Abstract

Exercise stress testing can have a central role in the assessment of cardiovascular disease. Contemporary data, however, has highlighted the added value of imaging modalities over the exercise electrocardiogram in the investigation of coronary artery disease. Given the physiological changes associated with exercise and the possibility to address other parameters such as rhythm changes and the chronotropic response, exercise stress testing with continuous electrocardiographic monitoring can still have an important place in contemporary clinical practice. We report the case of a complete atrioventricular block associated with exercise and discuss the current role of exercise stress testing with continuous electrocardiographic monitoring in this entity.

Introduction

Exercise testing can have an important role in the investigation of cardiovascular (CV) disease, in several clinical scenarios [1,2]. Although exercise stress testing with continuous electrocardiographic monitoring (ExECG) has been extensively used for the assessment of individuals with suspected coronary artery disease (CAD) [3], contemporary evidence has increasingly suggested the added value of imaging modalities [4]. This notion stems

greatly from the increased diagnostic performance of imaging stress tests when compared to ExECG [4,5]. Even though considering the hinderances associated with ExECG, this test can still yield important data beyond the classical assessment of the ST-T segment [6]. Specifically, the possibility of assessing cardiac rhythm changes as well as the chronotropic response to exercise can be of pivotal clinical importance [6-8].

Case Report

We present the case of an active 72-year-old man who was referred to an ExECG due to *de novo* recurring episodes of light headedness and fatigue during his daily activities. His prior medical history included hypertension, dyslipidemia and obesity. His current medication included an angiotensin-converting enzyme inhibitor, a thiazide diuretic, a statin and acetylsalicylic acid. The patient's physical examination was unremarkable, and no metabolic disturbances were present. His resting ECG showed sinus rhythm (SR) with a borderline PR interval as well as a left anterior hemiblock and a right bundle branch block (Figure 1). Prior to the ExECG he had undergone a transthoracic echocardiogram which revealed a mildly dilated left atrium, as well as Holter monitoring which showed SR with frequent premature supra-ventricular complexes as well as the presence of premature ventricular complexes (PVCs), with no other significant abnormalities.

His ExECG (standard Bruce protocol on a treadmill) was unremarkable except for the presence of occasional isolated PVCs up to about 07:30 minutes of the test when it was interrupted due to general discomfort and subsequent syncope with documentation of a complete atrioventricular block (CAVB), first with no ventricular escape rhythm and afterwards (at about 30 seconds of recovery) with an escape rhythm of circa 30 beats per minute (Figure 2A-C). The patient was managed in accordance with the European Resuscitation Council guidelines [9], and a temporary transvenous pacemaker was implanted given lack of recovery from the CAVB despite exercise interruption and interim management [9]. Given the patients' global CV risk profile and the presentation of CAVB during exercise, cardiac catheterization (CC) was performed as to exclude CAD. His CC demonstrated right coronary dominance, and no significant epicardial CAD was present (in neither the left or right coronary arteries or main branches). Given the clinical scenario presented, a permanent pacemaker was implanted, with the patient being rendered asymptomatic.

Discussion

CAVB during exercise is an infrequent finding [8,10-13]. A contemporary systematic review of the literature proposes several

potential mechanisms for this phenomenon [10]. Although intrinsic conduction tissue disease seems of paramount importance [8,10], an ischemic contribution can also be present and should be excluded [10,11,13]. Indeed, an ischemic defect affecting the atrioventricular (AV) node has been described as a possible cause of exercise-induced CAVB [10,13,14]. Besides significant epicardial CAD, arterial vasospasm has also been described a possible cause of CAVB [15]. In the present case, however, both etiologies seem unlikely, given the absence of significant epicardial CAD (specifically in the right coronary artery) and the absence of chest pain or ST segment elevation prior to the development of CAVB during the exercise test. Beyond an arterial component, venous obstruction could also lead to CAVB, possibly due to vagal imbalances as postulated by Simantirakis *et al.* [16]. Although in the present case a specific venous study was not done, the patients overall clinical history and the lack of abnormal findings on the physical examination make this hypothesis highly unlikely.

One limitation of the present report relates to the absence of an electrophysiological study (EPS). As previously described, most cases of reported exercise induced CAVB are infranodal [10,11,17], though there are also reports describing a supranodal block [8], suggesting the utility of EPS to ascertain the specific site in question [8,10,13]. One possible explanation for exercise

induced CAVB, as previously described [10,11,13], derives from the differences in the conduction properties and refractory periods between the AV node (with increased conduction and decreased refractory period associated with exercise) and the His-Purkinje system (not under autonomic control, and as such whose refractory period is not substantially altered by exercise). Contrary to the physiologic response elicited in a normal conduction system, in the presence of conduction tissue disease (such as the case presented, given the baseline ECG characteristics) the diseased His-Purkinje system could thus be unable to conduct the impulses from the rapidly conducting AV node, and as such lead to a CAVB [10,11,13].

Although this caveat should be kept under consideration, the patients' clinical history (with symptoms elicited by the exercise test) and the lack of recovery of appropriate SR despite exercise termination, in the absence of possible reversible secondary causes (such as negative chronotropic agents or an ischemic component amenable to revascularization), were an indication for a permanent pacemaker implantation, and as such an EPS would not be of clear benefit in this specific instance.

As reported in the present case, ExECG can be of great relevance in the clinical assessment of CV disease. This non-invasive and ubiquitous modality can provide valuable data, and its overall functional assessment (namely, in terms not only of the ST seg-

ment but also of the rhythm and rate response) make it especially attractive in selected cases, such as the one presented. Albeit uncommon, the occurrence of a CAVB in the context of exercise should be considered, and although most patients present with changes in their baseline ECG some can have a normal resting ECG, thus highlighting the ability of ExECG testing to address rhythm changes during physiologic stress (as elicited by exercise) [6,9,10]. When taking into consideration the protean physiological changes during exercise [18-20], ExECG can be an interesting source of valuable clinical information.

Conclusions

This case highlights the importance of the ExECG in the investigation of a patient with atypical symptoms. Albeit the noted shortcomings associated with ExECG should be acknowledged in the era of imaging tests, this exam (and specifically its ability to assess functional status and address rhythm changes) can still play a central role in the holistic evaluation of several groups of patients, as illustrated in this report.
