Abstract. Residential solid biomass cookstoves are important sources of aerosol emissions in India. Cookstove emissions rates are largely based on laboratory experiments conducted using the standard water-boiling test, but real-world emissions are often higher owing to different stove designs, fuels, and cooking methods. Constraining mass emissions factors (EFs) for prevalent cookstoves is important because they serve as inputs to bottom-up emissions inventories used to evaluate health and climate impacts. Real-world EFs were measured during winter 2015 for a traditional cookstove (*chulha*) burning fuel wood, agricultural residue, and dung from different regions of India. Average ($\pm 95\%$ confidence interval) EFs for fuel wood, agricultural residue, and dung were (1) $\text{PM}_{2.5}$ mass: 10.5 (7.7–13.4) g kg^{-1} , 11.1 (7.7–15.5) g kg^{-1} , and 22.6 (14.9–32.9) g kg^{-1} , respectively; (2) elemental carbon (EC): 0.9 (0.6–1.4) g kg^{-1} , 1.6 (0.6–3.0) g kg^{-1} , and 1.0 (0.4–2.0) g kg^{-1} , respectively; and (3) organic carbon (OC): 4.9 (3.2–7.1) g kg^{-1} , 7.0 (3.5–12.5) g kg^{-1} , and 12.9 (4.2–15.01) g kg^{-1} , respectively. The mean ($\pm 95\%$ confidence interval) OC / EC mass ratios were 6.5 (4.5–9.1), 7.6 (4.4–12.2), and 12.7 (6.5–23.3), respectively, with OC and EC quantified by the IMPROVE_A thermal-optical reflectance protocol. These real-world EFs are higher than those from previous laboratory-based measurements. Combustion conditions have larger effects on EFs

than the fuel types. We also report the carbon mass fractions of our aerosol samples determined using the thermal-optical reflectance method. The mass fraction profiles are consistent between the three fuel categories but markedly different from those reported in past literature – including the source profiles for wood stove $\text{PM}_{2.5}$ emissions developed as inputs to receptor modeling studies conducted by the Central Pollution Control Board of India. Thermally stable OC (OC3 in the IMPROVE_A protocol) contributed nearly 50% of the total carbon mass for emissions from all fuels.

1 Introduction

The Indian subcontinent is a regional hotspot for anthropogenic emissions (Ramanathan and Carmichael, 2008). Carbonaceous aerosol (black carbon, BC; and organic carbon, OC) in India is linked to surface dimming (Kambezidis et al., 2012), solar warming of the lower atmosphere (Ramanathan et al., 2001, 2007), changing regional monsoon patterns (Chung and Seinfeld, 2005; Menon et al., 2002; Ramanathan et al., 2005), and accelerated melting of Himalayan glaciers (Ramanathan et al., 2007). Particulate matter (PM) emissions – particularly particles with an aerodynamic diameters less than 2.5 μm ($\text{PM}_{2.5}$) – are also associated with nu-

merous adverse consequences for human health (Pope et al., 2009; Pope and Dockery, 2006). The Global Burden of Disease study has identified indoor air pollution as the largest risk factor and outdoor air pollution as the seventh largest risk factor for disability-adjusted life years in India (Murray et al., 2013).

The most recent emissions inventory for India indicated that residential biomass cookstoves are the largest contributors to total annual $\text{PM}_{2.5}$ emissions (Pandey et al., 2014; Sadavarte and Venkataraman, 2014). In 2010, 67 % of Indian households, more than 160 million total, relied primarily on solid fuels for cooking (Census, 2011). Commonly used cooking appliances are mostly mud stoves, with some three-stone-type brick stoves and metal stoves (Kar et al., 2012) that burn fuel wood, agricultural residue, and dried cattle dung. Traditional cookstoves have low combustion efficiencies, resulting in incomplete combustion and high PM emissions (Smith et al., 2000b).

Emissions performance of cookstoves is commonly expressed in terms of mass-based emissions factors (EFs) or mass of pollutant emitted per unit mass of fuel burned. PM emissions rates depend on fuel properties, combustion device, operator behavior, and cooking patterns (Leavey et al., 2015; Sahu et al., 2011; Roden et al., 2009). Cookstove heating efficiencies and EFs are often measured in a laboratory setting using a water boiling test with high- (boiling) and low- (simmering) power phases (Habib et al., 2008; Smith et al., 2000a; MacCarty et al., 2008). These standardized tests are useful for comparing different stove–fuel combinations, but they do not represent real-world stove behaviors found in the field (Roden et al., 2006, 2009; Smith, 2007). Habib et al. (2008) changed the amount of water boiled from 0.5 to 1.5 kg in the water boiling test, thereby changing the fuel burn rate and burn cycle duration, and they observed a factor of ~ 2.7 increase in the $\text{PM}_{2.5}$ EF and a factor of ~ 2 increase in the OC fraction. A real-world study of Honduran wood-burning cookstoves (Roden et al., 2006) found higher $\text{PM}_{2.5}$ EFs and OC content than those from previous laboratory studies. Roden et al. (2006, 2009) found that real-world fire tending and cooking practices (and therefore burn conditions) were important factors determining PM EFs and compositions.

Real-world EFs for commonly used fuel types and cooking technologies in India are needed for accurate bottom-up emissions estimates (Bond et al., 2013, 2004; Pandey et al., 2014). Inventory emissions rates serve as inputs to regional and global atmospheric transport models that predict spatiotemporal profiles of pollutant burdens and associated impacts on climate and human health (Bond et al., 2013; Guttikunda and Calori, 2013; Sadavarte et al., 2016; Schulz et al., 2006). Alternatively, these inventories are used in conjunction with impact metrics such as intake fraction (Grieshop et al., 2011) and global warming potential (Shindell et al., 2012) to evaluate mitigation policies (MHFW, 2015; Sagar et al., 2016). Such measurements identify key parameters to

be monitored during laboratory testing and appliance certification.

With the goals above, we measured cookstove emissions characteristics in a rural Indian household. Local meals were prepared with a traditional mud stove (*chulha*) using biomass fuels collected from different regions of India. Real-time measurements of emitted gas concentrations were conducted and PM filter samples were collected at regular time intervals during each cooking cycle. $\text{PM}_{2.5}$, OC, and EC EFs are reported here as a function of fuel type and combustion phase. Thermal carbon fractions provided by the IMPROVE_A protocol are also examined.

2 Methods

Between 19 and 30 December 2015, 30 separate cooking tests were conducted in a rural household on the outskirts of Raipur, a city located in the central Indian state of Chhattisgarh (abbreviated as Chh.). Approximately 77 % of Chhattisgarh households are located in rural areas and rely almost entirely on solid biomass fuels for cooking (Census, 2011). On a national level, fuel wood, agricultural residue, and dung are used as primary cooking fuels by 49, 9, and 8 % of Indian households, respectively (Census, 2011). Accounting for average combustion efficiencies and calorific values of these fuels, annual fuel usage estimates are 250 Mt of fuel wood, 73 Mt of agricultural residue, and 100 Mt of dung (Pandey et al., 2014). For this study, fuel wood was obtained from Uttar Pradesh (U.P.), Rajasthan (Raj.), Andhra Pradesh (A.P.), Bihar, and Punjab, which collectively account for 35 % of the total fuel wood user base in India. All wood fuels were in the form of chunks with typical dimensions of 5–15 cm. Cattle dung (in the form of dung cakes dried in the sun) was collected from U.P. and Bihar, which account for 60 % of the dung use for cooking in India. Agricultural residues from *tur* crops (a type of woody stalk) and rice straw were procured from a village near the study location. Test fuels were collected and stored in sealed bags and later analyzed for elemental (carbon, oxygen, hydrogen, nitrogen) composition and moisture content. Fuel compositions are compared in Table 1. Per real-world practice, fuel samples were naturally dried in the sun and stored indoors, bringing moisture contents to $< 9\%$. These compositions are consistent with those reported in other tests (Habib et al., 2008; Smith et al., 2000a).

Table 2 describes the fuels used and the foods cooked; replicate tests were made for some of these combinations with at least three for each fuel. Dung (20–50 g) was doused with approximately 10 mL of kerosene for initial ignition and the test fuel was added after a steady flame was achieved. Additional fuel of the same type was added as needed. A 10 min period following lighting of the fire is designated as *ignition* phase. The remainder of the cooking cycle was designated as the *flaming* phase when a visible flame was present. Com-

Table 1. Elemental composition and moisture content of the biomass fuels in this study.

Fuel	Elemental composition (%)				Moisture content (%)
	Carbon	Hydrogen	Oxygen	Nitrogen	
U.P. dung	33.1	4.0	30.0	1.6	7.5
Bihar dung	41.4	5.1	33.6	2.1	8.6
Chh. rice straw	40.7	5.5	39.0	0.8	5.3
Chh. <i>tur</i> stalk	48.4	6.5	42.7	0.6	4.8
Punjab wood	50.3	0.2	40.9	0.4	6.2
Raj. wood	49.7	5.6	42.9	0.1	8.1
U.P. wood	49.9	0.1	41.8	0.2	5.6
A.P. wood	48.3	0.1	43.4	0.7	3.1

bustion entered the *smoldering* phase when the flame died down. The U.P. dung and Chh. rice straw could not sustain the flaming phase for more than a few minutes. Dung is typically smoldered for low-power cooking applications, and it is used as kindling material for igniting fuel wood in a typical rural household. The low carbon content of U.P. dung (Table 1) possibly hinders its ability to sustain a flame, more so than Bihar dung. Rice straw has a low material density and high surface-to-volume ratio and therefore tends to burn out very quickly. It also produces large amounts of smoke, making its use as a stand-alone fuel impractical and harmful for the cook's health. To circumvent these limitations, a few experiments established a steady flame using U.P. dung or Chh. rice straw mixed with U.P. wood (approximately 2.5 : 1 ratio of test fuel mass to wood mass).

The test kitchen (Fig. S1 in the Supplement) was on the first floor of the house, separate from all other rooms. A permanently open door was the only entry from an open terrace. A partially covered window was a second ventilation source. The emissions testing system is shown in Fig. 1. The combustion device was a traditional mud *chulha*; such stoves have poor heat insulation, poor combustion efficiency, and do not allow proper mixing of fuel and air (Smith et al., 2000a; Venkataraman et al., 2010). An eight-armed stainless steel probe (based on Roden et al., 2006) sampled naturally diluted emissions at ~ 1.2 m above the top of the stove. Each arm of the probe was 0.5 m in length, with four uniformly placed holes facing the plume. This probe was connected to three real-time instruments – a Kanomax portable mobility particle sizer (PAMS) (Kulkarni et al., 2016), a TSI SidePak (Zhu et al., 2007), and a Testo 350 gas analyzer (Wang et al., 2012). The PAMS recorded particle size distributions from 10 to 400 nm mobility diameter. The SidePak provides a light-scattering (670 nm) surrogate for measured $\text{PM}_{2.5}$ mass that is calibrated with Arizona road dust (O'Shaughnessy and Slagley, 2002). PM concentrations exceeded the top range of these instruments for short periods during the plume monitoring. The Testo 350 gas analyzer was factory-calibrated prior to the experiments for carbon monoxide (CO) and carbon dioxide (CO_2). Measured concentrations (acquired ev-

ery second) were at least 5 times the detection limits of 1 ppm CO and 0.01 % CO_2 by volume. $\text{PM}_{2.5}$ was collected on 47 mm Teflon-membrane and pre-baked quartz-fiber filters several times during a cooking cycle using MiniVol (5 L min^{-1}) samplers (Airmetrics model 4.2) with greased impactor inlets located in the plume ~ 0.9 m above the stove. Filter sample durations ranged from 0.5 to 4 min, based on the continuous SidePak reports, to prevent filter overloading. Field blanks were collected (minimum sampling duration of 15 min) each day before testing. The Teflon filters were weighed before and after sampling to obtain the net mass deposit that was divided by the sample volume (flow rate times duration) to obtain the concentration. The mass of Teflon filter deposits ranged from 50 to 300 μg . Quartz filters were analyzed using the Interagency Monitoring of Protected Visual Environments-A (IMPROVE_A) thermal-optical reflectance method (Chow et al., 2007b, 2011) to determine EC and OC fractions in the sampled particulates. The minimum detection limits of the thermal-optical reflectance analysis are about 9 μg for OC and 1 μg for EC (Solomon et al., 2014).

Using the carbon mass balance technique, fuel-based EFs were calculated for each filter:

$$\text{EF}_i = \text{CMF}_{\text{fuel}} \frac{C_i}{\Delta C_{\text{CO}_2} \left(\frac{M_{\text{C}}}{M_{\text{CO}_2}} \right) + \Delta C_{\text{CO}} \left(\frac{M_{\text{C}}}{M_{\text{CO}}} \right)}, \quad (1)$$

where EF_i is the EF of species i in grams emitted per gram of fuel consumed. CMF_{fuel} is the carbon mass fraction of the fuel, which ranged from 33 to 50 % for the tested fuels. C_i is the concentration of emitter i , in this case $\text{PM}_{2.5}$, OC, or EC, in grams per cubic meter, determined for each Teflon and quartz filter. ΔC_{CO_2} and ΔC_{CO} are the concentrations above ambient levels of CO_2 and CO in grams per cubic meter, respectively. M_{C} , M_{CO_2} , and M_{CO} are the atomic or molecular weights of C, CO_2 , and CO in grams per mole.

Wireless optical particle sensors (details available in Patel et al., 2017) were attached to the MiniVol sampler and the sampling probe during six experiments to check for any significant differences in the particle concentrations measured at the two locations. Measurements where either sensor was

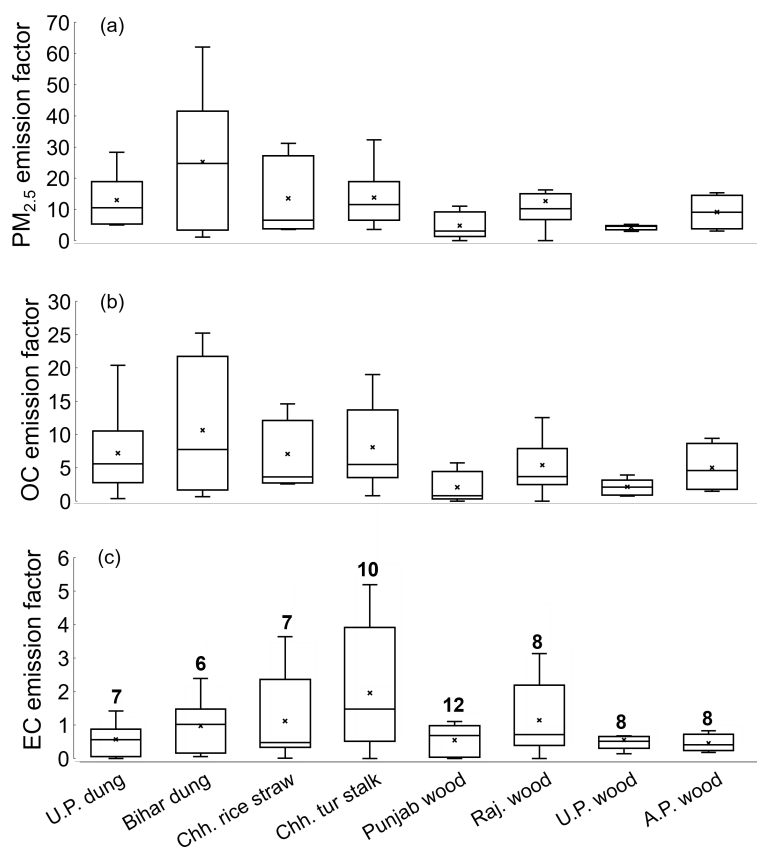

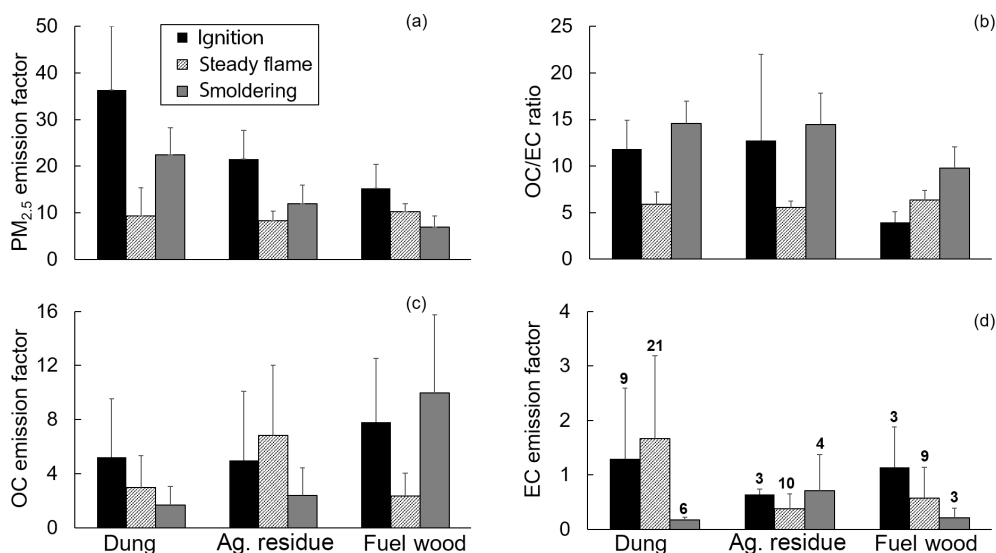

Figure 2. Box plots of (a) PM_{2.5} emissions factors, (b) OC emissions factors, and (c) EC emissions factors. All emissions factors are expressed in grams of pollutant per kilogram of fuel burnt. Boxes denote lower and upper quartiles; whiskers are 1.5 times the interquartile ranges of the upper and lower quartiles. The numbers above the error bars in panel (c) indicate the number of samples for each fuel.

Table 2. List of cooking experiments conducted during the 10-day intensive study period. Abbreviations for Indian states: U.P.: Uttar Pradesh; Raj.: Rajasthan; A.P.: Andhra Pradesh; Chh.: Chhattisgarh.

Day	Primary fuel used	No. of replicate experiments	Food cooked
1	Bihar dung	1	lentil, rice
2	U.P. wood	2	rice, vegetables
3	U.P. wood	1	tea
4	Raj. wood	4	lentils, rice, vegetables
5	U.P. wood	2	lentils
	A.P. wood	1	rice
6	A.P. wood	2	rice, vegetables
	Bihar dung	1	tea
7	Chh. <i>tur</i> stalks	3	rice, vegetables, tea
	U.P. dung*	3	vegetables, rice
	Bihar dung	1	tea
8	Chh. rice straw*	3	rice, vegetables
	Chh. wood	1	tea
9	Raj. wood	4	heated water, rice, curry
10	Punjab wood	1	milk porridge

* Two experiments for each fuel conducted with fuel wood mixed with the test fuel.

**Figure 3.** Fuel-wise average values of (a) $PM_{2.5}$ emissions factors, (b) OC/EC ratios, (c) OC emissions factors, and (d) EC emissions factors, categorized by observed combustion phases. All emissions factors are expressed in grams of pollutant per kilogram of fuel burnt. One-sided error bars are shown to denote 1 standard deviation from the mean. The numbers above the error bars in panel (d) indicate the number of samples for each fuel and combustion phase.

saturated were discarded, and a linear regression analysis was performed on the valid data points. A correction factor of 1.6 was applied based on the regression slope (in the Supplement). Equation (1) assumes that the carbon emitted in CH_4 , non-methane hydrocarbon, and PM is negligible compared to that in CO and CO_2 ; it was therefore corrected to account for the small fraction of fuel carbon that gets converted to gaseous volatile OC, assumed as 2.4% (Habib et al., 2008; Roden et al., 2006).

3 Results and discussion

Figure 2 compares EFs for all the test fuels. There are no statistically significant (unpaired Student's t test, 95% confidence intervals) EF differences for wood fuels from different regions of India. Bihar dung EFs exceeded those for U.P. dung, possibly owing to the addition of wood to sustain flaming. On average, $PM_{2.5}$ and OC EFs for dung were higher than those for fuel wood. EFs for dung, rice straw, and *tur*

Figure 4. Average PM_{2.5} emissions factors and OC / EC ratios for the three fuel categories in this study, compared with relevant studies. Error bars for values estimated in this study denote 95 % confidence intervals based on standard errors of the means. Error bars for other studies are the bounds reported within those studies.

stalk show a larger spread than corresponding EFs for fuel wood.

Figure 3 compares EFs for the different burning phases. PM_{2.5} EFs are highest during the ignition phase for all fuels. The OC / EC ratio (Fig. 3b) increases from ignition and flaming to smoldering for all fuels. CO EFs and modified combustion efficiencies (ratio of CO₂ concentration to CO+CO₂ concentration) show no correlation with PM_{2.5} EFs or OC / EC ratios (in the Supplement). Modified combustion efficiencies exceeded 0.9 – a value associated with flaming (Reid et al., 2005; Zhang et al., 2008) – for nearly 90 % of the test duration, even when no flaming was observed.

Average EFs for the entire burn cycle were calculated as a time-weighted sum of EFs for each phase of combustion. Fuel wood and agricultural residue are used predominantly in flaming conditions to carry out the bulk of cooking operations, resulting in weights of 17 % ignition, 66 % steady flame, and 17 % smoldering. For dung, the weights are 17 % ignition, 17 % flaming, and 66 % smoldering because dung was used for longer low-power operations such as heating water or milk and roasting vegetables. These EFs are compared with other reported EFs in Fig. 4. Average fuel wood PM_{2.5} EFs and OC / EC ratios in this study are 20 % larger than those reported by Roden et al. (2006) for Honduran cookstoves, but they are 2–8 times as large as those

reported for laboratory studies (Habib et al., 2008; MacCarty et al., 2008; Saud et al., 2012). For agricultural residue and dung, the average EFs and OC / EC ratios are 1.8–4.2 times and 1.3–2.2 times higher, respectively, compared to those reported by Saud et al. (2012) and Habib et al. (2008).

Thermal fractions of total carbon constituted by the IMPROVE_A protocol are compared in Fig. 5. OC1, OC2, OC3, and OC4 refer to carbon mass that evolves at temperatures of 120, 250, 450, and 550 °C, respectively, in the inert helium atmosphere. OP denotes pyrolyzed carbon, which is OC charring in the inert helium carrier. EC1, EC2, and EC3 fractions evolve in a 2 % O₂/98 % He oxidizing atmosphere at 550, 700, and 800 °C, respectively. Figure 5 compares fractions from this study with those reported for controlled biomass (hardwood and softwood) burning reported in Chow et al. (2007a). We also compare our results with a source profile developed for PM_{2.5} emissions from wood *chulhas*, as part of source apportionment studies conducted by the Central Pollution Control Board (CPCB) of India (CPCB, 2011). This profile was based on laboratory burns, but details of the test fuel and burn protocol are not known. OC3 was the most abundant fraction, ~ 50 % of the total carbon mass, while the profiles in literature ranged from 10 to 34 % in the OC3 fraction. The OC1 fraction for all fuels in this study was uniformly less than 3 %, a finding comparable only to the 5 % OC1 reported for softwood but not for the other two profiles.

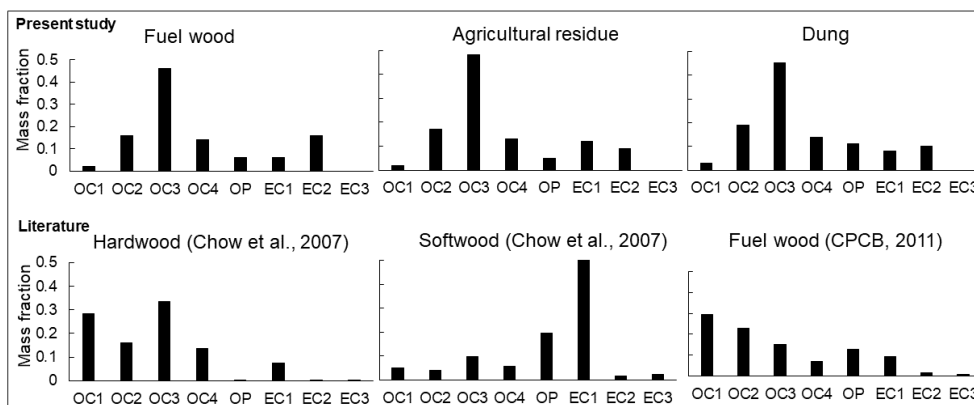

Figure 5. Fraction of total carbon emissions contributed by the IMPROVE_A thermal carbon fractions.

Carbonaceous aerosol source profiles are useful for source apportionment, and they may also have implications for climate and health impact assessments. In a previous study (Pandey et al., 2016), we reported that light-absorbing OC may play a larger role in light absorption by cookstove emissions than that from earlier work on biomass burning in the USA. The difference in constituents of OC emissions from the two sources might contribute to the observed difference in their optical characteristics since thermal stability is known to be inversely related to the light absorption efficiency of organic compounds (Andreae and Gelencsér, 2006; Saleh et al., 2013).

4 Conclusions

We estimated $PM_{2.5}$, OC, and EC mass EFs from real-world combustion of commonly used biomass fuels in India. EFs for fuel wood and dung are more than twice those derived from laboratory tests for similar appliances and fuels. Earlier studies have shown that fuel burn rate (Habib et al., 2008) and fire-tending practices (Roden et al., 2009) affect cookstove emissions; therefore, standardized burn protocols (typically a water boiling test) may not replicate cookstove performance in the field. In a controlled test, variability in wood size could be expected to affect emissions from fuel wood combustion; hence, laboratory studies typically used identical wood chunks. The four wood fuel types in this study were used as chunks in a range of sizes and yielded similar EFs even though these samples were gathered from widely separated parts of India. Overall, the variability in emissions between multiple measurements for the same fuel was larger than or comparable to the differences in average emissions rates for different fuels.

A short period immediately following the ignition phase showed the highest and most variable $PM_{2.5}$ EFs for all fuels, consistent with previous observations of high emissions from lighting and refueling of stoves (Roden et al., 2009). The use of variable amounts of kerosene and other kindling materials,

as required in any burn, may explain the large spread in emissions measurements during ignition. The highest OC/EC ratios were observed during smoldering (no visible flame present), when pyrolysis is the dominant process. The OC3 thermal fraction contributed nearly 50% of the total carbon mass for emissions from all fuels, indicating that most of the PM emissions are non-evaporative. This could have implications for the climatic impact effect of cookstove emissions, especially since volatility of OC emissions is inversely related to their light absorption efficiency in the near-UV and visible wavelengths (Andreae and Gelencsér, 2006). The thermal fractions found in this study differ from those found in other biomass burning tests, including the source profile used as an input to receptor models of particulate emissions in India (CPCB, 2011). Our findings suggest that combustion conditions may have a larger influence on intrinsic properties of biomass combustion emissions than fuel variability. Connecting aerosol emissions from a given source to their effects on climate and human health requires knowledge of their mass emissions rates and physiochemical properties. The EFs from this study could contribute toward improving evaluations of climate and health impacts of carbonaceous aerosols over India. Further investigation is needed on the relationship between the composition of OC emissions and their climate and health effects.

Data availability. The emissions factor data set is made available in Table S1 of the Supplement.
