Abstract: In order to realize the automation and intelligence of welding process, the visual sensor and image processing technology of weld pool edge feature has become one of the key points. During the course of gas metal arc welding (GMAW), since this kind of welding requires a larger current, it makes the arc very strong and products so many droplets transfer and spatter interference. Therefore it is so difficult to extract the edge of welding pool. A new edge extraction algorithm based on component tree is proposed in the paper. It can realize the image segmentation adaptively using local features, retain the useful edge effectively and remove the false edge and noise as well. The experiments show that this algorithm can get more accurate edge information. *Copyright © 2013 IFSA.*

Keywords: Gas Metal Arc Welding, Pool Image, Edge Extraction, Component Tree.

1. Introduction

Since the quality and formation of the welding seam are decisively affected by the size, shape, etc. of the welding pool, researching the changes on the welding pool during the welding process is significantly important for the welding process automation, the seam improvement and the welding quality [1]. Fig. 1 is a typical image of the welding pool based on the passive optical. In recent years, scholars both at home and abroad have carried out much research extensively on the welding pool edge extraction as well as on the seam and wire positioning. For instance, Xiangfeng Zhen, Qing Wang and Xiaoguang Liu have applied the grayscale morphology to the edge extraction of welding pool,

which has obtained an obvious effect [2]. Jiaxiang Xue, Lin Jia and Haibao Li from South China University of Technology have extracted the welding pool edge and the seam positions by the M band wavelet transform [3]. In 2009, Liu et al. introduced the active contour model into the field of GMAW (gas metal arc welding) and then proposed an active contour model algorithm based on snake line to realize the seam extraction in the welding process of GMAW [4]. Besides, there are several conventional extraction algorithms, such as Sobel and Canny Operators. These methods are very effective for the welding image of few interferences and small spatters such as TIG (tungsten inert gas) welding [5]. But for GMAW, it's hard to position the edge of welding pool precisely because the image background is

comparatively complicated due to the big interference produced by the strong arc light, droplets and spatters during welding. And few research has been carried out on this aspect both at home and abroad [6, 7].

Fig. 1. The weld pool image based on passive optical.

Because of the high production efficiency, GMAW has attracted great attention in the field of engineering. Recently, Jing Li et al. proposed an edge extraction algorithm for the welding pool based on the area positioning and CV model [8], which preliminarily validated the effectiveness of area rough positioning to the edge extraction of welding pool. In 2010, Michael Donoser put forward a new edge extraction method called Linked Edges as Stable Region Boundaries [9] whose effectiveness for image edge extracting had already been validated in the well-known data sets ETHZ Shape Classes and Weizmann Database. The two studies have opened a new phase for the research in this field. According to the traits of GWAM, this paper introduces the component tree model to the image edge extraction and proposes an edge extraction algorithm based on component tree, which represents the character and distribution of mages grayscale and merges the region according to the local feature to extract the edge of welding pool precisely and eliminates the false edges and noise caused by arc light. Finally, this algorithm is compared with other edge extraction methods like SOBEL, CV active contour model in real experiments.

2. Algorithm Design

Component tree concept was initially proposed for classification and cluster in statistics [10]. Component tree model utilizes a hierarchical data structure to describe the internal components and the related space position characteristics for a specific object. Reference [11] applies component tree to image representation and filtering. And this paper uses component tree to realize the image edge extraction of welding pool. The edge extraction is a kind of image segmentation technology. All the pixels in the image will be divided into the two categories: background and edge ones. That coincides with the purpose and categories of component tree algorithm. The following steps are required to realize the image segmentation by component tree.

2.1. Component Construction and Graph

During the process of image analyzing, the images are quantified in order to simplify the calculation and speed up the response. For instance, the grayscale ranges in the value from 0 to 255 and those 256 grades can be quantified into a number of grayscales. As shown in Fig. 2, it's a 5×5 grayscale image. If it's quantified into 10 grayscales, according to the principle of connectivity in digital image processing, the set of the interconnected pixel points of the same gray scale I is defined as the component $V_j(I)$, j is the component label. Then, according to the definition, Fig. 2 includes 11 components $V_1(1)$, $V_2(2)$, $V_3(3)$, $V_4(4)$, $V_5(5)$, $V_6(5)$, $V_7(6)$, $V_8(7)$, $V_9(8)$, $V_{10}(8)$, $V_{11}(9)$, among which, $V_5(5)$, and $V_6(5)$ represent the components of 5 grayscale for the left and right respectively; $V_9(8)$ and $V_{10}(8)$ are the components of 8 grayscale for the top left and bottom right respectively. Fig. 3 can be seen as the set including a number of vertexes and sides, which can reflect the connection between vertexes. Now, if the component is seen as the vertex, according to the principle of connectivity, there is a side between two vertexes if the two are connected. Then, as shown in Fig. 3, an undirected graph can be derived from the 11 components in Fig. 2.

Fig. 2. Grayscale classification and component diagram.

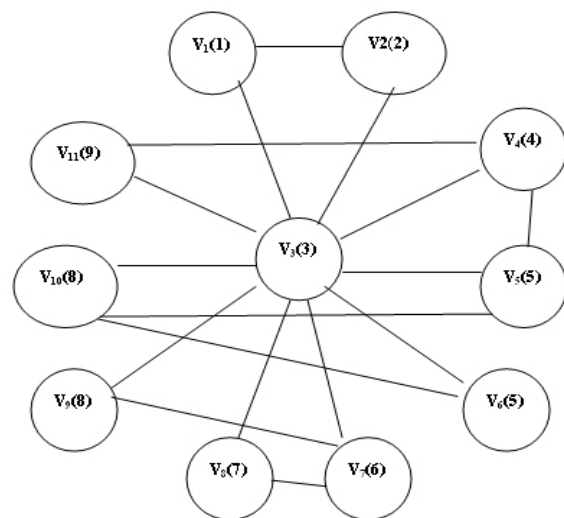

Fig. 3. Component tree.

2.2. Component Tree Construction

If a graph is connected, then there must be a tree containing all the vertexes in the graph [12]. According to connectivity of image, Fig. 3 must be a connected graph and then a tree can be got accordingly called as a component tree here. The rules for constructing a component tree are as follows:

1) From the bottom to the top. The leaf nodes first, then layer by layer, until the final root node.

2) In a descending order of grayscale. The component of high grayscale comes first. If there are two or more components of the same level, then follow the sequence from the top to bottom and from the left to right.

3) If $V_j(I)$ is the current component for processing, search the graph to find all the components connected with $V_j(I)$ of lower grayscale, and then choose $V_k(I')$ of the highest grayscale I' as the parent node for $V_j(I)$. By analogy, all the components can be processed like that.

According to the rule stated above, as shown in Fig. 4, a component tree can be generated from Fig. 3. The component tree reflexes the space position relations of all of the components in the graph: sibling nodes are not connected to each other, child nodes are connected with parent nodes and the grayscale of child nodes is always higher than that of parent nodes.

2.3. Component Tree Merge

The purpose of image segmentation is to put the connected pixels of similar character into one sort. In a component tree, the grayscale of each component stands for its region property and the overall structure of the component tree represents the space position relations of all the regions.

Fig. 4. Component tree constructing.

Thus, image segmentation can be achieved by merging the connected and similar components. The rules for merging components are:

1) Start with the bottom of the tree and process the parent nodes one by one. As shown in Fig. 4, $V_5(5)$ is the last parent node. Then the merge should start with this node until the root node.

2) If $V_j(I_p)$ is the current component for processing, check its grayscale relation with its child node $V_k(I_q)$. If it meets

$$| I_p - I_q |< \rho ,$$

where ρ is the merge threshold, then all the child and parent nodes which meet the condition can be merged to form a new component. Or else, it means there is no similarity among the components which can't be merged into one region. Then disconnect these nodes from each other.

3) How to calculate the grayscale I_{new} of the new constructed component if the two components can be merged? If it's simply to average the sum, when the pixels of the two components vary considerably, the grayscale of the component containing more pixels may contribute more to the merge grayscale. Apparently, the average couldn't well reflect the real grayscale for the new merge component. Thus, the new merge grayscale is calculated by the weighted method here.

$$I_{new} = \frac{n_p I_p + n_q I_q}{n_p + n_q},$$

where n_p and n_q are the number of pixels contained in the two components respectively.

4) Process all of the components one by one, until there are no nodes to merge. Then the left nodes in the component tree are isolated and quite different in grade gray. These isolated nodes are the final result of image segmentation.

Take the component tree in Fig. 4 for example and assume that ρ =3. Firstly, process the last node $V_{10}(8)$ on 6th layer. $V_{10}(8)$ can't be merged with its parent node $V_5(5)$ because their grayscale relationship doesn't meet rule (1). Then disconnect $V_{10}(8)$ which therefore turned into an isolated node. Next step, process node $V_4(4)$. Out of all the child nodes, only one node $V_5(5)$ can be merged with $V_4(4)$. First, disconnect $V_{11}(9)$ and $V_4(4)$. Then, merge $V_4(4)$ and $V_5(5)$. $V_5(5)$ according to the rule (2) and the grayscale of the new node is 4.5.

After that, process the next parent node $V_7(6)$ in the same way. By analogy, process the nodes one by one until the root node $V_1(1)$. The final result is shown in Fig. 5 that the graph is divided into 5 areas as shown in Fig. 6. And region 1, 9 and 8 turn out to be noise because they just contain only one pixel, and the rest two regions are normal segmentation areas containing 5 and 16 pixels respectively. This segmentation result is basically in agreement with the original image in Fig. 2 in view of visual aspects. Thus, a conclusion can be drawn that the component tree can make full use of the image local characteristics to have a good segmentation on images.

**Fig. 5.** Component tree merge result.

Fig. 6. Image segmentation effect.

3. Welding Pool Edge Extraction by Component Tree

Component tree model can realize the image segmentation and the edge extraction of welding pool is actually a process of image segmentation too to distinguish the boundary points from others. Thus, to introduce the component tree model to the edge extraction of GMAW welding pool can achieve a precise detect on the welding pool. The steps are as follows:

Process the images of the twelding pool with gradient operator to get the gradient map as shown in Fig. 7.

Quantify the gradient map

Build Components for the quantized gradient map and create component trees.

Merge component trees. Since the welding pool edge is the focus and the edge is the largest connected area except the background. Then the largest area is background and the second one is the edge of weld pool in merged result. If there are any other connected regions, they must be noise and false edges caused by strong arc. These areas can be ignored because the number of pixels contained must be much smaller than that in the real edge of the welding pool.

**Fig. 7(a).** Gradient-processing on the welding pool image – The welding pool original image.

Fig. 7(b). Gradient-processing on the welding pool image – the welding pool gradient map.

4. Experiment Results and Analysis

In order to verify the algorithm proposed by this paper, the experiment captured the seam image during welding by using the passive optical GMAW pipeline backing welding system of the CCD camera, which realized the experiments on the welding pool edge extraction algorithm based on the component tree. And further comparison was made with other edge extraction methods such as SOBEL operator, CV active contour model, etc.

The setting of grayscale in component tree model differs, the result differs. The Higher the grayscale set, the higher the precision of edge extraction will be but simultaneously the algorithm becomes too complicated to meet the demand of instantaneity. And the low grayscale can meet the instantaneity, but can't extract the edge of images precisely. Out of numerous experiments, when the grayscale I is set to 20, both the precision and instantaneity can be met. The merge threshold ρ is also very important, which can directly decide the extraction results. Fig. 8 shows the experiment result.
**Fig. 8(a).** Experiment result – the edge extraction based on Sobel operator.

Fig. 8(b). Experiment result – the edge extraction based on CV active contour model.

Fig. 8(c). Experiment result – the edge extraction based on component tree.

From Fig. 8, it can be seen that during the edge extracting based on Sobel Operator, the gradient is calculated first and then the image segmentation is achieved by binaryzation. Thus, Sobel Operator extraction depends too much on the threshold selection. When the background illumination is uneven, the extracted edge is difficult to be continuous. What's more, Sobel Operator is quite sensitive to noise. Thus, smooth processing is needed to remove the noise, which however will fuzzy the edge. CV active contour model can suppress noise well, but lack effective means for false edge. The edge extraction based on component tree model doesn't depend on some global threshold due to the grayscale quantifying processing. Instead, the merge is done step by step according to the local features. Since it makes full use of the image local features, the background and edge can be well distinguished even under uneven background illumination. And the needed region is judged according to the number of pixels contained, which can effectively get rid of noise and false edge. That's why the component tree model can comparatively get a better image segmentation. Table 1 shows the run-time of three methods. The component tree model is able to meet the demand of instantaneity although it is the most time-consuming method.

Table 1. Time consumption for different edge extraction methods.

	Sobel operator	**Cv active contour model**	**Component tree model**
Fifth frame	0.0030839	0.0135502	0.0470849
Seventh frame	0.0042028	0.0128273	0.0491684
Twentieth frame	0.0031586	0.0127638	0.0439432
Thirtieth frame	0.036985	0.0134948	0.0464315

5. Conclusion

The original CCD images taken during the welding process contain lots of noise due to the interference of dust, spatter, arc, etc. Thus, it's always a hot and difficult point to get an accurate, effective and quick method for the welding pool image processing in the field of welding quality control. According to the characteristics of GMAW, this paper proposes an edge extraction algorithm based on component tree which can well restrain the noise and false edges within the welding pool image. And a good segmentation can be therefore achieved by the step-by-step division and hierarchy based on the image local attribute. Experiments show that this algorithm is very suitable for the images of big noise, uneven illumination and target area like GMAW. This algorithm can also be applied to the common image segmentation. Especially for the images containing obvious and a small number of target areas, component tree algorithm can achieve a very good segmentation effect. But when the image is complex without clear target areas, the efficiency of this algorithm will be affected due to the large number of components.
