ABSTRACT

Thermal stability and effect of heat treatment on electronic structure and microhardness of electrodeposited Co–W alloy coatings using gluconate bath was characterized by DSC and XPS. XPS studies demonstrate that as-deposited alloy coating has significant amount of Co and W metals as well as Co²⁺ and W⁶⁺ species. There is a decrease in Co metal concentration in the alloy heated at 600 °C and Co is in fully oxidized form when it is heat treated at 800 °C. Marginal decrease in W metal concentration and presence of both W⁶⁺ and W⁵⁺ species are observed when the coating is heated at 600 °C, whereas mostly W⁶⁺ species along with a little amount of W⁵⁺ could be seen in the coating heated at 800 °C. Microhardness values of 1017 and 1336 HK are observed when Co–W coatings are heated at 500 and 600 °C, respectively and they are comparable with as-deposited hard chromium coatings.

1. INTRODUCTION

In recent years, nanocrystalline Co alloys have attracted much attention due to their magnetic, mechanical, corrosion and wear resistant properties and thermal stability.¹⁻⁹ They have also been used in aerospace and autobody components production as anticorrosive protectors. Among Co alloy materials, Co–W alloys have attracted much attention due to their exceptional hardness, wear resistant and corrosion resistant behaviour.⁵⁻⁸ Moreover, Co–W alloy deposits have been identified as one of the promising replacements for the conventional hard chromium deposits which are formed in an environmentally hazardous process based on hexavalent chromium.⁵⁻⁷ It has been observed that codeposition of hard material such as W with Co could enhance the thermal stability, electrochemical and mechanical properties of Co–W alloy coatings.

It is very well documented in the literature that heat treatment influences the structure, composition and the properties of alloys. Heat treatment in the electrodeposited Co–W and Co–W–P alloys enhances the corrosion resistance and this enhancement is attributed to the formation of stoichiometric compounds, surface oxides and the precipitation of stable phases in the microcracks.¹⁰⁻¹² Recently, we have studied the structure and morphology of heat treated Co–W coatings prepared by gluconate bath and found that there is no change in the structure till 500 °C and a remarkable change for the coating heat treated at 800 °C.¹³ This has led us to study systematically for the understanding of such behaviour of this system. In the present work, we report details of thermal stability, systematic research on electronic structure, elemental oxidation states, their relative concentrations and microhardness of Co–W alloy coatings after heat treatment at different temperatures using DSC and XPS techniques. Increase in microhardness in heat treated coatings is substantiated by XPS results.

It has also been found that heat treated Co–W alloy coatings show comparable microhardness of hard chromium coatings.

2. EXPERIMENTAL METHODS

Co–W alloy coatings were electrodeposited from baths containing cobalt sulfate heptahydrate (15 g L^{-1}), sodium tungstate dihydrate (16.5 g L^{-1}), boric acid (40 g L^{-1}), sodium gluconate (110 g L^{-1}) and sodium chloride (30 g L^{-1}). The pH of prepared bath was around 5.2 and the pH was adjusted to 5.0 ± 0.05 by the addition of H_2SO_4 . Analytical grade chemicals and deionized water were used to prepare the baths. For electrodeposition, approximately 200 mL solution was taken in a 250 mL glass beaker. Temperature of the bath was maintained at 80°C using a constant temperature water bath. A graphite bar was used as the anode and a mechanically buffed brass sheet with $10 \text{ cm} \times 2.5 \text{ cm} \times 0.1 \text{ cm}$ dimension was used as the substrate. For XPS and DSC studies plating was done on stainless steel substrates. The coating was peeled off from the substrate for analysis. Heat treatment studies were carried out on the coatings deposited on mild steel substrates. In all cases, substrate was degreased with acetone, rinsed with tap and deionized water, cathodically cleaned with 10% NaOH solution for 1 min at 15 A dm^{-2} , rinsed with tap and deionized water. Then the substrate was deoxidized with 10 vol.% H_2SO_4 for 30 s (50 vol.% H_2SO_4 for 5 s for stainless steel and mild steel substrates), rinsed with tap water and deionized water and loaded in the bath for electroplating. Electrodeposition was carried out by direct current (DC) electrodeposition method. DC electrodeposition was carried out galvanostatically by using an Aplab 7253 regulated DC power supply at an average applied current density of 4.7 A dm^{-2} . The plating was carried out for 1 h and the deposited coating was rinsed with deionized water and dried at room temperature.

The heat treatment temperatures were identified and chosen from DSC curves. The thermal stabilities of Co–W coatings were studied at 160, 350, 500, 600 and 800 °C with vacuum of 5×10^{-4} Pa. Molybdenum strips were used as heating elements to heat a stainless steel 316 thick plate, on which the test samples were placed. The accuracy of the set temperature was ± 10 °C. Heat treatment was done for 1 h with heating and cooling rates of 5 °C min^{-1} .

Differential scanning calorimetry (DSC) studies for the phase transformation of these Co–W alloy coatings were performed with a Diamond DSC (Perkin Elmer). The sample was taken in the form of a foil and cut into smaller pieces. About 0.5 g sample was put in an aluminium pan and crimped using a cover. Empty aluminium pan with cover crimped was used as a reference. The crimped specimen and reference samples were placed in a Pt furnace and heated with different scanning rates of 10, 20, 30 and 40 °C min^{-1} under continuous purging of the heating chamber with nitrogen flow of 30 mL min^{-1} to avoid sample oxidation. The plot of temperature against heat flow was obtained.

X-ray photoelectron spectroscopy (XPS) of as-deposited and heat-treated Co–W alloy coatings were recorded with a Thermo Fisher Scientific Multilab 2000 spectrometer using non-monochromatic $\text{AlK}\alpha$ radiation (1486.6 eV) as an X-ray source operated at 150 W (15 kV and 10 mA). The binding energies (E_B) reported here were calculated with reference to C1s peak at 284.5 eV with a precision of ± 0.1 eV. For XPS analysis, coatings were mounted on the sample holder after cutting into small pieces and they were kept in the preparation chamber with ultrahigh vacuum (UHV) at 10^{-9} Torr for 5 h in order to desorb any volatile species present on the surface. After 5 h, samples were transferred into the analyzer chamber with UHV at 10^{-9} Torr. All the spectra were obtained with pass energy of 30 eV and step increment of 0.05 eV. The experimental data were curve fitted with Gaussian peaks after

subtracting a linear background employing PeakFit v4.11 program. For Gaussian peaks, slightly different full width at half maximum (FWHM) was used for different chemical states. The spin-orbit splitting and doublet intensities were fixed as given in the literature.¹⁴

Microhardness measurements of these alloy coatings heated with different temperatures were carried out on the surface of the deposits using Buehler microhardness tester with a Knoop indenter under a test load of 50 g for 15 s. For microhardness measurements, samples were polished with 0.3 μm Al_2O_3 until mirror finishing was obtained. Average hardness (HK) value was estimated by making 5 indents on each sample.

3. RESULTS AND DISCUSSION

3.1 Chemical composition, structural and morphological studies

Effects of heat treatment on chemical composition, structure and morphology of Co–W coatings are discussed in details in our previous paper.¹³ In brief, EDXS analysis demonstrates an increase in tungsten content in alloy coatings after heating at 600 and 800 °C and W concentration is in the range of 46–59 wt.% in as-deposited and heat treated coatings. XRD patterns indicate the presence of amorphous structure in as-deposited coating and the coatings heated up to 500 °C, whereas Co_3W phase could be observed in the coatings heat treated at 600 and 800 °C. Electrodeposited Co–W coating consists of spherical and smooth bright nodules on its surface and is crack-free as seen from FESEM image, but cracks could be observed in the coatings heat treated at higher temperatures.

3.2 Thermal stability studies

It is well known that the metastable alloys, which are thermodynamically unstable, undergo phase transformation to become completely stable crystalline phase. DSC is a very useful tool to study the phase transformation behaviour of such metastable alloys. The DSC thermogram

of Co–W deposits, recorded over a temperature range of 100 to 575 °C at a scan rate of 20 °C min⁻¹ is shown in Figure 1. The presence of exothermic peaks suggests the occurrence of phase transformation. The peak temperatures and the corresponding enthalpy (ΔH) values are compiled in Table I. From the figure it is evident that the deposit displays two exothermic peaks at 159 and 335 °C and the corresponding enthalpy values are -11.5 and -5.4 J g⁻¹, respectively. Deposit has also exhibited the presence of one endothermic peak at 493 °C with an enthalpy value of 49.8 J g⁻¹. From the figure it is evident that the two exothermic peaks present are very shallow and are not very prominent. The presence of these exothermic peaks could be attributed to the structural relaxation such as annihilation of point defects and dislocations within the grains and grain boundary zones. In this sense, the increase in the crack density at higher heat treatment temperatures observed from our FESEM studies¹³ is well augmented by the shallow exothermic peaks obtained in the DSC curve and this increased crack density is due to the internal movements in the Co–W deposits upon heat treatment. It has also been observed that by varying the scan rate there is no significant change in the intensity of exothermic peaks. On the other hand, there is an appreciable change in the endothermic peak intensity at higher scan rates. From this it is evident that the crystalline transformation is not significant in the electrodeposited Co–W alloy in the temperature range up to 500 °C. Similar observation has been noticed in the XRD patterns obtained for these deposits annealed until 500 °C.¹³ The endothermic peak observed in all the four coatings might have formed due to increased disorderliness in the coating at this temperature. Increase in disorderliness actually means the increase in entropy of a system. Thermodynamics proves that the increase in disorderliness (entropy) of a system is accompanied by heat intake by the system which conforms to the appearance of the endothermic peak.

Chen et al.¹⁵ and Singh et al.¹⁶ have reported that there is a possibility of glass formation and melting point depression of electrodeposited Co–W alloy coatings. Chen et al.¹⁵ have noticed that the strong interaction with atoms of different atomic sizes which constitutes the eutectic composition produces a large melting point depression. Singh et al.¹⁶ have calculated the glass forming range to be 40–70 at.% W from the size difference rule, whereas the experimental results indicate the glass forming ability (GFA) of Co–W alloys at 20 at.% W. Therefore, it could be suggested that the electrodeposited Co–W coatings might have a very low melting point like 500 °C as seen from the DSC curves. Fedosyuk et al. observed low crystallization temperature of around 400 °C for Co–W coatings with low tungsten content obtained from citrate baths.¹⁷ The authors in their study also found that this crystallization temperature increased with increasing W concentration (for 28 at.% W), crystallization started at approximately 450 °C). Thus, coatings obtained from gluconate bath in this study are stable up to 500 °C.

3.3 XPS studies

To get the clear idea about effect of heat treatment on the electronic structure of Co–W alloys, XPS studies of as-deposited and heat-treated coatings have been carried out. We have done XPS of samples heated at 600 and 800 °C as there is no significant change in the XRD patterns of coatings heated up to 500 °C.¹³ XPS of Co2p core level region in as-deposited Co–W alloy coating and the same after heat treatment at 600 and 800 °C could be deconvoluted into sets of spin-orbit doublets along with associated satellite (S) peaks. Deconvoluted core level spectrum of Co2p in as-deposited Co–W coating and the same coating after heat treatment at 800 °C is shown in Figure 2. Accordingly, in the as-deposited coating, Co2p_{3/2,1/2} peaks at 778.3 and 793.1 eV with spin-orbit separation [$\Delta E_B (2p_{3/2}-2p_{1/2})$] of 14.8 eV correspond to Co metal, whereas peaks at 781.7 and 797.6 eV with 15.9 eV spin-

orbit separation could be assigned for Co^{2+} from highly ionic Co^{2+} type of species present in this kind of coatings.¹⁸⁻²⁰ On the basis of $2p_{3/2,1/2}$ peak positions at 780.5 ± 1.5 and 796.0 ± 1.5 eV, respectively, oxidized Co species could be distinguished from metallic Co. Previous studies have reported that differences in the 2p peak positions between Co^{2+} and Co^{3+} vary from 0.1 to 1.5 eV making it difficult to use the primary 2p peaks to distinguish between CoO and Co_3O_4 . These two oxides can be distinguished, however, by differences in satellite features. The Co2p spectrum of CoO contains prominent satellite peaks which are separated approximately by 4–6 eV higher in energy than the primary peaks. In the present as-deposited coating, the binding energy separation between $\text{Co}2p_{3/2}$ and its corresponding satellite [$\Delta E_B (2p_{3/2}-S)$] is 4.3 eV. These satellite features arise from shake-up phenomenon in which the excitation of unpaired valence electrons increases the number of relaxed final states. While Co_3O_4 also exhibits satellite peaks due to the Co^{2+} contribution, they are considerably less intense and situated 9–10 eV higher than the primary peaks. Therefore, oxidized Co is in +2 oxidation state in the as-deposited coating. Binding energies, relative intensities and FWHMs of different Co species as observed from Co2p spectra of Co–W coating subjected to heat treatment at different temperatures are summarized in Table II. Relative intensities in the table indicate the decrease in Co metal concentration along with simultaneous increase in Co oxide species when the coating is heat treated at 600 °C, whereas only oxidized Co species is present in the core level spectrum of the coating heated at 800 °C. Presence of oxidized Co species in the sample heated at 800 °C could be confirmed from the deconvoluted Co2p spectrum shown in Figure 2 (b).

$\text{W}4f_{7/2,5/2}$ core level peaks at 31.4, 33.6 and 36.1, 38.3 eV in as-deposited spectrum could be assigned for elemental W and W^{6+} species, respectively.^{19,21} Change in W4f peak characteristics could be observed in the coatings heated at 600 and 800 °C. A broad spectral

envelop in the higher binding energy region of W4f along with lower binding energy peaks in the coating heated at 600 °C indicates the presence of multiple oxidation states of W in this coating. The entire spectrum could be deconvoluted into three sets of spin-orbit doublets of several W components. Deconvoluted core level spectra of W4f in as-deposited Co-W coating and the same coating after heat treatment at 600 °C are displayed Figure 3. Accordingly, W4f_{7/2,5/2} peaks at 31.0, 33.0; 35.5, 37.7 and 36.8, 38.9 eV could be ascribed to W⁰, W⁵⁺ and W⁶⁺ oxidation states, respectively.²² Similarly, W4f_{7/2,5/2} peaks at 35.8, 38 and 36.4, 38.5 eV observed in the coating heated at 800 °C indicate the presence of W⁵⁺ and W⁶⁺ only. It is important to note that metallic W species is absent in the coating after heat-treatment at 800 °C indicating that W is fully oxidized at this temperature. Binding energies, relative intensities and FWHMs of different W species as observed from W4f spectra of Co-W alloy coating subjected to heat treatment at different temperatures are summarized in Table III.

XPS of O1s core level spectra of as-deposited as well as heat treated coatings could be deconvoluted into several components and are shown in Figure 4. The as-deposited coating shows main peak at 532.1 eV that corresponds to oxygen associated with hydroxyl (OH⁻) group, whereas small peaks at 530.7 and 533.4 eV could represent oxygen corresponding to CoO and H₂O species associated with the sample, respectively.²³ A small peak above 535 eV corresponds to NaKLL peak coming from Na salt in bath solution taken during electrodeposition.²⁴ There is a marginal change in relative intensities of several oxygen components after heat treatment.

Relative surface concentrations of Co and W in as-deposited and heat treated Co-W alloy coatings have been estimated by the relation:²⁵

$$\frac{C_{Co}}{C_W} = \frac{I_{Co} \sigma_W \lambda_W D_W}{I_W \sigma_{Co} \lambda_{Co} D_{Co}}$$

where C, I, σ , λ and D are the surface concentration, intensity, photoionization cross-section, mean escape depth and analyser detection efficiency, respectively. Integrated intensities of Co2p and W4f peaks have been taken into account to estimate the concentration, whereas photoionization cross-sections and mean escape depths have been obtained from the literature.^{26,27} The geometric factor was taken as 1, because the maximum intensity in this spectrometer is obtained at 90°. Relative surface concentrations (at.%) of Co and W in Co–W alloy coatings with different heat treatment temperatures are shown in Table IV.

3.4 Microhardness studies

Microhardness measurements were carried out with the surface of the as-deposited and heat treated Co–W deposits and the values are given in Table V. Co–W alloy exhibits a hardness value of 486 ± 20 HK in as-deposited condition. The hardness obtained is higher than electrodeposited Co (~ 300 HK) and the value agrees well with the values in literature.⁵ A marginal increase in hardness could be seen for the deposit annealed at 160 °C and approximately 45% increase in the hardness value could be noticed for the deposit annealed at 350 °C. Deposit annealed at 500 °C exhibits more than 100% increase in hardness value. Very high hardness value in comparison with as-deposited sample is obtained when deposit is heated at 600 °C. Variation of microhardness of Co–W alloy coatings with heat treatment temperatures is shown in Figure 5. Within this context, increasing trend in hardness in heat treated Co–W coatings is contrary to the behaviour of heat treated hard chromium coatings. It was well documented that hard chromium coatings exhibited very high hardness values of ~ 1000 HV,^{28,29} but hardness values decreased drastically upon heat treatment.²⁹ Hardness of conventional chromium coating decreased to 810, 585, 270, 100 HV when it was heated at

200, 400, 600 and 800 °C, respectively.²⁹ Chromium coatings showed a structure dependency of hardness,³⁰ while high dislocation densities were reported to be the reasons for high hardness.^{31,32} But heat treatment caused the formation of fine equiaxed grain structure, resulting in softening (decrease in hardness) due to recrystallization which was considered to be the main cause for the decrease in hardness of annealed chromium coatings.³²

In present study, amount of W ranges in 46–59 wt.% which indicates that Co and W are either in solid solution form or Co₃W phase. From the Co–W phase diagram,³³ it is clear that cobalt and tungsten (W content: 48–51 wt.%) remain in Co₃W phase. Therefore, the higher microhardness values shown by annealed Co–W deposits until 500 °C could be due to the solid solution form of W in Co which can be further confirmed with XRD patterns.¹³ Again, significant increase in microhardness has been observed when as-deposited coating is heat treated at 160, 350 and 500 °C though there is no structural change up to 500 °C. It could be attributed to changes in structural relaxation such as annihilation of point defects and dislocations within the grains and grain boundary zones as revealed by DSC studies. On the other hand, very high hardness observed in deposits annealed at higher heat treatment temperatures could be reasoned with the formation of Co₃W phase. Relative surface concentrations evaluated from the XPS studies demonstrate that Co is segregated over the alloy surface in the as-deposited coating and its concentration decreases upon heat treatment at 600 °C (Table IV). Concentrations of Co and W calculated from XPS of the coating heated at 600 °C could hint the formation of Co₃W phase over the surface at this temperature. Further heat treatment at 800 °C slightly increases the surface Co concentration. Again, 67% of hard material W species is in alloyed form in the coating heat treated at 600 °C (Table III) that could be the one of the reasons for high hardness at this temperature. However, hardness

values measured in Co–W coatings heat treated at 500 and 600 °C could be comparable with as-deposited conventional hard chromium coatings.

4. CONCLUSIONS

Low temperature region exothermic peaks in DSC curve of Co–W alloy coating are related to internal movement in the coating, whereas increased disorderliness and possible melting lead to endothermic peak observed at higher temperature. XPS studies demonstrate the presence of mainly oxidized species of Co and W in the heat treated coatings, whereas as-deposited coating contains both metallic and oxidized species. Nature of surface species and their compositions in Co–W deposits vary with heat treatment temperatures. Heat treatment influences the oxidation states and their relative concentrations. Relative surface concentrations of Co and W evaluated from XPS demonstrates that Co is segregated on the surface of the coatings and it varies with different heat treatment temperatures. Presence of alloyed species in terms of solid solution and Co_3W phase enhances microhardness of heat treated coatings very significantly. High hardness in the coating heat treated at 600 °C is due to greater amount of alloyed W species present in the coating. Increase in microhardness of the coatings heated up to 500 °C is due to change in structural relaxation. Hardness of heat treated Co–W coatings could be comparable with hazardous hard chromium coatings as they have higher hardness values.

	W ⁵⁺	35.5	32	1.71
	W ⁶⁺	36.8	35	1.82
800 °C	W ⁵⁺	35.8	26	1.81
	W ⁶⁺	36.4	74	1.82

Table IV. Relative surface concentrations (at.%) of Co and W evaluated from XPS of Co–W coatings at different heat treatment conditions.

Coatings	Co	W
As-deposited	87	13
600 °C	83	17
800 °C	90	10

Table V. Microhardness of Co–W coatings at different heat treatment conditions.

Coatings	Microhardness (HK)
As-deposited	486 ± 20
160 °C	538 ± 20
350 °C	709 ± 20
500 °C	1017 ± 20
600 °C	1336 ± 20
