19  
20 **Abstract**

21 The Arctic tundra is warming rapidly, yet the exact mechanisms linking warming and observed  
22 ecological changes are often unclear. Understanding mechanisms of change requires long-term  
23 monitoring of multiple ecological parameters. Here, we present the findings of a collaboration between  
24 government scientists, local people, park rangers and academic researchers that provide insights into

25 changes in plant composition, phenology and growth over 18 years on Qikiqtaruk–Herschel Island,  
26 Canada. Qikiqtaruk is an important focal research site located at the latitudinal tall shrub line in the  
27 western Arctic. This unique ecological monitoring program indicates the following findings: 1) nine  
28 days per decade advance of spring phenology, 2) a doubling of average plant canopy height per decade,  
29 but no directional change in shrub radial growth and 3) a doubling of shrub and graminoid abundance  
30 and a decrease by half in bare ground cover per decade. Ecological changes are concurrent with  
31 satellite-observed greening and when integrated suggest that indirect warming from increased growing  
32 season length and active layer depths, rather than warming summer air temperatures alone, could be  
33 important drivers of the observed tundra vegetation change. Our results highlight the vital role that  
34 long-term and multi-parameter ecological monitoring plays in both the detection and attribution of  
35 global change.

36

**37 Introduction**

38 Arctic tundra is responding rapidly to climate change (IPCC 2014). Annual temperatures in the Arctic  
39 have already increased by more than 2°C since 1978 (IPCC 2013) and there is growing evidence that  
40 this warming is leading to changes in vegetation communities at sites around the tundra biome (Myers-  
41 Smith et al. 2011a, Elmendorf et al. 2012b, IPCC 2014). Although the literature reports prominent  
42 ecological transformations, including changes in vegetation composition (Elmendorf et al. 2012b),  
43 plant phenology, and satellite-observed greening (Post et al. 2009a), recent studies also indicate high  
44 unexplained heterogeneity in vegetation responses at sites around the Arctic (Elmendorf et al. 2012b,  
45 Oberbauer et al. 2013, Guay et al. 2014, Myers-Smith et al. 2015a, Prevéy et al. 2017). One possible  
46 reason that tundra biome-scale data syntheses indicate high levels of heterogeneity is that different  
47 ecological parameters are measured in different places or at different points in time. Rarely are single  
48 sites monitored to a degree at which we can observe patterns of change over time from multiple lines of  
49 evidence (Hobbie et al. 2017). This omission also often precludes exploration of the potential  
50 mechanistic drivers of observed change. Thus, to understand the trends and drivers of change in tundra  
51 ecosystems, we require integrated assessments of multiple and concurrently monitored ecological  
52 parameters at focal research sites.

53

*54 Widely-observed ecological patterns*

55 Vegetation monitoring indicates an increase in total plant cover and decrease in bare ground in tundra  
56 ecosystems (Elmendorf et al. 2012b). Tundra plant community composition change indicates a shift  
57 towards increased deciduous shrub cover – shrub expansion (Myers-Smith et al. 2011a) and graminoid  
58 cover (Elmendorf et al. 2012b), while mosses and lichen species tend to be decreasing (Lang et al.  
59 2012, Elmendorf et al. 2012b). The same changes have been observed in warming experiments (Walker  
60 et al. 2006, Elmendorf et al. 2012a), suggesting that these vegetation changes are driven at least in part

61 by increasing temperatures (Elmendorf et al. 2015). Shrub and graminoid plants are also growing taller  
62 (Walker et al. 2006, Myers-Smith et al. 2011c) and reproducing more frequently (Klady et al. 2011).  
63 However, rates of shrub expansion vary greatly across sites, with some showing no evidence of change  
64 or climate sensitivity of growth (Hudson and Henry 2010, Myers-Smith et al. 2011b, 2015a, Elmendorf  
65 et al. 2012b, Martin et al. 2017, Isla H. and David S. 2017). Heterogeneity in vegetation change can be  
66 explained by a variety of site-level factors including soil moisture (Ackerman et al. 2017), topography  
67 (Tape et al. 2012, Ropars and Boudreau 2012), disturbance (Lantz et al. 2009, 2010), herbivory  
68 (Olofsson et al. 2009, Zamin and Grogan 2012), and plant-plant interactions (Bret-Harte et al. 2004,  
69 Dormann et al. 2004).

70

71 Increasing temperatures are widely expected to lead to advances in plant phenological events including  
72 leaf emergence and flowering (Peñuelas and Filella 2001, Peñuelas et al. 2009, Körner and Basler  
73 2010, Pau et al. 2011, Cleland et al. 2012). In tundra ecosystems, the timing of leaf emergence and  
74 flowering has advanced at some (Høye et al. 2007, Kerby and Post 2013, Iler et al. 2013), but not all  
75 sites (Bjorkman et al. 2015b). Satellite-observed green-up in the tundra is estimated to be advancing by  
76 1.6 to 4.7 days per decade (Myneni et al. 1997, Zeng et al. 2011, Park et al. 2016), corresponding with  
77 an advance in snow melt (Post et al. 2009b) and increased spring drawdown of CO<sub>2</sub> in the northern  
78 hemisphere (Barichivich et al. 2013, Forkel et al. 2016). However, growing season onset varies greatly  
79 by region and different remotely-sensed satellite records (Zeng et al. 2011, Xu et al. 2013), and some  
80 tundra sites have experienced decreased growing season length and delayed phenology as a result of  
81 higher snowfall (Wipf and Rixen 2010, Bjorkman et al. 2015a, Legault and Cusa 2015).

82

83 Satellite observations indicate a greening of Arctic tundra concurrent with recent warming that has  
84 been attributed to an increase in photosynthetic biomass (Jia et al. 2009, Forbes et al. 2010, Beck and

85 Goetz 2011, Bhatt et al. 2013, Ju and Masek 2016). However, recent studies indicate a decrease in the  
86 satellite greening trend (Bhatt et al. 2013) and heterogeneity in satellite observations across different  
87 sensor platforms (Guay et al. 2014). Non-ecological factors, including atmospheric change, drift in  
88 satellite sensors or earlier snow melt, can also produce greening signals (Gamon et al. 2013, Guay et al.  
89 2014). For example, the normalized difference vegetation index (NDVI), the most common index of  
90 remotely-sensed tundra greening, is also sensitive to other landscape-level parameters such as snow  
91 duration or standing water (Gamon et al. 2013, Raynolds et al. 2013, Pattison et al. 2015). Thus, there  
92 is current uncertainty in whether the greening patterns observed by satellites do indeed indicate a  
93 change in plants *in situ* at sites across the tundra biome.

94

95 *Multi-parameter evidence of change*

96 Comprehensive monitoring programs that incorporate environmental variables, community  
97 composition and phenology observations are rare in the Arctic, especially considering the rapid rate of  
98 environmental change and potential sensitivity of tundra ecosystems (CAFF 2013, Hobbie et al. 2017).  
99 These long-term integrated datasets are required to test the ability of remote sensing to capture *in situ*  
100 ecological change. At present, there are only a few circumpolar Arctic sites with such long-term, multi-  
101 parameter monitoring including research stations such as Abisko (68.35°N, 18.83°E) in Northern  
102 Sweden (Van Wijk et al. 2004, Callaghan et al. 2010, 2013, Hobbie et al. 2017), Toolik Lake (68.63°N,  
103 -149.60°E) in Northern Alaska (Van Wijk et al. 2004, Hobbie et al. 2017), Zackenberg (74.50°N, -  
104 27.77°E) in Eastern Greenland (Høye et al. 2007, Iler et al. 2013) and Alexandra Fiord (78.88°N, -  
105 75.80°E) on Ellesmere Island in Arctic Canada (Svoboda et al. 1994, Hudson and Henry 2009, 2010,  
106 Hudson et al. 2011, Bjorkman et al. 2015a).

107

108 The ecological monitoring program on Qikiqtaruk was established in 1999 uniquely combining multi-  
109 parameter monitoring using international protocols with the collaborative efforts of territorial park  
110 rangers, Yukon government researchers, and academic scientists (Box 1). Early outputs of the  
111 monitoring program indicated an increase in shrub cover at sites across this island (Myers-Smith et al.  
112 2011b). Qikiqtaruk is located in a region of the Arctic that has undergone a prominent greening trend  
113 according to different satellite records (Fraser et al. 2011, Guay et al. 2014, Ju and Masek 2016), and  
114 research is under way to determine how vegetation changes align with changes in phenology and  
115 overall community structure in the context of regional increases in NDVI. After 18 years of ecological  
116 monitoring, we can now test whether the original observations of vegetation change are continuing at  
117 this site and whether rates of change in environmental and ecological parameters are accelerating.

118

119 In this study, we combine multiple ecological parameters covering a 18-year timescale (1999-2017) to  
120 test three hypotheses: 1) The realized growing season length (time between leaf emergence and leaf  
121 senescence) has increased concurrent with earlier snow melt and warmer spring and autumn  
122 temperatures; 2) The canopy height of tundra shrubs is increasing, driven by high sensitivity of  
123 interannual growth to summer temperature; 3) Vegetation community composition change is occurring  
124 with an increase in shrub and graminoid abundance concurrent with a decrease in bare ground. We  
125 place these hypotheses in the context of environmental change in the western Arctic Region to  
126 understand the mechanisms, patterns, and implications of the observed vegetation change.

127

128 **Box 1. Collaborative Ecological Monitoring on Qikiqtaruk**

129 Ecological monitoring of community composition and phenology requires consistent and time-  
130 consuming observations recorded throughout the growing season. This poses major logistical  
131 challenges for researchers, and is a primary contributing factor to the scarcity of long-term Arctic

132 vegetation monitoring programs (CAFF 2013). Recently, the integration of local people into long-term  
133 ecological research has led to an increasing emphasis on community-based monitoring around the  
134 Arctic (Gill and Lantz 2014, Stern 2015). However, the different types of monitoring from community-  
135 based research, government-funded monitoring, and academic research are rarely integrated.

136  
137 Vegetation monitoring on Qikiqtaruk incorporates collaboration among government, park rangers  
138 including local Inuvialuit people, and university-based researchers. The vegetation monitoring program  
139 was initiated on Qikiqtaruk by Yukon Government biologists in 1999 and continues today (Smith et al.  
140 1989, Cooley et al. 2012). It is carried out by park rangers, and supplemented by government scientists  
141 and academic researchers who monitor long-term community composition plots and collect other  
142 associated ecological data. Researchers benefit by the access to long-term monitoring data and local  
143 knowledge, and in turn provide data analysis and additional protocols to enhance Yukon Parks'  
144 monitoring programs. Direct contact and collaboration takes place during the summer field season,  
145 providing valuable opportunities for the co-production of knowledge between local observations by  
146 those living in the region and working on Qikiqtaruk and those visiting to conduct scientific research.

147  
148 The Qikiqtaruk monitoring program (Figure 1) has one of the highest temporal resolutions among  
149 vegetation phenology monitoring datasets collected anywhere in the Arctic (CAFF 2013). Data are  
150 collected every 2-3 days from snow melt (April) to senescence (September). This comparatively high  
151 frequency of data collection over the whole growing season enables an understanding of ecological  
152 changes in the context of local observations (Cooley et al. 2012). Data from the ecological monitoring  
153 program have previously contributed to tundra-biome wide data syntheses (Elmendorf et al. 2012b,  
154 2015, Prevéy et al. 2017). The monitoring program is also important for communicating how climate  
155 change is influencing tundra systems in the western Arctic (Stern and Gaden 2015).

156 **Materials and methods**157 *Site description*

158 Qikiqtaruk - Herschel Island is located on the Arctic Coast of the Yukon Territory (69.6°N, 138.9°W)  
159 at the northern extent of tall shrubs and in a zone of ice-rich permafrost (Figure 2). In the larger western  
160 Arctic region, there is evidence for widespread shrub expansion (Tape et al. 2006, Myers-Smith et al.  
161 2011b, Lantz et al. 2013, Moffat et al. 2016). Qikiqtaruk is also located at the mid-Arctic latitudes  
162 where shrub vegetation has been found to be especially sensitive to climate (Myers-Smith et al. 2015a);  
163 though the climate sensitivity of shrub radial growth has been observed to be low at this particular site  
164 (Myers-Smith et al. 2011c, 2015a).

165

166 The island is made up of discrete vegetation types (Smith et al. 1989, Obu et al. 2015). The dominant  
167 vegetation types include the Herschel vegetation type: comprising relatively undisturbed moist acidic  
168 tussock tundra, the Komakuk vegetation type: comprising herbaceous and grassy tundra that is more  
169 influenced by cryoturbation and surface disturbance, the Orca vegetation type: comprising tall shrub  
170 and wet sedge vegetation across a floodplain: and other more transitional vegetation types in the areas  
171 with more topographic variation. These vegetation types have been mapped and correspond to different  
172 landscape contexts, soil conditions and disturbance histories across the island (Obu et al. 2015).

173

174 *Environmental parameters*

175 Climate data were compiled from monthly Climate Research Unit (CRU) TS3.21 gridded frost  
176 frequency data (0.5° resolution, Harris, Ian 2013), and the Herschel Island Environment Canada  
177 Weather station. Seasons were defined as spring: April - May, summer: June - July, autumn: August -  
178 September, winter: October - March. Sea ice data are from the Canadian Sea Ice Service for the CIA  
179 WA Beaufort Sea: Mackenzie region (CWA01\_02). We report climate data from the Environment

180 Canada weather station (red point on Figure 2) as temperatures across the monitoring locations do not  
181 differ substantially across these relatively flat upland or floodplain locations (IH Myers-Smith and HJD  
182 Thomas, unpublished data). Snow melt, soil temperature and active layer data are measure at the plot-  
183 level (see below).

184

185 Active layer depth was measured by vertically probing the soil using a metal stake and measuring the  
186 depth to frozen ground. Records from 1985 come from the ecological surveys prior to the establishment  
187 of Herschel Island – Qikiqtaruk Territorial Park (Smith et al. 1989). Records from 2003 – 2008 come  
188 from previous studies by Prof. Chris Burn (Burn and Zhang 2009) and the ArcticWOLVES project  
189 ([http://www.cen.ulaval.ca/arcticwolves/en\\_intro.htm](http://www.cen.ulaval.ca/arcticwolves/en_intro.htm), S Gilbert, D Reid, CJ Krebs and IH Myers-  
190 Smith, unpublished data). Records from 2016 – 2017 come from the NERC ShrubTundra project and a  
191 new active layer monitoring protocol developed in 2017 to accompany the species composition and  
192 phenology data collection.

193

194 Soil temperature was measured monthly from April to September at different depths, ranging from 1 m  
195 to 42 m below the surface, at two borehole stations (15 m depth: 2000 - 2017 and 43 m depth: 2005 -  
196 2017). The boreholes are located within 20 m of each other on a flat surface on Collinson Head on  
197 Qikiqtaruk and are equipped with BetaTHERM 2.2K3A1A thermistors, which were calibrated in a  
198 laboratory ice bath. Park rangers recorded resistance in the circuit using a multimeter, calibrated against  
199 a stable resistor of 7355 W before each set of measurements. Resistance values ( $\Omega$ ) were converted into  
200 temperature ( $^{\circ}\text{C}$ ) following (Burn and Zhang 2009), see Table S1 for formulas. We present minimum  
201 soil temperatures from 12, 15 and 16 m depths across the time series as these were the depths at which  
202 there were the most available data.

203

204 *Vegetation phenology*

205 Vegetation phenology methodology follows the ITEX protocols (Molau and Mølgaard 1996) and  
206 includes three monitored species: *Dryas integrifolia* Vahl, *Eriophorum vaginatum* L., and *Salix arctica*  
207 Pall. For each species, one transect, with 10 individuals, stems or plots per 50 m transect, is marked by  
208 wooden stakes. The first species, *Dryas integrifolia* (Mountain Avens), is a small prostrate-growing  
209 evergreen dwarf shrub with white flowers (Figure 1 - center top). Individuals are demarcated by 10  
210 quadrats (10 cm by 10 cm). The second species, *Eriophorum vaginatum* (Cottongrass), is a tussock  
211 grass that has large cotton-like seed heads (Figure 1 - center middle). Individuals are ten marked  
212 tussocks in a row. The third species, *Salix arctica* (Arctic Willow), is a prostrate-growing deciduous  
213 dwarf shrub with oblong leaves and large catkins (Figure 1 - center bottom). Individuals were initially  
214 marked by stem tags, but due to continued stem mortality this changed during 2015 to quadrats similar  
215 to the *Dryas integrifolia* transect. Phenology variables observed are indicated in Figure 1. Realized  
216 growing season length was estimated as the difference between the first leaf emergence date and the  
217 first leaf senescence date (P5-P2). We used first leaf senescence (P5) to represent the end of growing  
218 season due to a lack of last leaf senescence (P6) data in some years.

219

220 *Dendroecology methods*

221 Annual growth increments in woody species provide information on growth and climate sensitivity,  
222 particularly when no long-term monitoring data are available. Wood samples of deciduous willow  
223 species *Salix arctica*, *S. pulchra* Cham., *S. richardsonii* Hook., *S. glauca* L and *S. niphoclada* Rydberg.  
224 were collected in 2009 and 2015 (Myers-Smith et al. 2011c, 2015a), S Angers-Blondin and IH Myers-  
225 Smith, unpublished data). Wood processing followed methods adapted for tundra shrub species  
226 (Myers-Smith et al. 2015b). Thin cross sections of either the largest stem or the root collar were  
227 mounted on glass slides and photographed under a dissecting microscope. Rings were counted and

228 measured from the digital image for each shrub section along four radii with a resolution of 1  $\mu\text{m}$   
229 (Schneider et al. 2012). Temporal growth trends in raw ring width are presented here to complement  
230 ecological monitoring data, and to test whether secondary growth follows the same trends as primary  
231 growth.

232

### 233 *Community composition*

234 Community composition was measured in two vegetation communities (Figure 1): the Herschel  
235 vegetation type and the Komakuk vegetation type. Community composition was assessed using point-  
236 framing methods following the ITEX protocols (Molau and Mølgaard 1996). Twelve plots of 1  $\text{m}^2$  (six  
237 per vegetation type) were established in 1999 and resurveyed in 2004, 2009 and 2013 - 2017. A grid  
238 with 100 points at 10 cm spacing was placed over each plot at a height of approximately 50 cm. A  
239 metal pin was dropped vertically at each of the 100 grid points; all plant parts that touched the pin were  
240 recorded, noting species, plant part (leaf, stem, flower, flower stalk) and tissue status (live or  
241 dead). The maximum canopy height at each point and the height of the tall shrub species *Salix pulchra*  
242 were also recorded at every grid point. Soil surface cover was recorded including bare ground, rock,  
243 litter, moss, and lichen species. Species counts and bare ground were converted to abundance by  
244 calculating the proportion of points at which each species was present. Plant cover was represented  
245 using a vegetation cover index calculated by dividing the total number of vegetation hits per plot by the  
246 number of points per plot (100), such that a vegetation index of one would represent an average of one  
247 hit per sample point.

248

249 We measured the number of species adjacent to the species composition monitoring plots following the  
250 2017 International Tundra Experiment species pool monitoring protocol (C. Rixen,  
251 <https://www.gvsu.edu/itex/>). A survey of the local species pool within 100 m of the community

252 composition plots was conducted on 31<sup>st</sup> July and 1<sup>st</sup> August of 2017. We monitored a 50 by 50 cm plot  
253 within the central monitoring plot at each vegetation type, a 1 by 1 m plot (the central monitoring plot),  
254 a 2.5 m radius circular plot centred around the monitoring plot, and then walked concentric circles out  
255 to 100 m spaced approximately 5 m apart, recording all plant species observed and their distance to the  
256 center plot. These data were used to make species area curves to test the proximity of new species that  
257 could potentially occur in the monitoring plots in future.

258

259 *Statistical analyses*

260 Statistics were conducted with the software R (version 3.3.3, R Core Team 2014). Bayesian models  
261 were conducted in the package MCMCglmm (Hadfield 2010) except for the interval censoring models  
262 that were written in JAGS called from R using the programs rjags (Plummer 2014) and R2jags (Su and  
263 Yajima 2012). Convergence was assessed through examination of trace plots and autocorrelation  
264 values, and in the case of the interval censoring models using the Gelman-Rubin diagnostic (Gelman  
265 and Rubin 1992) available in the coda package (Plummer et al. 2006). Code is available at the  
266 following GitHub repository (link to be added at the time of publication).

267

268 We used Bayesian linear models to estimate change in seasonal temperature, frost frequency days,  
269 snow melt date and active layer depth. We used Bayesian linear models to estimate changes in  
270 minimum soil temperature (square transformed) at depths of 12, 15 and 16 m in different years in two  
271 boreholes located near the community composition plots. We used a Bayesian model with a binomial  
272 distribution to estimate change in minimum sea ice concentration over time as sea ice concentration is  
273 bounded between 0 and 1. We used hierarchical Bayesian linear interval censoring models with plot  
274 and year as random effects to estimate change in phenology over time to account for the uncertainty in  
275 the timing of the phenological event between monitoring observations (Bjorkman et al. 2015a). We

276 used hierarchical Bayesian models with plot and year as random effects to estimate change in overall  
277 canopy height, *Salix pulchra* height (Gaussian distribution), and change in vegetation cover, bare  
278 ground cover and species evenness (binomial distribution) over time as percent cover data are bounded  
279 between 0 and 1. We used four hierarchical Bayesian linear models with individual and year as random  
280 effects to estimate change in radial growth over time for the willow species *Salix arctica*, *S. pulchra*, *S.*  
281 *richardsonii*, and *S. glauca*. We estimated species richness at the site level (aggregated species richness  
282 across all plots) over time using a Bayesian linear model, as the hierarchical model would not  
283 converge. We used Bayesian linear models to estimate accumulation of species at different distances  
284 (log transformed) in the Herschel and Komakuk vegetation types. We used non-informative parameter-  
285 expanded priors for all coefficients in the MCMCglmm models that included random effects, and non-  
286 informative priors for all coefficients in the JAGS models. We used a uniform prior between 0 and 365  
287 for the intercepts and slope priors were normally distributed, centered on zero with a precision of  
288 0.001. We refer to predictors as ‘significant’ when the 95% credible interval for the corresponding  
289 parameter in the fitted models did not overlap zero.

290

## 291 **Results**

### 292 *Observed climate and environmental climate change*

293 Over the past 25 years Qikiqtaruk has experienced warming towards the end of the ice-free season  
294 (August and September) and a decrease in the annual number of frost days (inversely related to  
295 potential growing season length) by 3.6 days per decade (slope = -0.36, CI = -0.58 to -0.12,  $p < 0.01$ ),  
296 and warming during the growing season (slope = 0.16, CI = 0.01 to 0.31,  $p = 0.04$ , Figure 3b).  
297 Minimum sea ice concentration has also declined over the same period (slope = -0.11, CI = -0.17 to -  
298 0.05,  $p < 0.01$ ) and the day that snow is completely melted at plots along the phenology transects is  
299 occurring earlier (slope = -0.71, CI = -1.37 to -0.05,  $p = 0.04$ ). Minimum soil temperatures at 12, 15

300 and 16 m depths have increased across the monitoring period at both boreholes (slope = 0.004, CI =  
301 0.003 to 0.005,  $p < 0.01$  for soil temperature at 12 m depth in the first borehole, see Table S2 for all  
302 model outputs).

303

304 Data from different datasets in the Herschel and Komakuk vegetation types monitored within 1 km of  
305 the ecological monitoring sites from 1985 and 2017 indicate a mean increase in the active layer depth  
306 by as much as 20 cm (slope = 0.72, CI = 0.21 to 1.29,  $p = 0.02$ , Figure 4a). During the 2017 growing  
307 season, the active layer depth reached maximum depths of 58.5 cm in the Herschel vegetation type and  
308 87.2 cm in the Komakuk vegetation type (Figure 4b).

309

#### 310 *Observed vegetation change*

311 Vegetation change appears to be progressing rapidly in certain locations including across the floodplain  
312 vegetation type (Orca vegetation type) on Qikiqtaruk as indicated by the increase in shrub cover and  
313 height in the repeat photography time series across the monitoring period (Figure 5).

314

#### 315 *a. Plant phenology*

316 The timing of spring events has advanced for all species. *Salix arctica* leaf emergence has advanced by  
317 approximately nine days per decade (slope = -0.93, CI = -1.69 to -0.12) and flowering has advanced by  
318 approximately five to eight days per decade for all monitored species (Figure 6, Table S2). Realized  
319 growing season length (the difference between spring leaf emergence and autumn senescence for *Salix*  
320 *arctica*) has increased slightly by approximately two days per decade (slope = 0.21, CI = -0.92 to 1.36);  
321 this is largely due to an advance in spring phenology (leaf emergence), since leaf senescence also  
322 advanced by seven days per decade (slope = -0.74, CI = -1.53 to 0.03; Figure 6). However, only the

323 advance in leaf emergence was significant (the credible interval on slope estimate does not overlap  
324 zero).

325

326 *b. Plant growth*

327 Mean canopy height has more than tripled from 3.8 to 16.8 cm in the Herschel plots (slope = 0.59, CI =  
328 0.42 to 0.79,  $p < 0.01$ ) and from 1.6 to 11.3 cm in the Komakuk plots (slope = 0.31, CI = 0.20 to 0.43,  $p$   
329  $< 0.01$ ) over the monitoring period (Figure 7a). This increase in community-level plant height is  
330 explained by both changing composition, notably an increase in taller graminoid species, and by an  
331 increase in individual species such as *Salix pulchra* canopy height over time (Figure 7b). The radial  
332 growth of *Salix* spp. showed large inter-annual variability and no clear annual trend or climate  
333 sensitivity (Figure 7c).

334

335 *c. Community composition*

336 Repeat vegetation monitoring has identified changes to the overall structure of communities and  
337 directional changes in community composition (Figure 8). Plant cover (Figure 8a) has increased in both  
338 vegetation types since 1999, by 0.26 hits per point per year (slope = 0.26, CI = 0.09 to 0.42,  $p = 0.01$ )  
339 for the Herschel vegetation type and 0.11 hits per year (slope = 0.11, CI = 0.03 to 0.19,  $p = 0.02$ ) for  
340 the Komakuk vegetation type. Increasing vegetation cover is associated with a decrease in bare ground  
341 (Herschel vegetation type: slope = -0.18, CI = -0.35 to -0.02,  $p = 0.02$ ; Komakuk vegetation type: slope  
342 = -0.07, CI = -0.13 to 0.00,  $p = 0.06$ , Figure 8b) and an increase in canopy height (Figure 7a). Species  
343 richness and species evenness have not changed over time (Figure 8c and d, Table S2). In the Herschel  
344 plots, there was an increase in *Eriophorum vaginatum* (slope = 0.10, CI = -0.03 to 0.23,  $p = 0.12$ ;  
345 Figure 8e) and *Salix pulchra* cover (slope = 0.06, CI = -0.02 to 0.14,  $p = 0.11$ ; Figure 8e). Finally, two  
346 graminoid species, *Arctagrostis latifolia* and *Alopecurus alpinus*, have immigrated into the Komakuk

347 vegetation plots and expanded their cover over the last decade (*Arctagrostis latifolia*: slope = 0.20, CI  
348 = -0.01 to 0.41,  $p = 0.06$ ; *Alopecurus alpinus*: slope = 1.50, CI = 0.64 to 2.61,  $p < 0.01$ , Figure 8f).

349

350 We found faster accumulation of species in the Herschel vegetation type (slope = 6.50, CI = 5.70 to  
351 7.32,  $p < 0.01$ ) relative to the Komakuk vegetation (slope = 8.61, CI = 7.53 to 9.72,  $p < 0.01$ , Figure 9).

352 There were 13 vascular plant species within 100 m of the Herschel vegetation type and 26 within 100  
353 m of the Komakuk vegetation type that have not yet been observed in the long-term monitoring plots.

354 We have observed one species invasion into the plots the grass *Alopecurus alpinus* and one major  
355 change in abundance the grass *Arctagrostis latifolia* over the monitoring period (Figure 8).

356

## 357 **Discussion**

### 358 *Observed vegetation change*

359 Our results provide strong evidence for multi-dimensional vegetation change on Qikiqtaruk across the  
360 period 1999 to 2017 (Figure 10). We find that plant phenology, growth and community composition  
361 are changing on the island, with earlier leaf emergence, an increase in shrub canopy heights, and  
362 increased cover of shrub and graminoid species concurrent with a decrease in the cover of bare ground  
363 (Figures 5-8). These results are consistent with the initial findings reported for this site (Myers-Smith et  
364 al. 2011b) and indicate that vegetation changes have continued or accelerated over the 18-year period.

365 Our results also correspond with widespread observations of phenology change (Ellebjerg et al. 2008,  
366 Oberbauer et al. 2013), community composition change (Elmendorf et al. 2012b, 2015) and shrub  
367 expansion across the tundra biome (Tape et al. 2006, Forbes et al. 2010, Naito and Cairns 2011, Myers-  
368 Smith et al. 2011a, Martin et al. 2017) and with predictions from tundra warming experiments (Walker  
369 et al. 2006, Elmendorf et al. 2012b, 2015). However, our results are unique because the different lines  
370 of evidence for vegetation change reported in this study come from the same or adjacent vegetation

371 communities and can be compared directly to concurrent changes in environmental parameters (Figure  
372 10).

373

374 Spring phenology advanced for all three monitored species (*Salix arctica*, *Dryas integrifolia* and  
375 *Eriophorum vaginatum*), though these trends were weak due to high inter-annual variation (Figure 6).

376 Our results also suggest that date of snow melt is a key control on spring phenology in tundra  
377 ecosystems, with earlier snow melt corresponding with earlier leaf emergence (Figures 3 and 6).

378 Similarly, declining sea ice has also been associated with spring greening in a number of studies (Bhatt  
379 et al. 2010, Kerby and Post 2013, Post et al. 2016), which has also been observed at this site. In

380 contrast, some studies have identified trends towards later phenology in some species and locations  
381 usually aligning with later snow melt (Schmidt et al. 2006, Wipf and Rixen 2010, Bjorkman et al.

382 2015a).

383

384 Our findings indicate that the length of the realized growing season on Qikiqtaruk has not substantially  
385 increased due to both an advance in leaf emergence and senescence for the species *Salix arctica* (Figure  
386 6). This result could indicate a fixed leaf life span in the species *Salix arctica* as observed in deciduous  
387 tree species (Keenan and Richardson 2015). Lack of change in realized growing season length contrasts

388 with the observed increase in the potential growing season length (as estimated from the number of  
389 frost days; four days per decade). This is likely due to the importance of snow melt, rather than spring

390 temperature, in determining the start of the growing season at this Arctic tundra site (Høye et al. 2007,  
391 Oberbauer et al. 2013, Bjorkman et al. 2015a) and the lack of correspondence among trends of autumn

392 warming and end of season phenology (Figures 3 and 6). Our findings align with previous work that  
393 suggests photoperiod (Arft et al. 1999, Andrews et al. 2011) or deterministic leaf age (Oberbauer et al.

394 2013) could be more influential for the timing of senescence than temperature.

395

396 Plant canopy heights have increased across the period of monitoring (Figure 7), driven by both  
397 community composition change and plastic responses in existing individuals. We observed greater  
398 variation in *Salix pulchra* canopy heights in recent years, though this is most likely driven by increased  
399 abundance of this species. Data collection has mostly been carried out by the same observers from  
400 2009 to 2017 for both the plant cover and phenology datasets, suggesting minimal changes in observer  
401 bias across this period. An increase in both community and species-specific canopy heights aligns with  
402 additional site-level (Walker et al. 2006, Hudson et al. 2011, Myers-Smith et al. 2011a) and biome-  
403 level (Bjorkman et al. accepted) evidence that suggest tundra communities are becoming taller.

404

405 Radial growth was not very sensitive to climate at this site (Myers-Smith et al. 2011c, 2015a), but  
406 primary and secondary growth in woody species are not necessarily controlled by the same factors as  
407 shrubs can allocate resources to axial growth, new stems or below-ground biomass (Bret-Harte et al.  
408 2002). Shrub growth at this site appears to be much more clonal than at other tundra locations with  
409 highly interconnected root matrices below ground. Under these growing conditions, plant-plant  
410 competition or access to nutrients and other resources may be more important controls over interannual  
411 variation in growth than variation in growing season climate (S Angers-Blondin and IH Myers-Smith,  
412 unpublished data). Therefore, the lack of a positive trend in radial growth (Figure 7c) is not  
413 incompatible with the simultaneous observed expansion and vertical growth of willows on Qikiqtaruk.

414

415 Total vegetation cover increased in all monitoring plots (Figure 8), concurrent with observations of  
416 increased plant biomass across tundra communities (Hudson and Henry 2009, Elmendorf et al. 2012b,  
417 Hobbie et al. 2017). All functional groups showed absolute increases in abundance except for lichens,  
418 which declined over the monitoring period as observed at a number of other sites (Joly et al. 2009,

419 Hobbie et al. 2017). Increases in vegetation cover corresponded with a reduction in bare ground, which  
420 could result from a deeper active layer depth (Figure 4, (Burn and Zhang 2009) and decreased  
421 cryoturbation that can influence surface vegetation (Walker et al. 2004). Within communities,  
422 graminoids and deciduous shrubs showed the greatest increase in abundance, aligning with community  
423 composition changes both on Qikiqtaruk (Kennedy et al. 2001, Myers-Smith et al. 2011b) and across  
424 the tundra biome (Elmendorf et al. 2012b, Hobbie et al. 2017). However, functional group responses  
425 were largely driven by species specific changes, notably for example the increase in graminoids as a  
426 result of increases in the species *Eriophorum vaginatum*, *Arctagrostis latifolia* and *Alopecurus alpinus*,  
427 and did not necessarily represent the response of all species within each functional group. Finally, rapid  
428 colonization of several plots by two graminoid species, *Arctagrostis latifolia* (Kennedy et al. 2001) and  
429 *Alopecurus alpinus*, indicates that community change can occur quickly over a period of a few years,  
430 despite low recruitment rates and slow growth associated with most tundra plants (Elmendorf et al.  
431 2012b, 2015).

432  
433 *Attribution of vegetation change observations to environmental change*

434 Environmental change observed at this site include spring, summer, autumn and winter warming, fewer  
435 frost days, earlier snow melt, decreased sea ice extent, warming soil temperatures and increases in  
436 active layer depth across the period of ecological monitoring (Figure 3). We also observed advancing  
437 spring plant phenology (Figure 6). According to our multi-parameter analysis (Figure 10), one of the  
438 most likely mechanisms driving the observed vegetation changes is increased growing season length  
439 and the resulting environmental changes including greater active layer depths and permafrost thaw.  
440 Although growing season length and resulting ecosystem-level impacts have been acknowledged as a  
441 potential driver of tundra vegetation change (Barichivich et al. 2013), few studies have tested the  
442 influence of growing season length relative to other environmental variables such as summer

443 temperature in tundra ecosystems (Khorsand Rosa et al. 2015). The differences in species-level  
444 responses may also have implications for vegetation change at the plant community level, if more  
445 responsive species are better able to take advantage of changing conditions (Cleland et al. 2012). For  
446 example, we found that *Dryas integrifolia* exhibited both the least phenological change and smallest  
447 relative increase in percent cover of the three monitored species over the 18-year ecological monitoring  
448 period. However, the extent to which plant phenology change will influence community-level  
449 responses to warming as a whole remains unclear (Wolkovich et al. 2012, Ernakovich et al. 2014,  
450 Prevéy et al. 2017).

451

452 *Influence of changing active layer depth on the observed vegetation change*

453 We hypothesize that some part of the vegetation change observed on Qikiqtaruk is an indirect effect of  
454 increased autumn temperatures on active layer depth. Qikiqtaruk is underlain by ice-rich permafrost  
455 that has warmed in recent decades (Burn and Zhang 2009, Figures 3h and 4a). The active layer at a site  
456 near the long-term vegetation monitoring plots has deepened by about 15-25 cm since 1985, reaching  
457 depths of ca. 45-55 cm (Burn and Zhang 2009) and as much as 87 cm depth by 2017 (Figure 4). Higher  
458 autumn temperatures are likely to delay refreezing of the active layer, leading to a nutrient release that  
459 could be used by plants in the following growing season (Blume-Werry et al. 2016, Salmon et al. 2016,  
460 Keuper et al. 2017). A deeper active layer also increases rooting depth and decreases surface  
461 disturbance from cryoturbation (Walker et al. 2004, Iversen et al. 2015, Wang et al. 2017, Keuper et al.  
462 2017). In our study, we documented deeper active layers than previously reported, with warmer  
463 minimum soil temperatures at 12, 15 and 16 m soil depths (Figures 3h and 4, Table S2). Our results  
464 suggest permafrost thaw and a trend of a deeper active layer over time at this site, as has been observed  
465 at other locations (Burn and Zhang 2009, Liljedahl et al. 2016, Hobbie et al. 2017) concurrent with  
466 evidence of increasing thermokarst disturbances in the western Arctic (Lantz and Kokelj 2008,

467 Jorgenson et al. 2015, Segal et al. 2016, Kokelj et al. 2017), which could be changing available  
468 nutrients, rooting depths, surface cryoturbation and hydrology influencing plant cover and composition.

469

470 *Influence of herbivory on the observed vegetation change*

471 Observed tundra vegetation change at this site could in part be driven by variable herbivory due to  
472 cyclic lemming populations or spatial variation in muskox and caribou herbivory and/or trampling  
473 (Wal 2006, Olofsson et al. 2009, Kerby and Post 2013, Barrio et al. 2016). Key herbivores on  
474 Qikiqtaruk include muskox (*Ovibos moschatus*), caribou (*Rangifer tarandus caribou*), collared  
475 lemming (*Dicrostonyx groenlandicus*), brown lemming (*Lemmus trimucronatus*), tundra vole  
476 (*Microtus oeconomus*), and insects (Myers-Smith et al. 2011b). Ranger observations indicate that large  
477 mammals (muskox and caribou) on Qikiqtaruk are either increasing or fluctuating in unpredictable  
478 ways over the monitoring period from 1999 to 2017 (Cooley *et al.*, 2012, C Eckert, unpublished data).  
479 However, large herbivore group sizes and numbers of groups may not reflect herbivory pressure at the  
480 specific locations of the ecological monitoring plots. Lemmings follow 3–5 year cycles and vole  
481 populations and have relatively constant populations over longer time periods (Krebs et al. 2011). We  
482 began monitoring herbivory sign in 2014, but there are currently too few years of data to assess trends  
483 in herbivore impacts over time. An observed increase of herbivores could limit shrub or other  
484 vegetation increases (Olofsson et al. 2009), counter to the trends observed in this study. Exclusion of  
485 large herbivores over a two-year period on Qikiqtaruk also did not influence plant biomass (S Gilbert,  
486 D Reid, CJ Krebs and IH Myers-Smith, unpublished data); however, substantial herbivore impacts  
487 might only be observable over decades of exclusion (Olofsson 2006). Overall, the available evidence  
488 currently indicates that recent vegetation change on Qikiqtaruk is not primarily driven by changes in  
489 herbivory.

490

491 *Other factors influencing the observed vegetation change at this site*

492 Changes detected by ecological monitoring programs such as those observed in this study can be driven  
493 by a combination of site-level, regional or large-scale anthropogenic changes. Other factors that could  
494 be influencing tundra plant growth at this site include increasing atmospheric nitrogen deposition  
495 (Mack et al. 2004, Bobbink et al. 2010, Formica et al. 2014), increasing atmospheric CO<sub>2</sub> concentration  
496 (Wigley et al. 2010, Buitenwerf et al. 2012, Bond and Midgley 2012) and land-use change (Forbes et  
497 al. 2001, Kumpula et al. 2011) including recovery from the impacts of European whalers over  
498 wintering on the island for successive seasons from over 100 years ago (Burn 2012). However,  
499 statistically attributing vegetation changes to different ecological variables with varying extents of  
500 influence that have low inter-annual variability and correlate with each other is a major challenge in  
501 global change research.

502

503 *Impacts of the vegetation change observed at this site*

504 The observed vegetation changes on Qikiqtaruk could have substantial impacts on wildlife. Increased  
505 plant cover and growth could alter forage availability for large herbivores such as caribou (Joly et al.  
506 2009, 2010), and could provide shelter for predator avoidance in small mammals (Wheeler and Hik  
507 2014) or nesting habitat for birds (Boelman et al. 2015) for birds. For example, increased cover and  
508 abundance of tall shrub species, particularly in riparian areas, are likely altering bird habitats and  
509 changes in spring phenology can alter the timing of nesting of bird species on the island (Grabowski et  
510 al. 2013). Bird species that prefer shrub habitat of greater than 50 cm in height, specifically White-  
511 crowned Sparrow (*Zonotrichia leucophrys*), appear to be showing an increasing trend on Qikiqtaruk (C  
512 Eckert, unpublished data), and other shrub-nesting species may well increase there in the future  
513 (Cooley et al. 2012). Anecdotal observations indicate declines at Qikiqtaruk in two tundra nesting  
514 shorebirds, American Golden-Plover (*Pluvialis dominica*) and Ruddy Turnstone (*Arenaria interpres*, C

515 Eckert, unpublished data), species that nest on sparsely vegetated habitats associated with dry tundra  
516 and bare ground habitats. However, these species are also exhibiting continent-wide declines (Munro  
517 2017), thus declines on Qikiqtaruk could be a function of both subtle changes to local breeding habitat  
518 (Wauchope et al. 2017), and population declines of these migratory birds across their ranges (Bart et al.  
519 2007). Increased canopy heights could also change winter snow depths due to snow trapping (Myers-  
520 Smith and Hik 2013) and thus influence the ease of travel for large mammals. Finally, changes in  
521 temperature and plant phenology can alter fruit and berry production (Krebs et al. 2009), or create  
522 phenological mismatch among plant and animal species including birds and insect pollinators  
523 (McKinnon et al. 2012, Høye et al. 2013, Wheeler et al. 2014). All of these changes have the potential  
524 to restructure Arctic food webs and the interactions among plant and animal species, thus potentially  
525 altering wildlife species upon which humans depend (Stern and Gaden 2015).

526

### 527 *Implications for the observed biome-wide tundra greening*

528 The results presented in our study demonstrate substantial ecological changes across a broad range of  
529 ecological parameters at this focal study site. One challenge is understanding how representative these  
530 ecological changes are of vegetation change across the western Arctic region and tundra biome as a  
531 whole. To address this challenge, coarse-grain, remotely-sensed data are often employed to scale local  
532 observations to larger regions (Forbes et al. 2010, Macias-Fauria et al. 2012, Reynolds et al. 2013,  
533 Pattison et al. 2015, Walker et al. 2016). While there are often strong relationships between remotely  
534 sensed and *in situ* observations of ecological change (Forbes et al. 2010, Macias-Fauria et al. 2012,  
535 Reynolds et al. 2013, Pattison et al. 2015, Ju and Masek 2016), different time series of satellite data can  
536 show low correspondence (Guay et al. 2014) and analysis of remotely-sensed data suggests that the  
537 greening of the North American Arctic region has slowed in recent years (Bhatt et al. 2013, 2017). Our  
538 results indicate ongoing increase in canopy height and abundance of plants in the ecological monitoring

539 plots reported in our study (Figures 7 and 8); which is inconsistent with the saturation of greening  
540 patterns in satellite observations. The discrepancy between remotely sensed and *in situ* observations  
541 may be due to a mismatch in scales of observation, and hence there is a need to bridge the scale gap  
542 between high quality on-the-ground monitoring and remotely sensed observations of ecological  
543 changes.

544  
545 *Impacts of long-term ecological monitoring observations on ecosystems*

546 While long-term monitoring provides unique and valuable insight into a system, there are inevitably  
547 caveats associated with regular visits to a site. Over time, we have noticed increased disturbance  
548 around the phenology transects due to trampling. We found that metal tags on plants tend to damage  
549 leaves and stems over time, and have moved to using adjacent marker stakes rather than marking the  
550 plants themselves. New technologies make it easier to monitor some aspects of ecological change with  
551 minimal physical impacts on the vegetation, and we are working to integrate automated data collection  
552 (e.g., time-lapse photography using phenocams) and remotely-acquired information (e.g., drone-based  
553 data collection) with our monitoring program. In recent years, the ecological monitoring program has  
554 expanded to include proximal remote sensing of the landscape, using drones (a.k.a. remotely piloted  
555 aircraft systems or unmanned aerial vehicles) to acquire image data (Figure 2b &c). These drone-  
556 acquired data can provide accurate and fine-grain measurements of both the spectral and structural  
557 properties of vegetation (e.g., Fraser et al. 2016). We are now incorporating phenocams to monitor  
558 vegetation change and timing of phenological events (Westergaard-Nielsen et al. 2017), and motion-  
559 triggered camera traps to quantify wildlife habitat use on the island (Tape and Gustine 2014) into the  
560 ecological monitoring program (Figure 2). Analysis of novel data, in conjunction with the multi-  
561 parameter monitoring program, will help us to understand what satellite observations of the landscape  
562 can and cannot reveal about ecological changes at this focal research site and more widely across the

563 Arctic. Nevertheless, collecting long-term, ground-based data is as important as ever, and we call for  
564 thoughtful planning of future monitoring programs to lessen direct anthropogenic pressures on field  
565 sites.

566

## 567 **Conclusions**

568 The 18 years of ecological monitoring on Qikiqtaruk indicate: 1) an increase in the potential growing  
569 season length with warmer air and soil temperatures, fewer frost days and earlier snow melt, leaf  
570 emergence and flowering of monitored plant species, yet also earlier leaf senescence, 2) an increase in  
571 canopy heights of tundra plant species, and 3) changing vegetation community composition, including  
572 increases in shrub and graminoid species and decreases in bare ground corresponding with a deepening  
573 active layer. Multi-parameter ecological monitoring has allowed for a much-improved understanding of  
574 ecological change at this site, suggesting that growing season length and active layer depths, rather than  
575 summer temperatures alone or changing herbivory, are likely the most important drivers of the  
576 observed vegetation change. Overall our findings align closely with reported individual trends for the  
577 western Arctic region (Stern and Gaden 2015) and across the tundra biome as a whole (Myers-Smith et  
578 al. 2011a, Elmendorf et al. 2012b, 2015, Oberbauer et al. 2013). However, this study is one of the first  
579 to demonstrate such a range of changes occurring simultaneously at one site over a period of decades,  
580 providing very strong evidence for ongoing, directional vegetation change and offering insight into the  
581 potential drivers of change. Our study highlights the critical role that collaborations between local  
582 people, park rangers, government scientists and academic research programs play in global change  
583 research. It is only with the multiple lines of evidence collected through an integrated ecological  
584 monitoring program that we can synthesize observed vegetation changes and compare potential drivers,  
585 thus improving our understanding of global change responses of this tundra ecosystem.

586

587 **Acknowledgements**

588 We thank the Herschel Island-Qikiqtaruk Territorial Park management, Catherine Kennedy, Dorothy  
589 Cooley, and Dr. Jill F. Johnstone for establishing and maintaining the phenology and composition data  
590 from Qikiqtaruk. We thank previous rangers including LeeJohn Meyook, Jordan McLeod, Pierre Foisy,  
591 Colin Gordon, Jeremy Hansen, Albert Rufus and field assistants including Santeri Lehtonen, William  
592 Palmer, Louise Beveridge, Clara Flintrop, John Godlee, Eleanor Walker, Catherine Henry and Anika  
593 Trimble. We thank Sigrid S. Nielsen and Prof. Christopher Burn for providing feedback on the  
594 manuscript. We thank the Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research  
595 for providing logistical support for this research and in particular Prof. Hugues Lantuit. Funding was  
596 provided by Herschel Island-Qikiqtaruk Territorial Park and the UK Natural Environment Research  
597 Council ShrubTundra Grant (NE/M016323/1), and we thank the NERC GEF for loan of GNSS  
598 equipment (NERC GEF:1063 and GEF:1064). Haydn Thomas and Jakob Assmann were funded by a  
599 NERC doctoral training partnership grant (NE/L002558/1). Sandra Angers-Blondin was funded by  
600 NSERC and the Canadian Centennial Scholarship Fund. Meagan Grabowski was funded by NSERC  
601 and Yukon Parks. Data are available through the Polar Data Catalogue (DOI to be added at time of  
602 publication). We thank the Inuvialuit People for the opportunity to conduct research on their traditional  
603 lands.

1029 Figure captions

1030

1031 Figure 1. Ecological monitoring parameters from the Qikiqtaruk monitoring program (Cooley et al.  
1032 2012) following the protocols of the International Tundra Experiment (Molau and Mølgaard 1996).

1033

1034 Figure 2. The location of Qikiqtaruk within the circumpolar Arctic (a and b) and the location of the  
1035 phenology, community composition, and permafrost monitoring sites on Qikiqtaruk (c). The landscape  
1036 context is indicated by true color and normalized difference vegetation indices (NDVI) maps of the  
1037 community composition plots (d). The Herschel vegetation type plots are indicated in blue, the  
1038 Komaukuk vegetation type are indicated in yellow and the Orca floodplain vegetation type are  
1039 indicated in green (see also figures below). Stars indicate phenocams at the community composition  
1040 plots (d). The red dot indicates the location of the Herschel Island Environment Canada Weather  
1041 Station. Image data were obtained in the summer of 2016 with Sony  $\alpha$ 6000 and MicaSense Sequoia  
1042 cameras carried on multirotor drone platforms, and analyzed with image-based modelling approaches  
1043 to yield digital orthomosaics with spatial grains of 0.05 m.

1044

1045 Figure 3. Temperatures are warming (a-d), frost frequency is decreasing (e), the snow melt data is  
1046 getting earlier (f), sea ice concentrations are lower (g) and soil temperatures are warming (h) on  
1047 Qikiqtaruk. Changes in climate and environmental data from Qikiqtaruk including air temperatures (a –  
1048 d, Environment Canada data), frost day frequency (e, number of frost days, CRU TS3.21 data), snow  
1049 melt date (f, phenology monitoring), sea ice concentration (g, Canadian Sea Ice Service data for the  
1050 CIS WA Beaufort Sea: Mackenzie region), and soil temperature at 12, 15 and 16 m depths from two  
1051 different boreholes (h, soil temperature monitoring data). Three records with outlier values were not  
1052 included in the models in plot h for the years 2007 and 2012. Air temperature plots show mean values

1053 for the months indicated. Trends lines are Bayesian model fits with error of 95% credible intervals. Full  
1054 model outputs can be found in Table S2.

1055

1056 Figure 4. Active layer depth is increasing on Qikiqtaruk (a) across years and (b) mean active layer  
1057 depth across the growing season in 2017 are lower in the Komakuk (blue) versus Herschel (yellow)  
1058 vegetation types. The data from 1985 are from Smith et al. 1989, 2003-2007 data are from Burn and  
1059 Zhang 2009, 2007-2008 data are data collection for snow fence data from the ArcticWOLVES project  
1060 (S Gilbert, D Reid, CJ Krebs and IH Myers-Smith, unpublished data). The 2016-2017 data were  
1061 collected by the Qikiqtaruk ecological monitoring team. Points show mean active layer depth and error  
1062 bars show minimum and maximum active layer depth recorded at each site for (a) and each plot for (b).

1063

1064 Figure 5. Repeat photography indicates increases in tall shrubs in the Orca flood plain vegetation type  
1065 from the East Ice Creek catchment on Qikiqtaruk from 1987 through 2017 (Myers-Smith et al. 2011b).  
1066 The dominant shrub species in the photograph is *Salix richardsonii* which has reached a canopy height  
1067 of over a meter in the foreground of the images by 2017. Photographs were taken in the second half of  
1068 July in 2009-2017 and likely in early July in 1987. Similar increases are shown in photographs from  
1069 another location on the floodplain farther from the creek bed (IH Myers-Smith, unpublished data).  
1070 Repeat photography is now complemented by phenocam and drone observations at this and other  
1071 ecological monitoring sites allowing for changes to be captured across the landscape.

1072

1073 Figure 6. Spring plant phenology including leaf emergence (a) and flowering (b) is earlier and leaf  
1074 senescence has also advanced (c) leading to no substantial increase in realized growing season length  
1075 for the species *Salix arctica* (d). Note that *Eriophorum vaginatum* monitoring did not start until 2002  
1076 and we did not model 2001 for *Salix arctica* senescence (P5) because there was only one data point

1077 collected. Data points are the midpoint between the lower and upper bounds of the raw phenological  
1078 observation data for each plot in a given year, errors are 95% credible intervals. Green indicates records  
1079 for the willow species *Salix arctica*, purple for the flowering shrub species *Dryas integrifolia* and  
1080 orange for the tussock sedge species *Eriophorum vaginatum*. Full model outputs can be found in Table  
1081 S2.

1082

1083 Figure 7. Plot canopies are increasing in the Komakuk (blue) and Herschel (yellow) vegetation types  
1084 (a), with species-specific canopy height increasing for the tall willow shrub *Salix pulchra* (green, b),  
1085 yet high temporal variation indicated for *Salix* spp. radial growth (c). Trends lines are Bayesian model  
1086 fits with error of 95% credible intervals. Full model outputs can be found in Table S2.

1087

1088 Figure 8. Vegetation cover (a) is increasing and bare ground (b) is decreasing in the Komakuk (blue)  
1089 and Herschel (yellow) vegetation types from 1999-2017. Diversity metrics including species richness  
1090 (c) and evenness (d) have not undergone substantial change. However, increases have occurred for the  
1091 sedge species *Eriophorum vaginatum* (orange), the shrub species *Salix pulchra* (green) in the Herschel  
1092 vegetation type (e) and the two grass species *Alopecurus alpinus* (light yellow) and *Arctagrostis*  
1093 *latifolia* (light blue) in the Komakuk vegetation type (f). Trends lines are Bayesian model fits with error  
1094 of 95% credible intervals. Full model outputs can be found in Table S2 and results for trends in cover  
1095 of all species in the Herschel and Komakuk in Tables S3 and S4 respectively.

1096

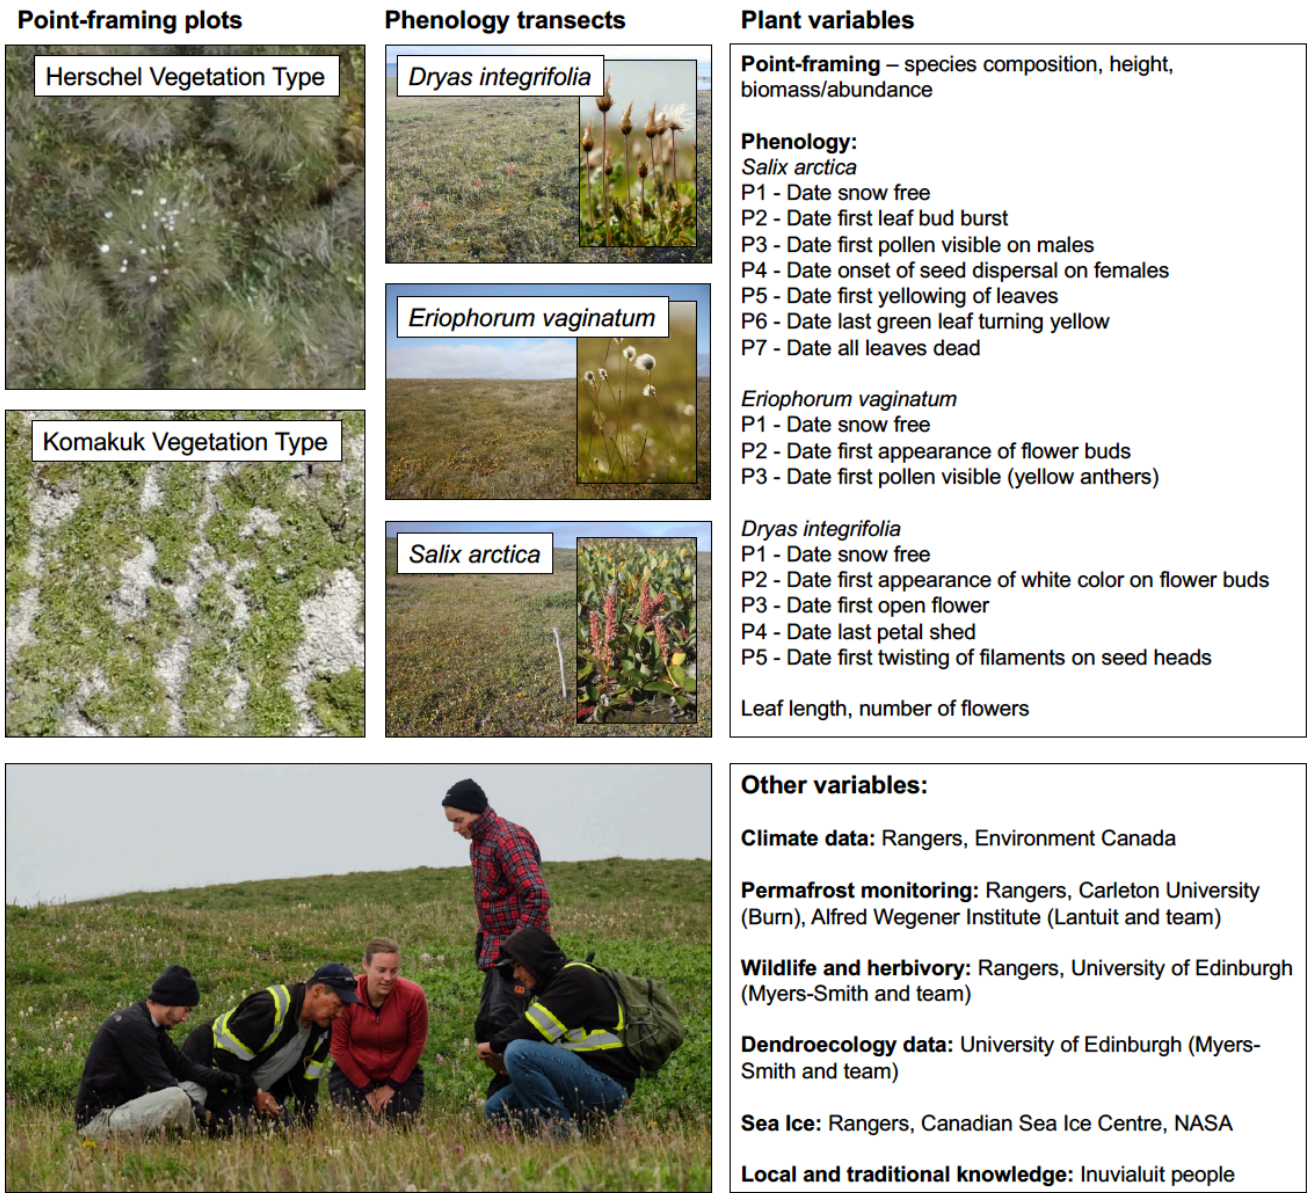

1097 Figure 9. Future increases in species richness could occur due to the proximity of species not presently  
1098 found within the long-term ecological monitoring plots. Vascular plant species accumulation curves for  
1099 the Herschel and Komakuk vegetation communities on Qikiqtaruk. Smooth curves were fit using the  
1100 loess method. Distance refers to distance away from the center of the community composition plots on

1101 Collinson Head. Photographs illustrate the vascular plant species that have invaded the Komakuk plots,  
1102 *Alopecurus alpinus*, and the four closest species growing within 5m of the Herschel and Komakuk  
1103 vegetation types in 2017.

1104

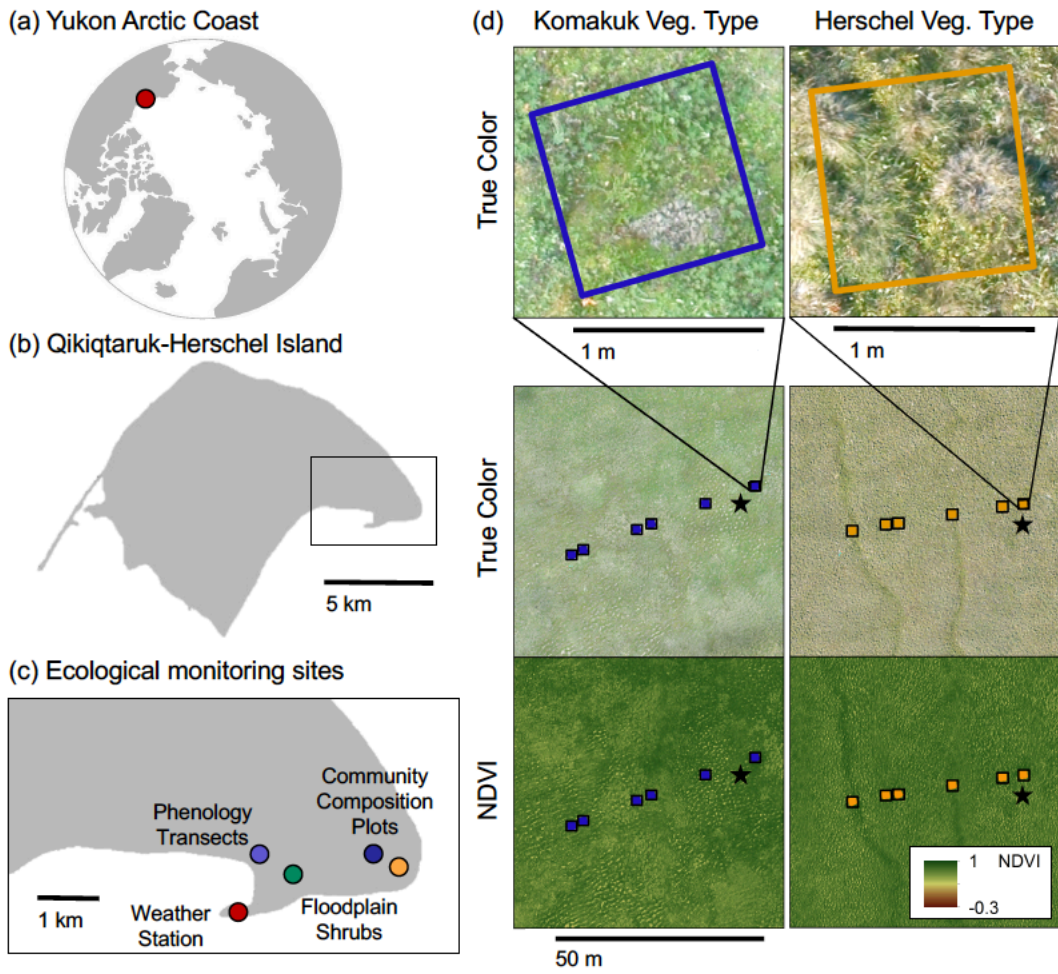

1105 Figure 10. The relative strength of the relationships between environmental and ecological drivers and  
1106 response parameters over time on Qikiqtaruk (a; effect sizes from Figures 3 – 8) and a simplified  
1107 summary of the likely mechanisms by which vegetation change on Qikiqtaruk occurs (b). The  
1108 standardized slope coefficients and credible intervals (slope coefficients or credible intervals divided by  
1109 the standard deviation of the data) for models of all the monitored parameters in this study indicate  
1110 weak increases in temperatures over the monitoring period, but stronger changes in active layer depths.  
1111 Vegetation responses are variable, but indicate strong increases in vegetation cover and canopy height,  
1112 decreases in bare ground and ring widths, and earlier leaf emergence, senescence, and flowering for  
1113 monitored plant species. Vegetation change parameters not directly measured that may also be  
1114 changing are shrub axial growth rates and stem numbers (Figure 7). Colors indicate the category of  
1115 variable and correspond to the variable colors in the previous figures. Red indicates temperature  
1116 variables, blue indicates variables associated with freezing temperatures, snow melt, sea ice and  
1117 permafrost, the other colors indicate the different plant species and vegetation communities (see above  
1118 figure captions). Frost days are calculated from temperature data, yet represent a variable associated  
1119 with ice-y conditions and are thus indicated in blue, yet in the temperature category.

1147

1148 Table S3. Trends in species cover over time for the Herschel Vegetation Type. Model results for a  
 1149 Bayesian linear model of cover change with year by species interaction and plot and year as a random  
 1150 effects. The slope estimates and significance tests are only approximate as the linear model does not  
 1151 capture the fact that percent cover data are bounded between 0 and 1 and are zero inflated. More  
 1152 complex modelling structures had poor convergence.

Species	Approx. cover change over time (% cover/year)	Lower 95% CI	Upper 95% CI	Effective sample size	pMCMC	Effect type
