Background: Many studies on fine-needle aspiration biopsy (FNAB) for undetermined pulmonary nodules reported that diagnostic accuracy tended to decline, whereas complication prevalence raised as the size of nodule decreased. Reconsideration on the effectiveness of FNAB would be appropriate considering the dramatic increase in the identification of small nodules with screening programs and new demands of target therapies. The aim of this study was to verify the efficacy of FNAB in pulmonary nodules smaller than 15 mm.

Methods: A retrospective, cohort study was conducted on patients with undetermined solitary pulmonary nodules (SPNs) who underwent computer tomography (CT) guided FNAB at our Institution from January 2012 to December 2014. Patients with SPNs with diameter up to 15 mm were considered; inclusion criteria comprised ASA 3, FEV1 <70% of predicted, cardiac comorbidity or previous chest surgery. FNAB diagnostic performance and clinical efficacy were calculated.

Results: Out of 225 patients referred for FNAB, 68 covered inclusion criteria. Forty-nine out of 68 smears (72%) were adequate for diagnosis. Specificity was 100% (95% CI: 77–100%), sensitivity was 100% (95% CI: 90–100%). Positive and negative predictive values were 1.0 (95% CI: 0.9–1.0) and 1.0 (95% CI: 0.77–1.0) respectively. A post-biopsy pneumothorax was detected in 27 cases (39%); the pneumothorax rate was significantly affected by the number of passages ($P=0.01$).

Conclusions: The satisfactory results of our study lead to reconsidering FNAB in patients with pulmonary nodules below 15 mm in diameter, especially in order to avoid unnecessary surgery.

Introduction

With technical advances in computed tomography (CT) technology, the growing use of multi-row detector CT and the diffusion of screening programs, we have observed a dramatic increase in the identification of small pulmonary lesion (1,2). Moreover, in the era of personalized medicine,

the mutational pattern acquired great importance in the therapeutic strategy for lung cancer (3). The cytohistologic identification of these undetermined nodules, especially if small, could be a difficult step in the management of patients with suspected lung cancer. On the other hand, whether early detection of small malignant nodules could

Figure 1 Adenocarcinoma of the right lung. The fine needle is inserted in the right thorax under CT guide.

lead to a potentially curative surgical treatment, it is relevant to avoid unnecessary operations in the case of benign nodules (4,5).

CT-guided transthoracic fine needle aspiration biopsy (FNAB) is an established and safe technique for the diagnosis of intrathoracic lesions with a reported sensitivity that ranges from 74% to 95%, and a specificity between 87% and 100% (6-9). Several studies demonstrated that cell blocks (CBs) derived from FNAB can also provide sufficient material for the molecular profiling, such as *EGFR* mutation and *ALK* gene rearrangement tests, which are mandatory for the therapeutic choice in lung adenocarcinoma (10-12). Thanks to the advances of the molecular techniques, which enable the identification of wide spectrum of mutations also using scant tissues, cytological specimens can represent the biologic source for molecular testing, avoiding further invasive procedures (13).

Few studies have been published regarding the diagnostic performance and complication prevalence of FNAB in the evaluation of small lung nodules (<20 mm). These studies reported that the diagnostic accuracy tends to decrease with the size of the lesions, and that the prevalence of complications, such as pneumothorax and chest tube placement, tends to rise as the size of lesion decreases (7-9,14-16).

The aim of this study was to determine the accuracy and the diagnostic value of FNAB of solitary pulmonary nodules under 15 mm in diameter, in high risk patients.

Methods

This was an observational, retrospective, single-centre, cohort study conducted at Ca' Granda Foundation

University Hospital in Milan. The medical records of patients who were referred to our institution from January 2012 to December 2014 were reviewed.

Inclusion criteria were patients with SPN ≤ 15 mm in diameter and American Society of Anesthesiologists (ASA) status III, previous chest surgery (lung resections) who required cytological assessment with FNAB. Nodules with diameter of 3 cm or less, single, spherical, well-circumscribed, and surrounded by aerated lung were considered SPN (1,2,17). Study end-points were FNAB adequacy, diagnostic accuracy, complications prevalence and clinical value.

All biopsies were performed according to a standard protocol after a multidisciplinary evaluation by thoracic surgeons, oncologists and pathologists. Patients were previously instructed to discontinue anticoagulation therapy if they took it routinely. CT and PET scans, routinely performed before multidisciplinary evaluation, were reviewed immediately before the procedure. All FNABs were performed by a thoracic surgeon with large experience (Dr Tosi D). Informed consent was obtained from all patients before the procedure. The SPN diameter, its location (peripheral, mid-lobar or hilar), and the clinical outcome were extracted from patients' charts.

At the time of biopsy, spiral CT scan was performed through the area of interest setting a slice thickness of 5 mm. The patient was then positioned on the CT table according to the best position for biopsy. Skin entry point was marked with a metallic marker and 10 mL of 2% lidocaine were administered to induce local anesthesia. Twenty-three Gauge Chiba needles were used in majority of the cases, but in case of lesions close to the chest wall, 22 Gauge needles were preferred, because of the limited risk of pneumothorax. The length of the needle was chosen according to the distance of the lesion from the chest wall. A step by step progression of the needle tip was then confirmed by CT scan (*Figure 1*). After confirmation of adequate position of the needle tip, aspirates were obtained; a part of the material was settled up with MGG (May-Grunwald-Giemsa) stain and submitted to a cytopathologist with experience in pulmonary pathology, in order to have a rapid on-site evaluation (ROSE). If the specimen was considered adequate, the procedure ended, if not, the aspirations were repeated up to three times.

A final CT scan of the region of interest was performed to exclude complications, in particular pneumothorax. Chest tube was inserted immediately under CT guide if the pneumothorax was large or if the patient was symptomatic; smaller asymptomatic pneumothorax was treated by placing

the patient in a recumbent position. All patients had an expiration chest X-ray in erect position one hour after the FNAB, in order to exclude pneumothorax or hemorrhage. Patients without complications were subsequently discharged with detailed instructions about possible late symptoms, while a second chest X-ray was obtained after one hour in patients with radiographic evidence of small pneumothorax. If the pneumothorax was “large” at one-hour chest X-ray, or when increasing pneumothorax has been documented on the second chest X-ray, the patients were treated with thoracostomy tube insertion. Symptomatic patients (shortness of breath, decreased oxygen saturation and substantial pain) had chest tube placement irrespectively to amount of pneumothorax (18).

The FNAB samples were fixed in formalin; samples were centrifuged in order to prepare paraffin blocks; immunohistochemistry was performed when an adequate specimen was available. According to well established criteria recommended by the World Health Organization (WHO 2004), the major histological criteria for adequate specimens are summarized.

- (I) Squamous cell carcinomas: cohesive sheets and single cells with evidence of keratinization, Nucleus/Cytoplasm ratios range from low to high; dense, waxy, hard orangeophilic cytoplasm with clearly defined borders, cells with bizarre forms and hyperchromatic nuclei with inconspicuous or pyknotic nucleoli.
- (II) Adenocarcinoma: cohesive sheets or clusters of cells with depth focus (three-dimensional); columnar, cuboidal, polygonal cells with scant/moderate cytoplasm with vacuolization, enlarged nuclei with prominent nucleoli.
- (III) Small cell carcinoma: highly cellular aspirate with prominent coagulative necrosis and a high nucleus/cytoplasm ratio: very little cytoplasm and hyperchromatic nuclei with dispersed chromatin with a “salt and pepper” feature. In this subset of lesions, the research of neuroendocrine differentiation was performed with immunohistochemical analysis using the following antibodies: CD56, synaptophysin, and chromogranin A; furthermore, a proliferation index (Ki-67) was analyzed.

All the mentioned criteria were taken into consideration by the cytopathologist in association with clinical-instrumental data (anamnesis, radiological history, CT-PET), especially in patients with a low suspicion for malignancy.

The final cytological findings were classified positive for

malignant tumor cells (MTC) or suspicious for malignancy. In this study MTC or “suspicious for malignancy” were considered as “positive” results. When there was evidence of a consistent cellular component but without any evidence of malignant tumor cells, the sample was recorded as negative for MTC; for the study aim, such findings were defined as a “negative” result after three punctures. We considered inadequate findings smears with insufficient or poor-quality cellular material from samples collected after three punctures. Patients with inadequate tests were submitted to surgical biopsy, repeated FNAB or clinical follow-up according to patients’ preference; such patients were excluded from the accuracy analysis (19,20).

Patients with positive results were considered for lung resection; patients with negative findings were followed up in order to exclude disease progression. After surgery, histological confirmation was obtained from formal fixed and paraffin embedded material when areas with squamous or glandular differentiation were observed. In poorly differentiated lesions, glandular differentiation was detected by TTF-1 and/or Napsin A immunohistochemical positivity as well as for P40 in squamous tumors or CD56 and/or synaptophysin for neuroendocrine differentiation.

Diagnostic accuracy was calculated by comparing the cytological diagnosis from the FNAB with findings obtained at surgical pathological examination or clinical follow-up.

Statistical analysis

Continuous data are presented as mean and standard deviation. Categorical variables are shown as numbers and percentages. Confidence interval for proportion was computed using normal approximation. Exact binomial confidence limits were calculated for sensitivity, specificity, and positive and negative predictive value (21). Confidence intervals for negative likelihood ratios were based on formulae provided by Simel (22). Chi square test was performed. Two-sided P values were computed. Statistical significance was considered when P value was equal or less than 0.05. Confidence interval was set at 95% confidence level. All analyses were carried out using R version 3.2.2 software (23).

Results

Out of 225 patients with SPN who were referred to our institution in the mentioned period, 68 matched the inclusion criteria. Demographics data are showed in *Table 1*.

Table 1 Demographics data

Variables	Value
Age, years, median [range]	65 [35–75]
Gender, male, n (%)	29 (42.6)
Lesion size, cm, median (range)	1.05 (0.5–1.5)
Body mass index, median (range)	26.4 (17.6–35.4)
Positive smoking history, n (%)	39 (57.4)
Comorbidities, n (%)	
Cardiac	48 (70.6)
Respiratory	53 (77.9)
Metabolic	15 (22.1)
Lobe, n (%)	
Right upper lobe	29 (42.6)
Right middle lobe	3 (4.4)
Right lower lobe	10 (14.7)
Left upper lobe	15 (22.1)
Left lower lobe	11 (16.1)
Location (distance from pleura), n (%)	
Peripheral, outer third	32 (47.1)
Mid-lobar, middle third	20 (29.4)
Hilar inner third	16 (23.5)

Chiba needles with a size of 23 Gauge were used in 85% of cases. Nineteen procedures (28%) were inadequate for diagnosis; 49 procedures resulted adequate and were considered for diagnostic accuracy (72%; 95% CI: 60–82%).

Out of the 49 adequate results, 35 were positive for malignant tumor cells and 14 were negative (1 case: tuberculosis). Among the 35 positive cases, 12 nodules (34%) were classified as “suspicious for malignancy” or non-small cell lung cancer (NSCLC), the remaining 23 cases had the histological type determined by immunohistochemistry: 9 (25%) adenocarcinomas, 8 (22%) squamous cell carcinomas, 2 well differentiated neuroendocrine tumors, 2 colorectal metastases, 1 uterine metastasis, and 1 bladder metastasis. Of the 35 cases positive for malignancy at FNAB, 33 patients had surgical confirmation (31 lung cancer and 2 pulmonary metastases). Two patients with lung metastases at FNAB findings were followed for more than 2 years with clinical confirmation; those patients were treated with chemotherapy or/and radiotherapy. Finally,

out of the 49 adequate samples, 35 were recorded as true positives. Among the 14 negative cases, 5 nodules were specific benign lesions (4 granulomas, 1 hamartoma); in 4 cases inflammatory cells with a positive bacterial or mycobacterial culture were found. The remaining 4 cases had a nonspecific benign cytology (macrophages, histiocytes, reactive bronchial epithelium). The 14 patients with negative FNAB results were considered as true negative after follow-up without evidence of disease progression (median follow-up: 39 months; range, 25–59 months). Specificity was 100% (95% CI: 77–100%), sensitivity was 100% (95% CI: 90–100%). Diagnostic accuracy value was 100% (95% CI: 93–100%). Positive predictive value was 1.0 (95% CI: 0.9–1.0), negative predictive value was 1.0 (95% CI: 0.77–1.0). Number needed to diagnose was 1.0 (95% CI: 1.0–1.5). No differences were found, comparing the diagnostic accuracy for lesion size of 10 mm or less and for lesion size ranging from 11 to 15 mm ($P>0.5$). Regarding 19 patients with inadequate results from biopsy, every case was discussed during multidisciplinary team meetings, and submitted to surgical biopsy or radiologically followed up, depending on the clinical suspicious of malignancy.

The total overall number of punctures was 129; of them, 44 were the punctures in positive samples (mean: 1.25/patient), 42 in negative samples (mean: 3/patient) and 43 in inadequate samples (mean 2.26/patient). In the group of malignant cases, a single aspirate was sufficient for diagnosis in 27 cases (77%), a second puncture was required in 7 cases (20%), a third in 1 (3%).

The most frequent complication related to the FNAB procedure was pneumothorax, that occurred in 27 patients (39%, 95% CI: 28–52%); 19 patients required a chest drainage (28%). Pneumothorax occurrence and chest drain requirement were significantly associated with the number of punctures ($P<0.001$ and $P<0.001$, respectively). The association between respiratory comorbidities and pneumothorax rate is not statistically significant in our study. It is to underline that respiratory comorbidities, particularly emphysema is quite high in our cohort of patients (78%, as reported in *Table 1*), and this can be related to the lack of strong association. No other statistically significant risk factors were found; there was a trend of higher prevalence of pneumothorax rate in the group of patients with “inner third” lesions, but this wasn’t statistically significant, probably due to the small size of such subgroup.

There was one case of hemoptysis, with spontaneous

resolution after a short time without any treatment; no cancer cell seeding occurred in this series.

Discussion

The increased availability of CT with improved technology (such as sub-millimeter CT scan) has increased the detection rate of small pulmonary nodules, including early peripheral lung cancer (1,2). The recent diffusion of cancer screening programs makes the management of small pulmonary nodules a challenging issue. Furthermore, many more patients undergo screening autonomously. Finally, current targeting therapies require tissue sampling for molecular tests. Percutaneous fine needle biopsy of the lung has over the years become a simple, quick, safe and highly accurate procedure in the clinical management of patients with pulmonary lesions, especially the solitary ones. FNAB is an alternative to video-assisted thoracoscopic surgery in the diagnosis of solitary pulmonary nodules (17). Despite significant percentage of non-diagnostic results, FNAB technique is less invasive than VATS, avoids general anesthesia, and is associated with a lower rate of complications. Considering such characteristics, FNAB is usually suggested in high risk patients (3-8).

Several studies had fixed the FNAB overall sensitivity at 70–100% for the diagnosis of malignancy, and most reported values range from 85% to 95% (6-9,14-16,24,25). The same diagnosis could be obtained by endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) for peripheral lesions, with lower complication rate, but lower sensitivity as well (26); for this reason, we still consider EBUS-TBNA as the gold standard in case of nodal involvement (27), but not as the first choice in case of peripheral lung cancer.

The issue about the possible role of the dimensions of the pulmonary lesions in terms of sensitivity, diagnostic accuracy and rate of complications is still open (14). Ohno *et al.* reported a diagnostic accuracy of 52% for lesion size of 10 mm or less and 74.4% for lesion size ranging from 11 to 15 mm (15). Wallace *et al.* reported an overall sensitivity and a diagnostic accuracy of 82% and 88% respectively in their series of FNAB of nodules ≤ 10 mm (16). In our study, the prevalence of adequate samples was 72%, a rate similar to Wallace (16). Interestingly, in our series the diagnostic accuracy for lesion size of 10 mm or less and for lesion size ranging from 11 to 15 mm was similar. It is well known that adequacy depends on the location, depth, diameter of the nodule and on the number of

punctures; in addition, high cancer prevalence in a study population increases the adequacy (28). We consider adequacy prevalence over 70% a good reason for use FNAB as a suitable alternative to surgical biopsy in high risk patients. Nevertheless, the previous considerations should be carefully evaluated in every clinical case: an accurate selection of patients to submit to FNAB could potentially increase the adequacy up to 80%, as indicated by the upper limit of 95% confidence interval in our study.

Including inadequate findings in the accuracy calculation is a discussed matter; usually authors reporting FNAB on suspected breast lesions considered the inadequate results as malignant (29). From a clinical point of view, this behavior increases the indications to surgical biopsies, but it is obvious that surgical risk for pulmonary resection is considerable higher than breast surgery. Therefore, we don't consider justified including inadequate samples as positive findings in the accuracy calculation, as well as in the clinical practice (19,20). On the other hand, some Authors included inadequate findings into negative results (28). Once again, we consider this assumption as a questionable clinical conduct: inadequate results should lead to repeat FNAB or consider further diagnostic strategy such as navigation bronchoscopy (30), surgical biopsy or close follow-up. From a methodological perspective, is it logical considering an inadequate finding a positive or negative result? According to other authors, we believe that inadequate samples can't be included in the accuracy calculation (20,31,32).

In our experience about FNAB of small pulmonary lesions (≤ 15 mm), sensitivity and diagnostic accuracy value is considerable, especially if compared with the results on bigger nodules. This good result can be partially explained by analyzing the nature of the lesions in terms of CT appearance. Performing a biopsy of a small nodule is technically challenging, due to the difficulty in reaching the small target area. In the same way it is possible to state that biopsy in a large lesion is sometimes disheartening for the presence of a large necrotic area, which frequently leads to inadequate results. This consideration allows understanding how, although dealing with a small lesion is technically complicated, it often gets good results in terms of diagnostic accuracy.

During FNAB procedures, a cytopathologist should be present to reduce the number of non-conclusive specimens and decrease the number of recurrent biopsies (24,25,33-38). Moreover, in case of a malignant lesion, the cytopathologist can require an additional sample to be kept in formalin, in order to have sufficient material for immunohistochemical

studies (39-43). In addition, the use of CBs obtained from FNAB for the molecular testing of the tumor, is essential for the benefit of the patient, whose treatment may depend on the *EGFR* and *ALK* status (3,44). The discussion of the clinical case with the cytopathologist can help to guide the strategy for the biopsy: for example, in the case of suspected granulomatous pathology, or in case of difficult malignancies, is possible to perform a tru-cut biopsy for the confirmation of the diagnosis (45,46). Core-needle biopsies have high diagnostic yield, with an acceptable increased complication rate, but were not included in the present study (47).

Although the estimated accuracy was extremely high in our study, its value must be cautiously considered: the lower limit of 95% CI indicates that, repeating the experience in a different scenario, the specificity and sensitivity should be at least 77% and 90%, respectively. Such values are similar to the performance obtained from the FNAB for larger SPNs. The intrinsic variability of FNAB could also be related to the pathological judgment. In this context, our selectiveness in determining sample adequacy and patients' selection have led to a high diagnostic accuracy.

Among the possible complications, pneumothorax is by far the most frequent; its reported rate ranges widely from 22% to 45% (48-50). Cox *et al.* demonstrated, with a study about the variables that affected the risk of pneumothorax during FNAB, how the only variables that have proved to be statistically significant were the dimensions of the nodules and the evidence of emphysema (51). In a meta-analysis published in 2017 by Heerink *et al.*, smaller nodule diameter, larger needle diameter and increased traversed lung parenchyma were risk factors for complications (52). In our series the pneumothorax prevalence was similar to that reported in the literature; we found an association between the number of punctures and pneumothorax rate as reported by others (53).

The possibility of cancer cells seeding is well known as a potential risk of FNAB; we did not find any cancer seeding in our series but, although the incidence is quite rare, the seeding must be taken in account in the follow up (54).

Study limitations were related to the small sample size and to a possible selection bias.

Conclusions

We believe that FNAB is a suitable tool for the diagnosis of lung nodule of 15 mm or less in high risk patients. Accurate patients' selection, expert operator, rapid on-site evaluation and selectiveness in adequacy judgment are essential to

reach high diagnostic accuracy that may avoid unnecessary surgical procedures. In fact, in our series, out of 49 patients who received adequate diagnosis, 14 (29%) of them resulted true negative and didn't need surgical diagnosis.

In conclusion our study demonstrated that FNAB is an effective procedure even in the diagnosis of small pulmonary nodules. The accuracy resulted satisfactory while positive and negative predictive values reached the top rate. In the era of cancer screening and target medicine a diagnostic strategy including FNAB as the first approach to small pulmonary nodule in "sub-critical" patients should be reevaluated.
