

Intramural aortic hematoma: no flap no warning?

Ematoma intramurale aortico: nessun flap, nessun allarme?

ABSTRACT: *Intramural aortic hematoma: no flap no warning?* R. Citro, A. Panza, P. Masiello, A. Ravera, L. Tedesco, R. Leone, M. Mirra, R. Giudice, S. Iesu, F. Silvestri, G. Di Benedetto, E. Bossone.

We report a case of type A intramural aortic hematoma (IMH) occurred in a 78 years old female. The clinical scenario (medical history of hypertension, severe substernal chest pain, early diastolic decrescendo murmur as for aortic insufficiency), the laboratory results (no significant troponin level), ECG and transthoracic echocardiography findings (no signs of myocardial ischemia) shifted the initial diagnostic suspicion from acute coronary syndrome to the acute aortic syndrome (AAS) and triggered further imaging tests. Computed tomography re-

vealed an aneurismatic dilatation with thickening of the wall of the ascending aorta without intimal flap. No particular “warning message” for evidence of AAS was sent to the clinician on call. Subsequently, due to the persisting high clinical suspicion transesophageal echocardiography (TEE) was performed. TEE confirmed the aneurysm of the ascending aorta and highlighted an extended and marked aortic wall thickness, consisting with the diagnosis of type A IMH. Patient underwent urgent cardiac surgery that confirmed the diagnosis.

Keywords: *intramural aortic hematoma, ascending aortic aneurysm.*

Case report

A 78-year-old woman presented to the emergency room complaining of severe substernal chest pain lasting for the last six hours unrelieved by sublingual nitroglycerin. The patient was not smoker and had a medical history of systemic hypertension and hypercholesterolemia treated with angiotensin converting enzyme inhibitors (ACE-I), diuretics and statin. On physical examination heart rate was 92 beats/m, respiratory rate 20 breaths/min, blood pressure 180/100 mmHg on the left arm vs 170/95 mmHg on the right arm. Carotid and peripheral pulses were present and valid bilaterally. A protomesosystolic murmur (grade II/VI) followed by early diastolic decrescendo murmur (grade III/VI) on the aortic area were heard. Few bilateral basal pulmonary rales were detected on lung fields. No neurologic deficit were noted. The electrocardiogram showed sinus rhythm, left axial deviation of QRS and complete right bundle branch block. Laboratory tests performed on admission showed: hemoglobin 10,2 gr/dl, white cells 7320 u/L, troponin I 0,05 (n.v. 0-0,10 µ/ml) and D-Dimer 160 (n.v. < 250 ng/dl) were within the normal limits while BNP 410 (n.v. 250 pg/ml) was slightly elevated. Arterial

blood gas analysis showed PaO₂ 82 mmHg and PaCO₂ 41 mmHg with pH 7,42. Transthoracic echocardiography (TTE) revealed hypertrophic left ventricle with normal systolic function without any evidence of segmental wall motion abnormalities or pericardial effusion. Aortic root dilatation and moderate aortic regurgitation were noted. On these grounds, the initial suspicion of acute coronary syndrome was shifted towards acute aortic syndrome (AAS). A multidetector computed tomography (CT) was then performed and revealed an aneurismatic dilatation of the ascending aorta (5,4 cm) without intimal flap. A thickening of the aortic wall was also documented (Fig. 1); however it should be underlined that no particular “warning message” for evidence of AAS was sent to the clinician on call. Due to the persisting of chest pain without any ECG ischemic changes a second TTE followed by transesophageal echocardiography (TTE) exam was requested. The TTE/TEE confirmed the dilatation of the ascending aorta but highlighted an extended and marked aortic wall thickness at the ascending aorta level sparing the aortic root, consisting with the diagnosis of type A intramural hematoma (IMH) (Fig. 2). The patient was taken to the operating room. A median sternotomy was performed, after

partial longitudinal pericardiotomy a dilated and hemorrhagic aorta was found. Following institution of cardiopulmonary bypass and aortic cross clamping, the aorta was opened. The findings were typical of intramural hematoma (Fig. 3). No intimal flap nor tears were present. The aortic valve and coronary ostia were intact. A tubular graft Intervas-

cular 30 was used to replace the ascending aorta. After 14 days of an unremarkable hospital course (except for one episode of atrial fibrillation cardioverted with i.v.amiodarone) the patient was discharged on beta-blockers, ACE-I, diuretics and statin medical therapy. At six months follow-up the patient was in generally good health; the systemic blood pressure was under control and no aortic aneurysm formation on CT scan was detected.

Figure 3. - Intraoperative visualization of the hematoma (see arrow) of the ascending aortic wall.

Figure 2. - A) Transesophageal echocardiography long-axis view showing ascending aortic aneurysm; B) The ascending aortic wall thickening (arrow) extending for 5 cm; no dissection flap or false lumen is seen; C) Marked (12 mm, see arrow), crescentic thickening of the anterior aortic wall; D) No flow within the type A IMH can be appreciated despite the low scale of color-Doppler flow mapping. (AAo= ascending aortic aneurysm; Av= aortic valve)

Discussion

Acute IMH is a potential fatal entity that falls under the spectrum of AAS including also classic acute aortic dissection (AAD) and symptomatic penetrating aortic ulcer (PAU) [1]. It is considered a precursor or "variant" to AAD and usually originates from ruptured vasa vasorum into the media [1-3]. It accounts for 5 to 20% of cases presenting with symptoms of AAD, is frequently (50%-80%) located in the descending aorta and is typically associated with systemic hypertension [3, 4]. The natural history of acute IMH continues to be debate with a regression seen in ~10% of patients [1, 4, 5]. It has usually prognosis and treatment similar to AAD, with surgery recommended in patients with acute IMH involving the ascending aorta and aggressive initial medical therapy advocated in patients with type B IMH [1, 5, 6].

When AAD is suspected, time is critical to improve survival [7]. Detection of AAS is based on clinical presentation but mainly relies on imaging techniques [6, 8]. The different imaging modalities, such as TEE, CT and magnetic resonance imaging, employed in the diagnosis of AAS are all extremely accurate and the selection mostly depends on experience and the local availability [6, 8]. In the emergency setting echocardiography is safe, fast, and readily available. It can be performed without delay in patients with suspected AAS, to evaluate the presence or absence of several important features such as intimal flap and false lumen for AD, saccular aneurismal formation for PAU and aortic wall thickness for IMH. Moreover echocardiography is useful to guide differential diagnosis excluding other pathologies such as acute coronary syndrome, pericarditis, and pulmonary embolism. Transesophageal echocardiography has, compared with TTE, higher sensitivity (94-100% vs 59-83%) and specificity (77-100% vs 63-93%) respectively for identifying an intimal flap, classic sign of aortic dissection. Therefore, a high index of clinical suspicion and the rapid availability of diagnostic tests that are safe, sensitive, and specific are required to make the correct diagnosis and identify those patients who need early surgery. In the International Registry of Acute Aortic Dissection (IRAD) CT scan was used most frequently as the first test in 61% of cases, and TTE or TEE as a secondary technique in 56% of cases with an average of 1.8 methods for each patient [6]. We have to keep in mind that the absence of intimal flap exclude only the absence of aortic dissection, but not the other form of AAS, such as the IMH. As in this case and according to the IRAD recommendations, when the diagnosis is elusive despite an high clinical suspicion of AAS clinicians should not hesitate to use more than one imaging modality. Moreover, increment of D-Dimer has been associated to the AAS especially AD, but it should be underlined that the lack of elevation of D-dimer level does not exclude the presence of IMH [9]. Finally, careful clinical and imaging long term monitoring is

essential in order to detect early signs of disease progression or aneurysm formation and to achieve optimal blood pressure control.

Riassunto

Riportiamo un caso di ematoma intramurale dell'aorta di tipo A in una donna di 78 anni. Lo scenario clinico (storia di ipertensione arteriosa, dolore retrosternale urente, soffio diastolico in decrescendo da insufficienza aortica), i dati laboratoristici (assenza di incremento significativo della troponina), i dati dell'ECG e dell'ecocardiografia trans toracica (non mostravano segni di ischemia miocardica) hanno modificato il sospetto diagnostico iniziale da sindrome coronarica acuta a sindrome aortica acuta (AAS) e avviato ulteriori indagini con test di imaging. La TC rivelava una dilatazione aneurismatica con ispessimento della parete dell'aorta ascendente senza "flap" intimale. Nessun particolare "messaggio di allarme" di sindrome aortica acuta veniva trasmesso al clinico. Successivamente, per il persistere di un elevato sospetto clinico, veniva eseguita una ecocardiografia transesofagea (TEE). La TEE confermava l'aneurisma dell'aorta ascendente, visualizzando un esteso e marcato ispessimento della parete aortica, compatibile con diagnosi di ematoma intramurale dell'aorta di tipo A. La paziente veniva avviata ad intervento cardiocirurgico, che confermava la diagnosi.
