced by CTZ in the same set of ionic conditions is also shown (right axis, blue). Data are mean ± SEM, from six (NaCl, NaI) or seven (NaBr) independent patch experiments.

Figure S2. Mutation of residue Leu504 disrupts anion modulation of AMPAR desensitization, Related to Figure 3. (A-B) Side (A) and zoom-in (B) views of the GluA2$_i$ LBD dimer interface highlighting the Ser775 and Leu504 residues in proximity to bromide ions (brown spheres) at the anion binding site. **(C-D)** Typical current responses of GluA2$_i$ L504C (C) and L504A (D) receptors to a 250 ms application of 10 mM L-Glu in external NaCl (black), NaBr (dark grey), and NaF (light grey). Inset: scaled responses in different external anions to compare decay kinetics. The uppermost trace (black) shows the junction current recorded after each experiment to monitor solution exchange. **(E-F)** Mean time constants of current decay (E) and mean equilibrium current amplitude as a percentage of the peak response (F) after a 250 ms L-Glu application for the experiments described in panels C and D, in the presence of different external anions. **(G)** Average height changes of GluA2$_i$, GluA2$_o$ and GluA2$_i$ L504A in response to L-Glu. Data are mean ± SEM for 10-14 receptors. **(H)** Average height changes of GluA2$_i$, GluA2$_o$ and GluA2$_i$ L504A in response to anion switches. Data are mean ± SEM for 10-15 receptors.

Figure S3. The GluA2$_i$ T765N/P766A mutations do not influence anion sensitivity unless S775N is present, Related to Figure 3. (A-B) Typical current responses of GluA2$_i$ T765N/P766A (A) and T765N/P766A/S775N (B) receptors to a 250 ms application of 10 mM L-Glu in external NaCl (black), NaBr (cyan), and NaI (blue). Inset: scaled responses to compare decay kinetics including a representative response in NaF (grey). The uppermost trace (black) shows the junction current recorded after each experiment to monitor solution exchange. **(C-D)** Representative voltage-clamp traces showing recovery from desensitization for GluA2$_i$ T765N/P766A (C) and T765N/P766A/S775N (D) receptors in external NaCl (black) and NaI (dark blue). Both ionic conditions were recorded from the same patch. **(E)** Mean time constants of current decay after a 250 ms L-Glu application (τ_{des}) for the experiments described in panels A and B, in the presence of different external anions. **(F)** Mean time constants of recovery from desensitization for GluA2$_i$ T765N/P766A and T765N/P766A/S775N receptors in the presence of different external anions.

Figure S4. **AFM imaging of bilayer-integrated AMPARs, Related to Figure 4**. **(A)** Isolation of HA-tagged GluA2$_i$, GluA2$_o$ and GluA2$_i$ S775N, by anti-HA immunoaffinity chromatography. Samples were analyzed by SDS-PAGE followed by either silver staining (left panels) or immunoblotting using an anti-HA antibody (right panels). **(B)** Schematic illustration of the engagement of the AFM tip with a single AMPAR. **(C)** AFM image (2 μm x 2 μm) of a protein-free lipid bilayer. Scale bar, 400 nm; color-height scale, 0-10 nm. **(D)** AFM image (2 μm x 2 μm) of bilayer-integrated GluA2$_i$ receptors. Arrows indicate receptor positions. Scale bar, 400 nm; colour-height scale, 0-10 nm. **(E)** Frequency distribution of heights of the GluA2$_i$ particles in bilayers. The curve indicates the fitted Gaussian functions. The peaks of the distribution (±SEM) are indicated. Based on our previous experience with AFM imaging of NMDA receptors (Suzuki et al., 2013), we assumed that particles in the taller population (peak 7.2 nm) represent assembled AMPARs. Particles in the shorter population (peak 4.7 nm) likely represent a mixture of unfolded or incompletely assembled receptors, together with receptors integrated into the bilayer cytoplasmic side-up. Only the assembled receptors were subjected to analysis. **(F)** Zoomed AFM image (200 nm x 200 nm) of a GluA2$_i$ receptor decorated by two anti-HA antibodies. Scale bar, 50 nm; color-height scale, 0-13 nm. The paired-globule appearance of the NTD layer is clearly visible in this zoomed image. The height of the antibody-decorated receptor falls within the taller of the two populations shown in (E). A schematic illustration of the decorated receptor is shown at the right of the AFM image.

Figure S5. Effect of L-Glu and anions on AMPAR height, Related to Figure 4. (A-L) Heights of individual GluA2 AMPARs before (left-hand point) and after (right-hand point) the indicated anion switch or addition/washout of L-Glu. The asterisks indicate statistical significance (*p < 0.05; **p < 0.01; ***p < 0.001; Student's paired, two-tailed t-test). Drug concentrations were: L-Glu, 10 mM; CNQX, 0.5 mM; CTZ, 0.1 mM.

Figure S6. **Effect of L-Glu and anions on the height of individual truncated AMPARs, Related to Figure 4. (A-C)** Isolation of HA-tagged GluA2$_i$ ΔNTD (A), GluA2$_i$ ΔNTD-GFP (B) and GluA2$_o$ ΔNTD-GFP (C) by anti-HA immunoaffinity chromatography. Samples were analyzed by SDS-PAGE followed by either silver staining (left panels) or immunoblotting using anti-HA antibody (right

panels). **(D-F)** Heights of individual GluA2$_i$ ΔNTD (D), GluA2$_i$ ΔNTD-GFP (E) and GluA2$_o$ ΔNTD-GFP (F) receptors before (left-hand point) and after (right-hand point) either addition of L-Glu or Cl$^-$-to-I$^-$ anion switch. Asterisks indicate statistical significance (*$p < 0.05$; **$p < 0.01$; Student's paired, two-tailed t-test).

Figure S7. GluA2(R)-containing heteromers are not blocked by polyamines, Related to Figure 8. (A-C) Example traces from GluA1$_i$+GluA2$_i$ (A, patch 190201p7), GluA1$_i$/γ2+GluA2$_o$ (B, patch 190204p4), and GluA1$_i$/γ2+GluA2$_i$/γ2 (C, patch 190215p5) exposed to 5 mM L-Glu (250 ms) at different membrane potentials (range, -100 to 100 mV, 10-mV increments) in the presence of 30 μM internal spermine (Spm). **(D-F)** Mean I–V plots, normalized to +100 mV in Spm, for the receptor complexes shown in A-C. **(G-H)** Mean G–V plots for the receptor complexes shown in A-C. Data are mean ± SEM.

Table S1. Gating behavior of GluA2 receptors in the presence of different external anions, Related to Figures 1, 3, and 6. Wildtype and mutant GluA2 flip (i) and flop (o) isoform receptors were expressed alone or with γ2.

GluA2 receptors were activated by long application (250 or 500 ms) or short (1 ms) applications of 10 mM L-Glu to measure desensitization and deactivation kinetics, respectively. In the presence of auxiliary subunits, current decay associated with desensitization was fit using bi-exponential functions to obtain the components τ_{fast} and τ_{slow}. Weighted time constants ($\tau_{desensitization}$) were calculated based on the relative area fit by the fast and slow components. Time constants are listed in ms and I_{norm} refers to peak current amplitudes relative to the same receptor recorded in chloride. The number of patch recordings for each condition (n) is indicated, and all values are mean ± SEM.

For native receptors, outside-out and nucleated patches were excised from cerebellar Purkinje and stellate cells, respectively, and exposed to rapid application of 10 mM L-Glu (250 ms or 1 ms duration) to measure desensitization and deactivation kinetics. Recombinant GluA1/A2 heteromers were activated by application of 5 mM L-Glu (250 ms) to measure receptor desensitization. Current decay was fit using bi-exponential functions to obtain the components τ_{fast} and τ_{slow}. Weighted time constants ($\tau_{desensitization}$) were calculated based on the relative area fit by the fast and slow components. Time constants are listed in ms. $I_{equilibrium}$ refers to the steady-state current as a percentage of the peak response. The number of patch recordings for each condition (n) is indicated, and all values are mean ± SEM.
