Keywords: Inoculum load; Ornamental Trees; *Pinus*; *Quercus*; Urbanization

Abstract

Non-native tree species are often used as ornamentals in urban landscapes. However, their root-associated fungal communities remain yet to be examined in detail. Here, we compared richness, diversity and community composition of ectomycorrhizosphere fungi in general and ectomycorrhizal (EcM) fungi in particular between a non-native *Pinus nigra* and a native *Quercus macrocarpa* across a growing season in urban parks using 454-pyrosequencing. Our data show that, while the ectomycorrhizosphere community richness and diversity did not differ between the two hosts, the EcM communities associated with the native host were often more species rich and included more exclusive members than those of the non-native hosts. In contrast, the ectomycorrhizosphere communities of the two hosts were compositionally clearly distinct in nonmetric multidimensional ordination analyses, whereas the EcM communities were only marginally so. Taken together, our data suggest EcM communities with broad host compatibilities and with a limited numbers of taxa with preference to the non-native host. Furthermore, many common fungi in the non-native *Pinus* were not EcM taxa, suggesting that the non-native host communities may be enriched in non-mycorrhizal fungi at the cost of the EcM taxa. Finally, while our colonization estimates did not suggest a shortage in EcM inoculum for either host in urban parks, the differences in the fungi associated with the two hosts emphasize the importance of using native hosts in urban environments as a tool to conserve endemic fungal diversity and richness in man-made systems.

Introduction

Ectomycorrhizal (EcM) fungi are critical to the ecosystem function in temperate and boreal forest ecosystems (Read 1991; Smith and Read 2008). Urbanization leads to severe soil disturbance and has been proposed to compromise the mycorrhizal communities by either reducing inoculum loads (Cousins et al. 2003) and colonization (Baxter et al. 1999; Timonen and Kauppinen 2008; Bainard et al. 2011; Karpati et al. 2011) or by rearranging the fungal community composition (Baxter et al. 1999; Jumpponen et al. 2010a, Karpati et al. 2011). The reduced inoculum potential and colonization in urban environments are likely attributable to challenging urban environments – compacted and often salt or heavy metal enriched urban soils (Pouyat and McDonnell 1991; Kaye et al. 2006; Polanco et al. 2008; Pavao-Zuckerman 2008) can compromise plant performance and hinder mycorrhizal colonization. In addition to anthropogenic impacts on soil properties, urban stand management may lead to lower fungal richness and altered community composition compared to surrounding areas (Jumpponen and Jones 2010, Jumpponen et al. 2010a). Accordingly, studies that target the effects of urban management activities on fungal communities are few but necessary to identify drivers that may lead to the decline in fungal richness (Newbound et al. 2010).

Human population living in cities and suburbs is increasing (Ash et al. 2008) and ornamental urban trees are becoming increasingly important because of their high esthetic, recreational and economic value. However, urban stands may also provide means for conservation on local scales. Although studies evaluating the importance of mycorrhizal associations in urban systems are few (but see Polanco et al. 2008), it is likely that mycorrhizae are fundamental for the health and growth of urban ornamental trees. Therefore, maintaining EcM communities that may best support longevity of urban trees is crucial. Host taxon selection in the maintenance of symbiotic communities is similarly important as locally adapted symbioses may outperform introduced ones (Bonfante et al. 1998; Bahram et al. 2013). EcM communities in planted, man-constructed stands with non-native hosts often differ from native stands compositionally, even if the fungal richness may remain unaltered (O’Hanlon and Harrington 2012). Evaluating different host taxa in urban settings is important to evaluate the consequences of ornamental tree selection.

While a number of environmental and anthropogenic drivers likely interact in urban systems and can cause community rearrangement (e.g. Baxter et al. 1999; Jumpponen and Jones 2010; Jumpponen et al. 2010b), host selection is likely to be crucial to facultatively biotrophic organisms such as the EcM fungi (Kranabetter et al. 1999; Jumpponen et al. 2010a). The use of non-native species in urban ecosystems can have cascading effects. Once introduced, non-native taxa can promote further introduction of peripheral symbionts or companion taxa that may compromise the establishment, restoration, or maintenance of original native systems – resulting in loss of ecological memory (Schaefer 2011). Management practices in urban ecosystems, including selection of ornamental non-native species, use of fertilizers and pesticides, as well as inadvertent biogeochemical alterations and pollutant enrichment likely exaggerate shifts from native to non-native communities furthering the loss of ecological memory.

EcM fungi vary in host specificities and can range from narrow (limited to a level of a genus) to broad (across families and orders) compatibilities (Molina et al. 1992). The non-native EcM hosts may expediently adopt local fungal communities (Cullings et al. 2000; Bahram et al. 2013; O’Hanlon et al. 2013), or alternatively, rely on EcM fungi that are co-introduced (Vellinga et al. 2009; Dickie et al. 2010). Because of the previously observed EcM fungus selectivity for particular hosts (Jacobson and Miller 1992; Molina et al. 1992; Richard et al. 2005; Walker et al. 2005; Tedersoo et al 2008; Morris et al. 2009), we expected that the fungal communities associated with the ectomycorrhizospheres of two non-confamilials would support distinct communities differing also in their EcM species richness (see Trocha et al. 2012). In other words, we hypothesized that the non-native host would support a limited number of broad host range fungi in our urban environment, whereas the native host would support an overlapping community of broad host range fungi but also a number of narrow host range taxa. As a result of our choice to use high throughput next generation sequencing, we acquired data that broadly characterized fungal communities in the ectomycorrhizosphere in general. Additionally, we filtered non-mycorrhizal fungi and performed additional analyses that focused on EcM taxa only. Our data suggest that both hosts support high EcM colonization and diverse communities that differ between the two hosts and are likely enriched for endemic EcM taxa in the native host.

Materials and Methods

Study sites

The city of Manhattan is located in the Flint Hill region of northeastern Kansas, USA. It contains a population of approximately 50 000 residents, with an additional > 20 000 transient student population. *Quercus macrocarpa* (Bur oak) is a native Kansas tree commonly used as an ornamental. *Pinus nigra* (Austrian pine) is native to Mediterranean Europe but often chosen as an ornamental in Kansas and mixed with various *Quercus* spp. Although exotic to North America, inoculation and common garden studies show that *P. nigra* is broadly compatible with cosmopolitan EcM taxa (Martin-Pinot et al. 2006) and share fungi with other Pinaceae (Lazarevic et al. 2012) as well as Fagaceae (Trocha et al. 2012). One isolated individual of each species was selected at each of the six urban sites for a total of twelve trees across the study (Table 1). The sites were sampled three times (June 13th, August 8th, and October 3rd) at eight-week intervals during the growing season of 2011 resulting in a total of 36 samples.

Sampling and evaluation of EcM colonization

At each of the three sampling occasions, three evenly distributed, 15 cm deep 5 cm (diam.) cores were sampled ~3 m from the bore of each tree resulting in a total of 36 subsamples per sampling occasion; 108 subsamples in total. The cores were stored on ice until frozen in the laboratory at -20 °C until further processing. Roots were manually separated from the soil cores and cleaned from the adhering soil. We used isolated trees to visually identify EcM from the abundant grass roots in the park soils. All EcM root tips were collected from all three cores under 10× magnification based on their visual appearance and presence of a mantel. Total number of root tips and EcM tips were enumerated in one random core to estimate colonization and volumetric densities of root tips and EcM. The EcM tips were stored in MoBio Bead Tubes (UltraClean Soil DNA, MoBio Laboratories) in the bead solution and frozen at -20 °C until DNA was extracted separately from all EcM in each core. The root colonization data were arcsine square root transformed prior to analyses to satisfy the assumptions of Analysis of Variance (ANOVA). The between (host species) and within (sampling time) subject effects were analyzed using a repeated

measures ANOVA. Additionally, we analyzed the differences between the two host species separately for each of the three sampling times using one-way ANOVA.

DNA extraction and qPCR to estimate inoculum loads

Total DNA was extracted with UltraClean Soil DNA kit following manufacturer's instructions and eluted in 50 μL of molecular grade H_2O . The DNA yields were quantified with a Nanodrop ND1000 spectrometer (Thermo Scientific, Wilmington, Delaware) and adjusted to a final 2 $\text{ng}/\mu\text{L}$ concentration. We selected one random sample for each experimental unit from each sampling time to estimate inoculum loads by quantitative real-time PCR (qPCR) using primers ITS1F and 5.8S as described in Fierer *et al.* (2005). Each qPCR reaction contained the following final concentrations or absolute amounts of reagents: 1 nM each primer, 5 ng template DNA, 12.5 μL iQTM SYBR[®] Green Supermix (BioRad Laboratories, Hercules, California), and 7.5 μL molecular grade H_2O for a 25 μL per reaction. The qPCR reactions were performed in triplicate in an iCycler iQTM (Bio-Rad Laboratories, Hercules, CA) RT-PCR detection system with iCycler software (v. 3.1.7050). Cycling parameters included an initial denaturing at 95° C for 5 minutes, and 55 cycles of 95°C denaturation for 1 minute, 53°C annealing step for 30 seconds, and 72° extension step for 1 minute. Standard curves based on a 10-fold dilution series (4×10^{-7} to 4×10^{-3} ng of the plasmid DNA per reaction) were used to estimate ITS1 copy numbers per sample (Pfaffl, 2001) accounting for the target region length and assuming an average dsDNA molecular mass of 660 g mol^{-1} . The qPCR data were \log_{10} transformed prior to analyses to satisfy the assumptions of Analysis of Variance (ANOVA). The between (host species) and within (sampling time) subject effects as well as the differences between the two host species separately for events were analyzed as described above.

PCR amplification and sequencing

The template concentration, annealing temperature, and cycle numbers were optimized for PCR amplification of the fungal Large SubUnit (LSU) of the ribosomal RNA gene. We used a two-step PCR protocol as suggested by Berry *et al.* (2011) to avoid the DNA-tag related 3'-end bias during the amplification. Each primary PCR reaction contained the following final

concentrations or absolute amounts of reagents: 1 nM of each primer (LR0R and LR3; Amend *et al.* 2010), 10 ng of the template DNA, 200 μ M of each deoxynucleotide triphosphate, 2.5 mM MgCl₂, 1 unit of GoTaq DNA polymerase (Promega, Madison, Wisconsin), and 5 μ L of PCR buffer (Promega, Madison, Wisconsin). The parameters consisted of an initial denaturation at 94 °C for 4 min, then 30 cycles of denaturation at 94 °C for 1 min, annealing at 53 °C for 45 sec and extension at 72 °C for 2 min, followed by a final extension step at 72 °C for 8 min. All PCR reactions were performed in 96-well PCR plates on MasterCyclers (Eppendorf, Hamburg, Germany) in three technical replicates to account for potentially heterogeneous amplification from the environmental template. In the secondary PCR, a total of 5 μ L of the LSU amplicons from the primary PCR were reamplified with DNA-tagged primers that combined the 454-A adapters and the sample specific DNA tags (LR0R-A) and the 454-B adapters (LR3-B). The primers and DNA tags are available in Supplemental Table S1. The reaction conditions and reagents were identical to those described above, but the number of cycles was reduced to five. Possible PCR amplification of contaminants was determined using a blank sample run through the extraction protocol simultaneously with the actual samples and a negative PCR control in which the template DNA was replaced with ddH₂O. These remained free of PCR-amplicons. The three technical replicates for each experimental unit were combined into one sample prior to purification with a magnetic bead clean up system (AmPure SPRI; Beckman Coulter, Inc., Brea, CA). The clean amplicons were quantified with the ND1000 spectrometer and 100ng for each experimental unit pooled for subsequent 454-sequencing. The pools representing the three seasonal samples of the twelve experimental units were aliquoted to 1000ng in a 100 μ L volume (10ng/ μ L) and sequenced in one quarter sequencing reaction on a Roche GS-FLX Titanium 454-pyrosequencer at the Integrated Genomics Facility at Kansas State University. Two samples yielded no amplicons and were omitted from further analyses. The sequence data are available at the NCBI Sequence Read Archive (BioProject PRJNA225487, BioSamples SAMN02384774–SAMN02384804).

Bioinformatics and operational taxonomic unit (OTU) designation

The sequence data were processed using mothur (v. 1.30.2; Schloss *et al.* 2009) following a modified standard operating protocol (Schloss *et al.* 2011). Briefly, we extracted the quality,

flow, and sequence data from raw files (.sff). Sequences without a forward primer or sample-specific DNA-tags were omitted and remaining sequences denoised (Quince et al. 2009). Sequences with long homopolymers (maxhomop=8) and shorter than minimum length threshold (minlength=200) were removed. The 454-sequences were aligned against mafft-aligned (Kato et al. 2005) LSU training dataset from the Ribosomal Database Project (RDP) compiled of high-quality public Sanger sequences spanning the first 1,400 bp of the LSU gene (Liu et al. 2012), screened for proper alignment, unique representatives pre-clustered to 99% similar representatives to further reduce potential noise in the final data analyses, and reads with potential chimeric origin removed (uchime; Edgar et al. 2011). The data were assigned to Operational Taxonomic Units (OTUs) at 97% similarity using the average neighbor joining algorithm and global singletons omitted (see Tedersoo et al. 2010). OTUs were assigned to taxa using the naïve Bayesian classifier (Wang et al. 2007) against the Ribosomal Database Project's training dataset at a 60% bootstrap support cutoff (Liu et al. 2012). Based on the genus-level affinities, OTUs were assigned to fungi with known ectomycorrhizal habits (Supplemental Table 2) or those with uncertain or unknown ecologies. Two datasets comprised of all fungi in the ectomycorrhizosphere and of EcM fungi only were analyzed separately. As recommended by Gihring et al. (2012) the data were randomly sub-sampled to the lowest number of OTUs per experimental unit for further analysis.

We estimated the rarefaction curves (Magurran 1988) for each experimental unit to evaluate the representativeness of our sampling effort. Observed and extrapolated OTU richness (S_{obs} and Chao1), diversity (Simpson's complement; $1-D = 1 - \sum p_i^2$), evenness (Simpson's equitability; $E_D = (1/\sum p_i^2)/S$), and Good's coverage (complement of the ratio between singleton OTUs and the total sequence count) were estimated after subsampling the data to 158 sequences for all ectomycorrhizosphere fungi and to 120 for EcM fungi to eliminate bias stemming from unequal sampling effort across experimental units (Gihring et al. 2012). The richness and coverage data were \log_{10} -transformed; diversity and evenness data arc sine square root transformed to satisfy the assumptions of ANOVA. Similarly to the colonization and inoculum load analyses, the data were analyzed both by repeated measures ANOVA as well as separately for each sampling time.

Community composition

To visualize and infer compositional differences in the fungal communities colonizing the two hosts, we used Non-metric MultiDimensional Scaling (NMDS) as implemented in *mothur* (v. 1.30.1; Schloss et al. 2009). In brief, we derived a Bray-Curtis distance matrix and estimated NMDS axis scores for first four ordination axes in the ectomycorrhizosphere dataset and first three in the EcM dataset to obtain a stress ≤ 0.20 . We analyzed the resultant axis scores as described above for other derived metrics. Additionally, we used Analyses of MOlecular VAriance (AMOVA; PERMANOVA in Anderson, 2001) to infer community-wide differences based on Bray-Curtis similarity values between the two hosts. However, this iterative permutation test does not permit repeated measures analyses. Rather, it provides an overall test of community differences for our two hosts and is used to corroborate treatment differences inferred from ANOVA.

In addition to the ordination analyses to visualize community level differences, we also separately analyzed those OTUs that occurred in counts greater than a total of 50 sequences in the dataset. This resulted in a total of 43 focal OTUs in these analyses. The relative frequencies of the OTUs were \log_{10} transformed and analyzed for host species separately for each of the three sampling times. Since these analyses are likely sensitive to erroneous conclusions because of multiple comparisons, the results were further evaluated after False Detection Rate (FDR) corrections ($Q = 0.10$). Few of the observed differences remained significant (those with P -values ≤ 0.0090) after the correction suggesting limited statistical power with six replicates per hosts; we present the uncorrected tests here but advise the reader to observe the determined FDR threshold.

Results

Colonization and inoculum loads in the native and exotic hosts

Although the native *Q. macrocarpa* tended to have a greater density of root tips (Figs. 1a), the hosts did not differ in EcM tip densities when analyzed across the growing season (Fig. 1b; Table 2). The two hosts were heavily colonized (*Q. macrocarpa*: $86.1\% \pm 7.5\%$; *P. nigra*: $79.6\% \pm 24.1\%$) despite being isolated ornamentals in an urban environment (Fig. 1c). Colonization did not differ between the hosts but the nearly significant “Time” term in our repeated measures ANOVA (Table 2) suggests seasonal dynamics, mainly driven by the small decline in *Q. macrocarpa* colonization during the growing season (Fig. 1c). *Q. macrocarpa* and *P. nigra* root and EcM tip densities tended to fluctuate differently during the growing season as indicated by the within subject interaction (Time \times Species; Table 2). When analyzed separately for each of the three sampling times, *Q. macrocarpa* total ($F_{1,9} = 9.89$, $P = 0.0118$) and EcM ($F_{1,9} = 9.26$, $P = 0.0139$) root tips were in higher densities than those of *P. nigra* in August (Fig. 1a, 1b). Similar differences were not visible at any other sampling events. Neither the EcM colonization (Fig. 1c) nor the qPCR-estimated ITS1 copy numbers (Fig. 1d) differed between the two hosts (Table 2).

High throughput sequencing of the ectomycorrhizosphere and ectomycorrhizal fungi

After quality control, we analyzed a total of 17,977 sequences that were retained from the total of 51,275 sequences after denoising. The heterogeneous yields across the experimental units necessitated subsampling of 158 sequences per sample for all ectomycorrhizosphere fungi and 120 for those representing OTUs assigned to EcM taxa. The subsampling also led to loss of three experimental units from analyses for all ectomycorrhizosphere fungi and loss of nine experimental units from the EcM analyses.

Of all sequences, a total of 52.8% belonged to Basidiomycota, 45.9% to Ascomycota, and less than 1% to each of Chytridiomycota and Blastocladiomycota (Supplementary Table S3). A majority of sequences (66.8%) were assigned to EcM taxa and the remaining sequences represented a heterogeneous mix of potential pathogens and antagonists, saprobes, or soil fungi.

The acquired sequences were distributed to a total of 188 non-singleton OTUs at 97% similarity and 244 singleton OTUs, which were removed from subsequent analyses as they may represent PCR or sequencing artifacts (Tedersoo et al. 2010). Only 41 OTUs were assigned to EcM genera, whereas the large majority (147) of the non-singleton OTUs represented non-mycorrhizal fungi that occurred mainly in low frequencies. *Russula* dominated EcM communities with 17.3% of all sequences and 14 OTUs, followed by Thelephoraceae (15.6% of sequences and three OTUs), *Tuber* (12.3% of sequences and 17 OTUs), *Inocybe* (10.7% of sequences and 14 OTUs), and a single *Hebeloma* OTU (5.4% of all sequences). The most common non-mycorrhizal OTUs were assigned to *Gibberella* (4.0% of sequences and 11 OTUs) and *Hypocrea* (3.4% of sequences and 12 OTUs) – likely inhabitants of dead woody tissues or common plant antagonists.

Richness and diversity

Rarefaction analyses indicated that the target sequencing depth was inadequate to saturate the species richness in the ectomycorrhizosphere, particularly so in the subsampled data set (158 reads per experimental unit; Fig. 2a-c). Good's coverage estimators for the subsampled dataset ranged from 0.96 ± 0.02 for *Q. macrocarpa* and 0.95 ± 0.02 for *P. nigra* suggesting an overall good sampling and providing a view different from the rarefaction analysis. In contrast to the entire ectomycorrhizosphere fungal community, the EcM richness approached saturation prior to subsampling suggesting low EcM diversity (Fig. 2d-f). Good's coverage estimators (0.99 ± 0.01 for both *Q. macrocarpa* and *P. nigra*) for the subsampled EcM dataset corroborated the near saturation observed in the rarefaction analyses.

The overall richness (S_{Obs} ; Fig. 3a), extrapolated richness (Chao1; Fig. 3b), diversity (Simpson's 1-D; Fig. 3c), or evenness (E_{D} ; Fig. 3d) did not differ between the native *Q. macrocarpa* and the exotic *P. nigra* ectomycorrhizospheres in repeated measures analyses (Table 2) or at any of the three sampling times (Fig. 3; Supplemental Table S4; ANOVA: $P > 0.05$). However, the significant or nearly significant within-subjects tests (Species \times Time; Table 2) suggested differing seasonal trends in observed (Fig. 3a) and extrapolated (Fig. 3b) richness estimators between the two hosts. These differing trends were attributable to declining richness in *Q. macrocarpa* and stable or slightly increasing richness in *P. nigra*.

In contrast to the overall ectomycorrhizosphere, the EcM richness (Fig. 3e) was greater in the native *Q. macrocarpa* than in the exotic *P. nigra* in June (ANOVA: $F_{1,7} = 7.78$, $P = 0.0316$), but only marginally or not significant in the subsequent samplings in August (ANOVA: $F_{1,7} = 2.93$, $P = 0.1306$) and October (ANOVA: $F_{1,7} = 4.26$, $P = 0.0845$). These early season differences in richness were also reflected in extrapolated richness (Chao 1; Fig. 3f) as well as diversity and evenness estimators (Fig. 3g, 3h). The extrapolated richness and diversity tended to be greater in the native *Q. macrocarpa* than in the exotic *P. nigra* in the early sampling in June and in the late sampling in October, but not in the August sampling (Fig. 3). In contrast, the EcM communities in the non-native *P. nigra* tended to be more even than those colonizing the native *Q. macrocarpa* (Fig. 3h), suggesting less pronounced highly dominant OTUs, such as the single dominant Thelephoraceae OTU in August and October (Fig. 4). However, none of the observed richness or diversity patterns were clear when the data were analyzed by repeated measures ANOVA ($P > 0.06$; Table 3) – a result likely attributable to high variability or contrasting seasonal trends of the two hosts.

Community composition

We analyzed the communities comprised of 188 non-singleton ectomycorrhizosphere and 41 EcM fungi by NMDS using subsampled datasets. The ectomycorrhizosphere community data were resolved on four axes, whereas the EcM community data were resolved on three axes. Our AMOVA clearly distinguished the ectomycorrhizosphere fungal communities of the two hosts indicating strong differences ($F_{1,30} = 4.43$; $P < 0.001$). Similarly, ANOVA suggested that the communities differed among the two hosts on the first axis ($F_{1,10} = 7.48$; $P = 0.0230$) in the June sampling (Fig. 5a) and on the fourth axis ($F_{1,10} = 5.16$; $P = 0.0491$) in the August sampling, and only marginally so in the final October sampling (ANOVA: $P > 0.08$). In the repeated measures analyses, these ordination analyses did not distinguish the ectomycorrhizosphere communities (Table 2). The EcM communities of the two hosts were only marginally distinguished based on AMOVA ($F_{1,24} = 1.89$; $P = 0.057$). Consistently, the EcM communities were marginally distinct in NMDS analyses when analyzed separately for the three sampling events. While the EcM communities did not differ between the two hosts in August (ANOVA: $P > 0.19$) or October

(ANOVA: $P > 0.45$) on any of the three NMDS axes, they differed marginally in June (ANOVA: $F_{1,7} = 5.33$; $P = 0.0603$) on the third NMDS axis (Fig. 5b). Similarly to the analyses focusing on all ectomycorrhizosphere fungi, the NMDS ordination did not distinguish the EcM communities based on the repeated measures analyses (Table 3).

The analyses of the 43 most common OTUs identified few responsive taxa – mainly dominated by non-mycorrhizal taxa. Five EcM OTUs (OTU4 and 37 assigned to *Inocybe* plus OTU9, 22, and 42 assigned to *Tuber*) were frequent in *Q. macrocarpa*, but never occurred in *P. nigra* (Fig. 4; Supplemental Table S6). Similarly, OTU29 (*Inocybe*) and OTU43 (*Suillus*) never occurred in *Q. macrocarpa*, while present in *P. nigra*. A suite of non-EcM OTUs (27, 40, 41 representing families Vibresseaceae, Myxotrichiaceae, and Melanommataceae, respectively) was exclusive to *P. nigra* (Fig. 4). Only one EcM OTU (OTU1; assigned to uncultured Thelephoraceae) was more frequent in *Q. macrocarpa* than in *P. nigra* after correction for multiple comparisons (Figure 4). This OTU was more frequent in *Q. macrocarpa* in the last sampling event in October ($F_{1,10} = 6.66$; $P = 0.0297$), but not in samplings prior to that or when the data were analyzed by repeated measures ($F_{1,3} = 0.89$; $P = 0.4160$). However, this OTU – like many others – highlights the seasonal dynamics. While consistently low in *P. nigra*, this OTU peaked in August in *Q. macrocarpa* – a pattern visible also in the repeated measures analyses: variability within the growing season was indicated by the within subjects effect (Time: $F_{2,2} = 85.04$; $P = 0.0116$) and the different dynamics among the two hosts by the significant between subjects interaction term (Time x Species: $F_{2,2} = 103.94$; $P = 0.0095$).

Interpretation of these results is complicated by multiple comparisons as well as the seasonally dynamic OTU frequencies. For example, OTU23 (assigned to *Immersiella*, Sordariales) occurred more frequently *Q. macrocarpa* than in *P. nigra* in June ($F_{1,11} = 10.45$; $P = 0.0090$), but not in the subsequent samplings ($P > 0.10$), or when analyzed by repeated measures ANOVA ($F_{1,3} = 1.14$; $P = 0.3638$). However, some OTUs were more consistent in their responses. When data were analyzed separately for each of the three sampling events, OTU14 (assigned to *Cochliobolus*, Pleosporales) occurred more frequently in *P. nigra* than in *Q. macrocarpa* in August ($F_{1,10} = 12.77$; $P = 0.0060$) and October ($F_{1,10} = 7.33$; $P = 0.0482$). These analyses were consistent with the repeated measures analyses, which also indicated that OTU14 was overall

more frequent in *P. nigra* than in *Q. macrocarpa* (between subjects effect: $F_{1,3} = 25.33$; $P = 0.0151$), variable over the growing season as indicated by the within subjects effect (Time: $F_{2,2} = 141.76$; $P = 0.0070$), and more so in *P. nigra* than in *Q. macrocarpa* as indicated by the significant between subjects interaction term (Time x Species: $F_{2,2} = 131.63$; $P = 0.0075$). Similarly, OTU6 (assigned to *Gibberella*, Hypocreales), when analyzed separately for each of the three sampling events, occurred more frequently in *P. nigra* than in *Q. macrocarpa* in August ($F_{1,10} = 12.59$; $P = 0.0062$) and October ($F_{1,10} = 6.10$; $P = 0.0356$). Consistently, the repeated measures analyses indicated that OTU6 was overall more frequent in *P. nigra* than in *Q. macrocarpa* ($F_{1,3} = 15.29$; $P = 0.0297$), but in contrast to OTU14 did not vary over the growing season ($P > 0.20$).

Discussion

This research was motivated by our earlier effort that concluded that fungal communities associated with urban trees tend to be less species rich and compositionally distinct compared to adjacent non-urban trees (Jumpponen and Jones 2009; 2010; Jumpponen et al. 2010a). Accordingly, our goal was to evaluate whether or not the choice of ornamental trees in such environments would further impact the resident fungal richness, diversity, or community composition. Our data show that EcM fungi heavily colonize the selected hosts. Both ectomycorrhizosphere and EcM fungal communities show considerable overlap; the EcM communities are marginally distinct but include members that are unique to a specific host. The differences between the EcM fungi associated with the two hosts highlight the importance of thoughtful management choices in urban settings to best preserve the endemic communities that may be declining as a result of human activities (Arnolds 1991; Watling 2005; Newbound et al. 2010). Urban systems are increasing in their importance in conservation ecology (Newbound et al. 2010), as urban land use has been predicted to increase by more than 200% by 2030 (Angel et al. 2005). Although some studies have highlighted the anthropogenic atmospheric pollution as one primary negative driver for EcM fungi (Arnolds 1991; Dighton et al. 2004 Newbound et al. 2010), pinpointing the exact drivers is difficult without experimental testing of hypotheses on specific mechanisms (Jumpponen et al. 2010b). Our current study specifically examines the effects of ornamental tree species selection in highly managed urban environment.

Although mycorrhizal fungi are present in urban environments, their inoculum loads and colonization have been proposed to be lower than in non-urban environments (Cousins et al. 2003; Ochimaru and Fukuda 2007; Bainard et al. 2011; Karpati et al. 2011). This tends to be the case if the soils have undergone recent or severe disturbances (Boerner et al. 1996; Karpati et al. 2011), although others have reported no effect of disturbance on EcM colonization in natural systems (Byrd et al. 2000; Jones et al. 2003). Other proposed mechanisms underlying the low colonization include environmental stresses that may have negative impacts on mycorrhizal associations (Gehring and Whitham 1992). The reported low colonization and its potential adverse effects on trees have led to calls for considering inoculation programs for urban trees (Stabler et al. 2001; Appleton et al. 2003; Fini et al. 2011), although commercial mycorrhizal inocula often yield inconsistent results (Gilman 2001; Ferrini and Nicese 2002; Rao et al. 2006). Our relatively high EcM colonization is in contrast with other observations (Baxter et al. 1999; Ochimaru and Fukuda 2007; Bainard et al. 2011) and suggests presence of a readily available inoculum pool. It is of note that our qPCR estimators of ITS1 copy numbers aimed to test inoculum loads, but included likely a large proportion of non-EcM taxa as indicated by the presence of many non-EcM OTUs in the ectomycorrhizospheres. Further, the high colonization of the non-native pine suggests readily available and compatible inoculum, a result consistent with other studies that have shown *P. nigra* broad compatibility with cosmopolitan EcM fungi as well as species typically associated with members of Pinaceae or Fagaceae (Martin-Pinot et al. 2006; Lazarevic et al. 2012; Trocha et al. 2012). Our high and rather stable colonization may relate to minimal soil disturbance near our urban mature trees, the adjacency of the two hosts at each of the sites, or the relatively adjacent undisturbed non-urban inoculum sources around the small urban center. Taken together, we consider that urban inoculation programs may be unnecessary to ensure EcM colonization, if adequate inoculum sources are available and the sites have not been severely disturbed, for example, by topsoil removal or addition. Even so, if endemic inocula were to prove successful in establishing reservoirs or enriching the diversity of native fungal populations and/or communities, inoculation programs warrant attention for high-value urban trees. Furthermore, EcM taxa or strains may be locally adapted; EcM fungi and hosts naturally occurring in similar environments may show superior symbiotic performance (Bonfante et al. 1998). It is of note that a number of EcM taxa were observed only with one host.

We analyzed both general, broad fungal communities and EcM communities inhabiting roots of our hosts. The two communities show some contrasts. The overall communities did not differ in richness or diversity, but were compositionally distinguishable despite large overlaps. The EcM communities were seasonally dynamic, differed in richness and diversity in early growing season and were comprised of members that were often unique to one host. While these and earlier data (Jumpponen et al. 2010a) suggest low fungal richness and compositional shifts in urban EcM communities compared to surrounding non-urban environments, the functional consequences of these shifts remain unclear. Mycorrhizal fungi have diverse functions with a potential to facilitate nutrient uptake by accessing resources not readily available for the plants (Marschner and Dell 1994), improve drought tolerance (Lehto and Zwiasek 2011), increase disease resistance (Whipps 2004), and permit interplant transfer of nutrients through common mycelial networks (Simard and Durall 2004). EcM species differ in their functional attributes and physiological tolerances (Baxter and Dighton 2001; 2005). Thus, greater diversity of root-associated symbionts should translate to more diverse benefits to the host, or alternatively, to greater flexibility under changing conditions (Druebert et al. 2009; Pena et al. 2010). However, the importance of mycorrhiza-mediated ecosystem services and/or host benefits in intensively managed, fertilized and watered urban systems remains unclear and requires further investigation.

Habitat loss is perhaps the main threat to fungal richness and diversity, stemming from fungal requirements for specific substrates or hosts (Watling 2005; Newbound et al. 2010). To counter and minimize habitat loss and fragmentation resulting from urbanization, selection of host species that may best preserve the resident biodiversity is of particular importance. Our data highlight the differences in the ectomycorrhizosphere and EcM fungal communities associated with two host species in an urban setting. While the former was minimally influenced by the host taxon, the EcM communities of the non-native host were less speciose and lacked community constituents when compared to the native host. A common garden study evaluating pairs of native and non-native con-generics (species of *Pinus* and *Quercus*) found that, while the native *Quercus* hosted a more diverse EcM community than the non-native one, the opposite was true for the two *Pinus* taxa compared (Trocha et al. 2012). Other studies focusing on non-native species have reported that introduced or invasive non-natives expediently recruit native EcM

symbionts (Cullings et al. 2000; Gebhardt et al. 2007; Tedersoo et al. 2007; Kohout et al. 2011; Bahram et al. 2013), although the host establishment may be facilitated by co-introduction with compatible root symbionts (Tedersoo et al. 2007; Vellinga et al. 2009; Dickie et al. 2010). Additionally, while native forests and adjacent non-native plantations can host rather similar EcM fungus richness (O’Hanlon and Harrington 2012; Bahram et al. 2013), the community constituents may differ (O’Hanlon and Harrington 2012), particularly so in stands isolated from inoculum sources (Bahram et al. 2013). Similarly to O’Hanlon and Harrington (2012), our data suggest host-taxon driven EcM community rearrangement and re-ordering in urban environment in absence of a dramatic loss of biodiversity. Our study is among first to so comprehensively dissect the EcM and ectomycorrhizosphere fungal communities in native and non-native hosts in an urban environment and our results are in line with an expedient recruitment of compatible EcM fungi by non-native hosts in a fragmented urban environment.

The fungal communities in our study included a large proportion of non-EcM fungi. Among the 43 most abundant OTUs were putative plant antagonists (*Gibberella*, *Bionectria*), saprobes (*Chaetomium*, *Gerronema*), and common soil fungi (*Eupenicillium*, *Aspergillus*). It is notable that while the ectomycorrhizosphere communities of the native host included a large number of common EcM taxa (Russulaceae, Thelephoraceae, Tuberaceae), many top ranked taxa that do not form mycorrhizae (*e.g.* *Cochliobolus*, *Gerronema*, *Gibberella*, *Vibrissea*) were exclusively or more commonly associated with the non-native host. It is open to speculation whether this observation suggests a lesser abundance of compatible EcM partners for the non-native host, or a compromised health of the host plant resulting in greater susceptibility to colonization by non-EcM fungi. Curiously, our observations on the fungal communities colonizing the native and non-native hosts seem to suggest patterns analogous to those in response to nutrient enrichment: EcM richness often declines, whereas the lignicolous and saprobic taxa either remain unchanged or increase (Peter et al. 2001; Högberg et al. 2003; Trudell and Edmonds 2004).

To evaluate the differences of native and non-native hosts in an urban setting, we sampled co-occurring isolated ornamental trees. Characteristically to urban stands, the sampled trees occurred in small landscape fragments. This may limit the dispersal, viability, and genetic variability of fungi (Edman et al. 2004; Peay et al. 2007). While it is possible that fungi

associated with non-native hosts suffer from the isolation and dispersal limitation more than those associated with native hosts, the observed differences among the two hosts are more likely attributable to incompatibility between non-native host and indigenous fungal communities (see Jacobson and Miller 1992; Walker et al. 2005; Tedersoo et al. 2008). This is supported by our observation that EcM taxa consistently and exclusively occurred in the native host (common EcM in *Q. macrocarpa*: three *Inocybe* OTUs and two *Tuber* OTUs). However, the non-native host also included exclusive EcM taxa (*Inocybe* and *Suillus*) as well as many shared EcM taxa (*Inocybe*, *Russula*, and *Tuber*). The former is in line with other studies that observed a small number of unique EcM taxa in a non-native host (Bahram et al. 2013), whereas the latter is in line with the broad compatibility between non-native hosts and native EcM fungi (O’Hanlon and Harrington 2012; O’Hanlon et al. 2013). It is unclear whether the observed unique EcM taxa indicate differing preferences among hosts or introduction of novel fungal taxa with the exotic host as suggested for *Amanita phalloides* and European oaks in Australia (Nicholson and Korman 1997) and for *Rhizopogon vinicolor* and *Pseudotsuga menziesii* in New Zealand (Chou-Chou and Grace 1983). Alternatively, our finding may suggest differing environmental preferences among the fungal taxa when associated with different host species. Our studies fail to clearly pinpoint the mechanisms that drive EcM community rearrangements. Yet, our study directly compares two common ornamental hosts and identifies differences in a fixed environmental setting afforded by the coexistence of the two hosts in close proximity in the selected six stands.

Our studies described here aimed to evaluate the importance of host selection in urban settings to maintain fungal biodiversity. Our data show that while the richness and diversity of host associated fungal communities did not perhaps consistently differ between a native and non-native host, the communities included a strong signal of community rearrangement compositionally and functionally: the fungal communities associated with the native host were enriched or included exclusive EcM taxa, whereas the non-native host communities were enriched with non-EcM fungi. We speculate that this observation signals either absence of compatible EcM symbionts or poor health of the exotic trees outside their non-native range. Our observations emphasize the need for caution in selection of ornamental trees as native trees may serve as a superior reservoir for native fungal symbionts and the non-natives may bear a higher

load of putative antagonists.

Table 2. Repeated Measures ANOVA tables of total and ectomycorrhizal root tip densities (number of tips cm⁻³), colonization (%), and qPCR estimates of the ITS1 copy numbers in the ectomycorrhizosphere. Additionally, richness, diversity, and evenness estimators as well as the NMDS score analyses are included for all ectomycorrhizosphere fungi. Between subject effect “Species” refers to *Quercus macrocarpa* vs. *Pinus nigra* comparison, within subject effect “Time” refers to comparisons among the seasonal samples and its interaction with the between subject effect. F-test variables are exact values. Significant differences ($P < 0.05$) are highlighted in **bold** and marginally significant differences ($0.05 \leq P < 0.10$) are underlined. Means and standard deviations for these estimators are available in Supplemental Table S4.

Response	Species F _{1,9} ^P	Time F _{2,8} ^P	Time* Species F _{2,8} ^P
Tip Density	<u>3.78</u> ^{0.0845}	0.60 ^{0.5743}	<u>3.81</u> ^{0.0689}
EcM Density	<u>3.26</u> ^{0.1045}	1.05 ^{0.3932}	<u>6.65</u> ^{0.0746}
Colonization (%)	0.02 ^{0.8962}	<u>4.64</u> ^{0.0521}	<u>3.06</u> ^{0.1029}
ITS1 Copies	0.17 ^{0.6935}	<u>0.56</u> ^{0.5982}	0.25 ^{0.7894}
Richness (S _{Obs})	1.13 ^{0.3360}	0.74 ^{0.5317}	<u>6.87</u> ^{0.0508}
Chao1	1.10 ^{0.3430}	3.32 ^{0.1414}	8.02 ^{0.0399}
Simpson’s (1-D)	1.25 ^{0.3141}	0.41 ^{0.6887}	1.64 ^{0.3013}
Evenness (E _D)	0.78 ^{0.4165}	0.85 ^{0.4916}	0.55 ^{0.6154}
NMDS1 (0.3%)	0.62 ^{0.4657}	0.63 ^{0.5801}	0.57 ^{0.6045}
NMDS2 (52.7%)	0.01 ^{0.9284}	1.58 ^{0.3124}	1.11 ^{0.4141}
NMDS3 (14.4%)	1.23 ^{0.3172}	0.59 ^{0.5960}	1.69 ^{0.2940}
NMDS4 (5.9%)	3.27 ^{0.1303}	0.28 ^{0.7690}	3.23 ^{0.1463}

Table 3. Repeated Measures ANOVA tables of ectomycorrhizal richness and diversity estimators as well as the analyses of the NMDS ordination scores. Between subject effect “Species” refers to *Pinus nigra* vs. *Quercus macrocarpa* comparison, within subject effect “Time” refers to comparisons among the seasonal samples and its interaction with the between subject effect. F-test variables are exact values. Marginally significant differences ($0.05 \leq P < 0.10$) underlined. Means and standard deviations for these estimators are available in Supplemental Table S5.

Response	Species $F_{1,2}$^P	Time $F_{2,1}$^P	Time* Species $F_{2,1}$^P
S_{Obs}	5.81 ^{0.1375}	3.82 ^{0.3403}	0.49 ^{0.7119}
Chao1	5.32 ^{0.1474}	2.61 ^{0.4011}	0.20 ^{0.8474}
Simpson’s 1-D	2.66 ^{0.2445}	12.85 ^{0.1935}	10.85 ^{0.2151}
Evenness	<u>12.95^{0.0693}</u>	36.73 ^{0.1159}	26.20 ^{0.1368}
NMDS1 (5.4%)	0.28 ^{0.6479}	0.27 ^{0.8060}	0.47 ^{0.7173}

FIGURE LEGENDS

Figure 1. Root and ectomycorrhizal tip densities (a, b), ectomycorrhizal colonization (c), and qPCR-estimated fungal ITS1 copy numbers (d) of the native *Quercus macrocarpa* (solid black bars) and exotic *Pinus nigra* (open grey bars) urban ornamental trees. The roots were sampled in June, August, and October to capture the root and ectomycorrhizal seasonal dynamics. Asterisks above the bars indicate differences ($P < 0.05$) between the two hosts at those sampling events. Note that although the root and ectomycorrhizal densities were higher in *Quercus* than in *Pinus* in August, the ITS copy numbers and ectomycorrhizal colonization were comparable between the two hosts.

Figure 2. Rarefaction curves for the 36 samples analyzed for all fungi (a-c) and ectomycorrhizal (d-f) fungi in the ectomycorrhizosphere of the native *Quercus macrocarpa* (solid lines) and exotic *Pinus nigra* (dashed lines) urban ornamental trees. The roots were sampled in June (a,d), August (b,e), and October (c,f) to capture the seasonal dynamics in the fungal communities. The ectomycorrhizal communities were sampled more thoroughly than the ectomycorrhizosphere communities as indicated by the near plateau of many samples (d-f). Note that y-axis scales differ between the ectomycorrhizosphere (a-c) and ectomycorrhizal (d-f) communities.

Figure 3. Observed (S_{Obs} ; a,e) and extrapolated richness (Chao1; b,f) plus diversity (Simpson's complement, $1-D = 1 - \sum p_i^2$; c,g) and evenness (Simpson's equitability, $E_D = (1/\sum p_i^2)/S$; d,h) for 36 samples analyzed for all (a-d) and ectomycorrhizal (e-h) fungi in the ectomycorrhizosphere of the native *Quercus macrocarpa* (solid black bars) and exotic *Pinus nigra* (grey open bars) urban ornamental trees. The roots were sampled in June, August, and October to capture the seasonal dynamics in the fungal communities. Asterisks above the bars indicate differences ($P < 0.05$) between the two hosts at those sampling events, those in parentheses indicate marginally significant differences ($0.05 \leq P < 0.10$). Note that while the overall communities never differed between the hosts, the ectomycorrhizal communities differed in richness, diversity, and evenness in the early and late samplings. Note different y-axis scales for different metrics.

Figure 4. Rank orders of the 43 fungal OTUs that were represented by more than fifty sequences in June (a), August (b), October (c) in the ectomycorrhizospheres of native *Quercus macrocarpa* (solid black bars) and exotic *Pinus nigra* (open grey bars) urban ornamental trees. Asterisks above the bars indicate differences ($P < 0.05$) between the two hosts for that OTU, those in parentheses indicate marginally significant differences ($0.05 \leq P < 0.10$). Note that only the differences in Thelephoraceae 1 frequencies remain significant after correction for multiple comparisons. The crosses identify OTUs that occur exclusively in one host. For convenience, black symbols identify OTUs associated with the native host, grey symbols those with exotic host. Means and standard deviations are available in the Supplemental Table S6.

Figure 5. NMDS (Nonmetric MultiDimensional Scaling) ordination of the ectomycorrhizosphere (a) and ectomycorrhizal (b) fungal communities in native *Quercus macrocarpa* (solid symbols) and exotic *Pinus nigra* (open symbols) urban ornamental trees sampled in three occasions (June, August, October). For clarity, sampling times that differ in ANOVA have been highlighted in black, whereas others are grey. Note that only early season (June) ectomycorrhizosphere and ectomycorrhizal samples differ.

SUPPLEMENTAL MATERIALS

Supplemental Table S1. Primer and dna-tag sequences used for sample specific PCR and 454-sequencing.

Supplemental Table S2. Putative assignments to ecological roles of the 378 genera detected in the 36 ectomycorrhizosphere samples. AM – Arbuscular Mycorrhiza; ECM – EctoMycorrhizal; ENT – ENTomopahtogen; PAR – PARastitic, PAT – PAThogenic; SAP – SAProbic; UNK – UNKknown.

Supplemental Table S3. Taxon assignments of 188 OTUs that occurred more than once in the entire dataset. K_Sup, P_Sup, C_Sup, O_Sup, F_Sup, G_Sup refer to Ribosomal Database Project's naïve Bayesian classifier bootstrap support for Kingdom, Phylum, Class, Order, Family and Genus, respectively. Ecology refers to assignments using list in Supplemental Table S2. Last two columns list total counts of sequences assigned to each OTU for *Quercus macrocarpa* and *Pinus nigra*.

Supplemental Table S4. Mean (± 1 standard deviation) root and ectomycorrhizal tip densities, EcM colonization, qPCR derived inoculum load (ITS1 copy number), Good's coverage, observed richness (S_{Obs}), Simpson's diversity complement (1-D), Shannon's diversity, extrapolated richness estimate (Chao I), and evenness as estimated by Simpson's equitability (E_D) for all ectomycorrhizosphere inhabiting fungi. Note that only the root and ectomycorrhizal tip densities differ in the second sampling in August, other comparisons of the two hosts at each sampling time (one way ANOVA) are non-significant (see Figs 1-2). Compare these ectomycorrhizosphere analyses to those for ectomycorrhizal fungi only (Supplemental Table S5).

Supplemental Table S5. Mean (± 1 standard deviation) Good's coverage, observed richness (S_{Obs}), Simpson's diversity complement (1-D), Shannon's diversity, extrapolated richness estimate (Chao I), and evenness as estimated by Simpson's equitability (E_D) for all ectomycorrhizal fungi. Note that while the two hosts did not differ in repeated measures ANOVA. In contrast, many richness and diversity estimators differed in early sampling in June and marginally so in the late sampling in October (see Fig. 3).

Supplemental Table S6. Frequencies (mean \pm standard deviation) of the 43 most abundant OTUs analyzed for OTU-level responses in June, August, and October 2011.
