Evolution of acid nociception: ion channels and receptors for detecting acid

Luke A. Pattison, Gerard Callejo and Ewan St. John Smith

*Department of Pharmacology, University of Cambridge, Tennis Court Road,
Cambridge, CB2 1PD; ESJS ORCID 0000-0002-2699-1979***Keywords:** Acid, acid-sensing ion channel, TRP channel, two-pore potassium channel, proton-sensing GPCR, nociception, pain

Summary

Nociceptors, i.e. sensory neurones tuned to detect noxious stimuli, are found in numerous phyla of the Animalia kingdom and are often polymodal, responding to a variety of stimuli, e.g. heat, cold, pressure and chemicals, such as acid. Due to the ability of protons to have a profound effect on ionic homeostasis and damage macromolecular structures, it is no wonder that the ability to detect acid is conserved across many species. To detect changes in pH, nociceptors are equipped with an assortment of different acid sensors, some of which can detect mild changes in pH, such as the acid-sensing ion channels, proton-sensing G protein-coupled receptors and several two-pore potassium channels, whereas others, such as the transient receptor potential vanilloid 1 ion channel, require larger shifts in pH. This review will discuss the evolution of acid sensation and the different mechanisms by which nociceptors can detect acid.

Nociception Evolution And The Drive For Nociceptor Acid-Sensitivity

In the 160th anniversary of their publication, Charles Darwin's words still ring true, "any variation...if it be in any degree profitable to an individual of any species...will tend to the preservation of that individual, and will generally be inherited by its offspring" (1). It could be argued that one of the most profitable facets of any organism is the ability to detect and react to potentially damaging stimuli in its environment, hence nociception (derived from the Latin *nocere* meaning to hurt/harm), the neural process of encoding noxious stimuli, is common to many species in the Animalia kingdom (2–6). However, not all Animalia have a complex nervous system, for example, Porifera (sponges) contract in response to changes in extrinsic conditions (e.g. turbulent water) and glass sponges transmit electrical signals through their syncytial tissues (7). Although a number of genes associated with neuronal function have been identified in *Amphimedon queenslandica* (8), as is the case with Placozoa (9), the presence of neuronal genes and electrical conductivity does not constitute a nervous system and experimental work to determine if neuronal gene expression is linked to sensory function in Porifera and/or Placozoa remains to be determined (10). By contrast, Cnidaria (e.g. jellyfish and sea anemones), possess diffuse nerve nets (11) and mechanical stimulation of *Calliactus parasitica* produces nervous impulses, strong stimulation (i.e. potentially nociceptive) evoking a closure reflex (12). Similarly, Ctenophores (comb jellies) also possess sensory receptors and nerve cells (13), but

†Present address: Department of Pharmacology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1PD, United Kingdom

1 there has, to our knowledge, been no investigation of the potential nociceptive function of their nervous
2 system. It is therefore in Bilateria (e.g. Animalia other than Porifera, Placozoa, Ctenophores and
3 Cnidaria) where an integrated nervous system has fully evolved (14) and nociception has been most
4 frequently studied. In humans, the importance of a nociceptive system is illustrated by individuals with
5 congenital insensitivity to pain, who often accumulate injuries and whose heightened risk-taking
6 behaviour is thought to contribute to higher early-life mortality (15). There are also genetic variations
7 that result in excessive nociception and studying these variations at a functional level has contributed
8 to understanding of how the nociceptive system works, as well as highlighting points for therapeutic
9 intervention (16). It should be noted that nociception and pain are not the same, even though the
10 terms are often used interchangeably. As above, nociception is the neural process of encoding
11 noxious stimuli, which involves specialised sensory neurones called nociceptors. By contrast, pain is
12 usually defined as an unpleasant sensory and emotional experience associated with actual or
13 potential tissue damage, or described in terms of such damage. Using the term pain (rather than
14 nociception) for non-mammalian species has produced rigorous discussion in the field due to the
15 debate over which organisms have the capacity for emotional processing, however, this is beyond the
16 scope of this article and has been reviewed elsewhere (17–19).

21 In many species, nociceptors are polymodal, i.e. they respond to multiple stimuli (e.g. heat, pressure
22 and chemicals such as acid), owing to the expression of different receptors. Polymodality has been
23 determined using a range of electrophysiological and imaging approaches, but recent single-cell RNA-
24 sequencing studies show that sensory neurones usually express a multitude of different receptors that
25 confer polymodality and enable transcriptomic segregation of sensory neurones into subtypes, whose
26 function can be interrogated *in vitro* and *in vivo* (20–24).

30 Here, we will focus on proton-induced nociceptor activation, others having previously reviewed
31 sensory neurone mechanosensitivity (25–27) and thermosensitivity (28,29). Protons influence ion
32 homeostasis and modulate enzyme activity, and thus organisms have evolved the ability to regulate
33 extracellular and intracellular pH through membrane transporters and a range of proton buffering
34 systems (30–32). Expression of a range of proton-sensitive receptors, summarised in Fig. 1, permits
35 detection of protons by nociceptors, proton-induced activation/inhibition of these receptors can in turn
36 modulate nociceptor excitability. The ability of protons to activate nociceptors and/or evoke
37 nocifensive behaviour has been demonstrated in a wide range of species, including: the nematode
38 worm *Caenorhabditis elegans* (33), the medicinal leech *Hirudo medicinalis* (34), the Northern grass
39 frog *Rana pipiens* (35–37), the rainbow trout *Oncorhynchus mykiss* (38,39), the chicken *Gallus gallus*
40 (40,41), the mouse *Mus musculus* (42,43), the rat *Rattus norvegicus* (44) and the human *Homo*
41 *sapiens* (45,46); however, acid nociception is not universal, the naked mole-rat (*Heterocephalus*
42 *glaber*), the Cape mole-rat (*Georychus capensis*) and the East African root rat (*Tachyoryctes*
43 *splendens*) displaying no acid-induced nocifensive behaviour (42,47). The presence of acid
44 nociception in such a wide variety of species, both aquatic and terrestrial, demonstrates the likely
45 evolutionary pressure to maintain selection for being able to detect and respond to changes in the pH
46 of an organism's environment, whereas presumably any cost to those organisms that do not display
47 acid nociception is outweighed by some other benefit. A phylogenetic summary depicting the evolution
48 of nociceptors, acid nociception and different acid-sensors is illustrated in Fig. 2.

54 In humans, perhaps the first demonstration that acid evokes pain was from von Gaza and colleagues
55 who reported that pain and a change in the proton concentration were common to inflammation, and
56 that tissue alkalinisation could reverse pain associated with abscesses (48). Indeed, work in humans
57 (49–52) and rodents (53) supports the fact that tissue acidosis occurs during inflammation, but equally
58 inflammation can occur in the absence of acidosis (54,55). In terms of the mechanisms by which acid
59 causes pain, Krishtal and colleagues were the first to demonstrate that protons could excite sensory
60 neurones by evoking transient inward currents (56). Subsequent analysis of various mammalian

1 nociceptors demonstrated that protons produce three main types of excitation: transient inward
2 currents (current inactivation in the presence of protons), sustained inward currents (continuous
3 inward current in the presence of protons) and mixed (both transient and sustained phases) (46,57–
4 61). Underpinning these different responses are a variety of different mechanisms and this review will
5 discuss the different mechanisms and what is understood about their roles in different species.
6
7

8 **Acid-Sensing Ion Channels**

9 The acid-sensing ion channels (ASICs) are part of the epithelial sodium channel (ENaC)/degenerin
10 (DEG) ion channel superfamily, which in mammals consists of nine genes, four encode ENaC
11 subunits, four encode ASICs and one encodes the bile acid-sensitive ion channel (BASIC, sometimes
12 termed ASIC5, ~30% homologous to other ASICs, but proton-insensitive(62)). The four ASIC genes
13 encode six ASIC subunits, splice variants of the ASIC1 and ASIC2 genes resulting in: ASIC1a (63),
14 ASIC1b (64,65), ASIC2a (66), ASIC2b (67), ASIC3 (68) and ASIC4 (69,70). Although there was initial
15 debate surrounding the subunit stoichiometry of functional ASICs, both X-ray crystallography (71) and
16 atomic force microscopy (72) have demonstrated that ASICs are trimeric ion channels. However, not
17 all ASIC subunit configurations produce proton-sensitive ion channels, ASIC2b and ASIC4 homomers
18 are proton-insensitive, but can form proton-sensitive heteromers and/or regulate ASIC subunit surface
19 expression (67,73); the naked mole-rat ASIC3 is also proton-insensitive, a potential adaptation to a
20 subterranean lifestyle (74). When proton-sensitive ASICs are activated, an inward cation flux (largely
21 Na⁺, although ASIC1a shows Ca²⁺ permeability) leads to neuronal depolarisation and in nociceptors,
22 if of sufficient magnitude to produce action potential firing, would lead to nociception. With regard to
23 their expression profile, in mammals, all ASIC subunits are expressed in sensory neurone cell bodies
24 in the dorsal root ganglia (DRG), albeit that ASIC4 is expressed at comparatively much lower levels
25 (22,23,75); interestingly the ASIC3 transcript is down regulated in sensory neurones of the proton-
26 insensitive rodents, naked mole-rats, Cape mole-rats and the East African root rat (47).
27
28
29
30
31
32

33 The chicken ASIC1a crystal structure identified a region termed the acidic pocket containing three
34 carboxylate pairs (D238–D350, E 239–D346 and E220–D408; chicken ASIC1a numbering), which
35 were suggested to be the primary sites for proton sensing (71). Mutational analysis shows that these
36 residues, whilst regulating pH sensitivity, do not fully abolish ASIC1a proton sensitivity (76,77).
37 Moreover, the proton-sensitive ASIC2a lacks D350, which might explain why it is the least proton
38 sensitive of the functional mammalian ASIC homomers (78), but ASIC2b, which is proton-insensitive,
39 also only lacks D350 (79). Together, these results suggest that sites outside of the acidic pocket are
40 important for ASIC proton sensitivity and several studies have identified further amino acids that are
41 required for normal proton sensing by ASIC1a (76,77,80,81). Furthermore, comparative analysis of
42 rat ASIC2a/ASIC2b (82) and zebrafish (*Danio rerio*) zASIC4.1 (proton-sensitive) and zASIC4.2
43 (proton-insensitive) (83) have demonstrated the critical importance of the extracellular domain
44 proximal to the first transmembrane domain for conferring ASIC proton sensitivity and in particular the
45 importance of the histidine residue H73 (mouse ASIC1a numbering) (Fig. 1) (79,84). In first attempting
46 to determine when proton sensitivity arose in ASICs, it was demonstrated that the spiny dogfish
47 (*Squalus acanthias*, a cartilaginous fish) produces proton-sensitive ASICs (85), but that neither the
48 lamprey *Lampetra fluviatilis* (86), nor the tunicate *Ciona intestinalis* (87) do. However, more recent
49 analysis of ENaC/DEG sequences from several phyla has demonstrated that ASICs from a variety of
50 deuterostome lineages are not only expressed in the nervous system, but are also proton-sensitive
51 (including the tunicate *Oikopleura dioica*) (88). It was also demonstrated that the conserved H73
52 residue (mouse ASIC1a numbering), proximal to the first transmembrane domain, was critical in
53 determining proton sensitivity in both the lancelet *Branchiostoma belcheri* and mice (i.e. distantly
54 related species), suggesting that the appearance of this histidine coincided with the emergence of
55 ASIC proton sensitivity with further lineage specific changes occurring over time (88). Further evidence
56 for the importance of the extracellular domain proximal to the first transmembrane domain comes from
57 studying ASIC4, whereby West Indian Ocean coelacanth (*Latimeria chalumnae*), African clawed frog
58
59
60

1 (*Xenopus laevis*) and chicken (*G. gallus*) ASIC4s all respond to protons, but rat ASIC4 does not: 24
2 amino acids in the β 1 strand running from the first transmembrane domain into the extracellular
3 domain (including H73) were shown to confer proton sensitivity and insertion of a single amino acid in
4 mammalian ASIC4 resulted in proton-insensitivity (88). Overall, the extensive recent analysis by
5 Lynagh et al. (88) clearly demonstrates that ASIC proton sensitivity is conserved across many animal
6 phyla, including invertebrates, although little is known about the contribution to nociception of ASICs
7 in these species.
8
9

10 When considering the ENaC/DEG family more broadly, members, such as HaFaNaC from the mollusc
11 *Cornu aspersum* (previously *Helix aspersa*) (89) and HyNaC from the cnidarian *Hydra magnipapillata*
12 (90) are activated by peptides, rather than protons, suggesting a potential role for evolutionary ASIC
13 precursors as peptide sensors; indeed, mammalian ASICs are modulated, but not activated, by a
14 variety of peptides (91–95). Interestingly, the non-proton agonist of ASIC3 2-guanidine-4-
15 methylquinazoline (GMQ) activates HaFaNaC and related mollusc ENaC/DEG channels by a
16 mechanism distinct to their activation by the endogenous agonist FMRFamide (96), which highlights
17 that dual activation/modulation of ASICs and related channels is a conserved feature.
18
19
20

21 In addition to peptides, ASIC function can be modulated by numerous endogenous mediators and
22 other compounds (see (97,98) for a review), some of which, like arachidonic acid (44,57,99), nitric
23 oxide (100) and protein kinase C (PKC) (101), are, like protons, upregulated in inflammation and thus
24 likely work synergistically to activate ASICs and produce pain. In terms of how protons modulate
25 mammalian nociceptor function, they both activate and sensitise rodent nociceptors (58,102), ASIC3
26 being particularly important. For example, protons activate mouse C-fibre nociceptors in an ASIC3-
27 dependent manner, mice lacking ASIC3 showing less nociceptor firing at pH 5.0 than wildtype mice
28 (although no difference was observed at pH 4.0 and ASIC3^{-/-} mice showed no difference in acid-
29 evoked licking behaviour) (43). Similarly in rats, blockade of ASIC3 with APETx2 inhibits acid-evoked
30 nociceptor firing and reduces acid-evoked pain behaviour (44,103), but a caveat of interpreting this is
31 that APETx2 also inhibits the voltage-gated sodium channel subunit 1.8, Na_v1.8 (104). Considering
32 the role of tissue acidosis in some forms of inflammation, there has been considerable investigation
33 of how ASICs contribute to hyperalgesia in numerous animal models and overall evidence supports
34 the targeting of ASICs to relieve pain (105,106). Although evidence supports targeting of ASIC1a/1b
35 subunits (107,108), there has been more extensive investigation of ASIC3, most likely due to its
36 activation producing a pronounced sustained phase following the initial transient phase, i.e. ASIC3
37 can likely transduce sustained tissue acidosis into nociceptor activation and pain behaviour (68). For
38 example, arachidonic acid potentiates the sustained phase of ASIC3 (57), arachidonic acid potentiates
39 acid-evoked pain in rats that is reversed by ASIC3 inhibition (44), chronic hyperalgesia induced by
40 repeated intramuscular acid injections is abolished in mice lacking ASIC3 (109) and a peptide from
41 *Conus textile* venom potentiates ASIC3 activity concomitant with enhancing acid-evoked hyperalgesia
42 (94).
43
44
45
46
47
48
49

50 In humans, there is some evidence to support acid-evoked pain being ASIC dependent, (45,110), but
51 not all studies support these findings (111). Experimentally, acute application of acid is associated
52 with certain limitations, for example, not being sure of what pH nerve terminals actually encounter and
53 how acute acid application corresponds to the acid stimulation that nociceptors encounter under
54 pathological conditions. Moreover, pharmacological targeting of ASICs for the treatment of pain is
55 complicated by the fact that ASICs are expressed throughout the mammalian nervous system (75) as
56 homo- and heterotrimers and they are implicated in many physiological processes, e.g.
57 mechanosensation (112), proprioception (113) and synaptic plasticity (114).
58
59
60

In summary, ASICs are proton-sensitive in a wide range of phyla with more distantly related ion
channels being activated by peptides, whereas ASICs undergo peptide modulation. Alongside roles

1 in normal neurophysiology, ASICs play a key role in inflammatory pain in mammals, which warrants
2 further investigation as potential sites for therapeutic intervention.
3

4 **Transient Receptor Potential Ion Channels**

5 The *trp* (transient receptor potential) gene was first identified from a *Drosophila melanogaster* mutant
6 which exhibited insensitivity to light despite retaining normal eye structure (115), the protein product
7 of this gene was later shown to be a cationic ion channel (116). Several homologous genes have
8 since been identified in *D. melanogaster*, leading to the emergence of the TRPs as an independent
9 family of ion channels comprising several subgroups (117). TRP channels appear to have emerged
10 before the divergence of fungi and animals, with TRPP and TRPV homologs being identified in the
11 protist *Thecamonas trachens* and ancestral genes representing five of the mammalian TRP
12 subfamilies arising by the speciation of choanoflagellates (118). Given TRPs can be traced back to
13 unicellular eukaryotes, and their common expression at the plasma membrane, they likely evolved as
14 sensors of the extracellular environment. Over evolutionary time, the number and diversity of TRP
15 channels has increased: a total of thirteen TRP genes have been discovered for *D. melanogaster*, *C.*
16 *elegans*' genome contains seventeen, there are twenty-eight mouse TRPs and twenty-seven human
17 TRPs have been identified. TRPs are generally considered to function as homotetramers, each
18 subunit comprises intracellular N- and C- termini and 6 transmembrane domains, a re-entrant loop
19 between the fifth and sixth transmembrane domains forms the channel pore (119); it should be noted
20 that there is however recent evidence of heteromeric TRP channel configurations (120). Variations in
21 motifs and modalities present within the receptors permit them to respond to a diverse range of stimuli
22 including both chemicals and physical properties such as pressure, light and temperature.
23 Additionally, TRPs are heavily influenced by levels of plasma membrane phospholipids and exhibit
24 extensive phosphoregulation, enabling integration of external and internal signals. Given the
25 sensitivity of TRPs to numerous stimuli it is perhaps unsurprising that many are expressed throughout
26 the nervous system, particular by sensory neurones where they confer a high degree of polymodality
27 (121).
28
29
30
31
32
33
34

35 The ability of TRPs to respond to protons was first demonstrated for TRPV1: acidic pH potentiating
36 capsaicin-induced inward currents (122) and protons later being shown to directly activate TRPV1
37 (123). Since this finding other TRPs have been shown to be activated or positively modulated by
38 extracellular pH, including TRPV4 (124), TRPM7 (125), TRPP2, TRPP3 (126), TRPC4, TRPC5 (127)
39 and TRPA1 (128). There is evidence that all of these TRPs are expressed in nociceptors, albeit at
40 differing expression levels (22,23), and whereas some TRPs are inhibited by extracellular acidosis
41 (127) or activated by intracellular acidosis (129), in most instances proton-induced TRP activation on
42 nociceptors results in cation influx, depolarisation and nociception activation. While the ability of most
43 of these TRPs to respond to protons was discovered with rodent variants of the receptors,
44 interestingly, only the human variant of TRPA1 (hTRPA1) displays proton sensitivity. hTRPA1 was
45 found to be active within an extracellular pH range of 7.0 – 5.4, while the closely related Rhesus
46 monkey (*Macaca mulatta*) TRPA1, which shares 98% sequence homology with human *TRPA1*, was
47 shown to be proton-insensitive. Comparisons of the primary sequences of the two channels identified
48 four non-conserved amino acids distributed around the start of the sixth transmembrane domain,
49 which when mutated reduced hTRPA1 proton sensitivity (128). Molecular studies of TRPV1 have also
50 pinpointed residues around transmembrane domain six as conferring proton sensitivity independently
51 of capsaicin- and heat-sensitivity (130). Similarly, the mutation of glutamate residues present in the
52 re-entrant loop of TRPC5 abolishes acid-induced activation (127). Although the specific residues
53 differ, the importance of the re-entrant loop and transmembrane domain six in conferring proton
54 sensitivity of TRPs is evident (Fig. 1). Taken together, the fact that the residues important for proton
55 sensitivity are not conserved and the finding that only the hTRPA1 is proton-sensitive, it is likely that
56 the ability of TRPs to respond to protons evolved separately within each subfamily, highlighting the
57 evolutionary importance of acid-sensation.
58
59
60

Avoidance of acidic environments by *C. elegans* suggests an ability of the nematode to detect extracellular pH and avoid acidic areas. This has been shown to be mediated by *osm-9*, a proposed homolog of mammalian TRPV channels, as reduced acid-avoidance behaviour was observed in *osm-9* mutants and following treatment of wildtype nematodes with the broad-spectrum TRP inhibitor ruthenium red (33). Evidence explicitly linking proton-induced TRP signalling as contributing to the manifestation of pain is relatively scarce for higher-order organisms, perhaps due to the promiscuous nature of TRP activation, and there is conflicting evidence for an involvement of TRPV1 in acute acid-induced nociception in humans (110,111); however, a large body of evidence implicates TRPs in thermal hyperalgesia and the role of TRPs in pain has been comprehensively reviewed (131). Indeed, studies of knockout mice suggest that both TRPV1 and ASIC3 are relatively redundant in the development of acute pain, but significantly contribute to hypersensitivity (132). Given the prominence of acidosis in many conditions associated with pain, particularly at chronic stages following influx of immune cells, the establishment of a hypoxic environment (133,134), and the high expression of proton-sensitive TRPs by nociceptors (135) it is widely accepted that acidosis likely potentiates TRPs resulting in hyperalgesia, something well supported by *in vitro* evidence with substantiation needed *in vivo* (123,127,128). In addition to TRP potentiation priming nociceptors, leading to more frequent action potential discharge, activation of TRPs in sensory neurones has been shown to coordinate release of the neuropeptides substance P and calcitonin gene-related peptide, which can in turn prime other neurones leading to hyperalgesia as well as contribute to central sensitisation (136–138). To summarise, TRP channels are clearly implicated in nociception, but the promiscuous nature of these receptors makes it difficult to specifically attribute proton-activation as causing TRP-mediated nociception. However, given the correlation between localised acidosis and inflammation it is likely proton-induced TRP-signalling is important in the manifestation of inflammatory pain.

Two-Pore Potassium Channels

The two-pore (K2P) domain ion channel family comprises membrane proteins, encoded by the *kcnk* genes, that share a common molecular architecture, consisting of four transmembrane domains (TM1–4), two pore-forming domains (P1 and P2) and an extracellular cap between the TM1 and the P1 domains, assembling as either homo- or heterodimers (Fig. 1) (139–141). K2P channels underlie the background K⁺ current observed in excitable and non-excitable cells, playing a key role in setting the resting membrane potential and input resistance in neurones, therefore regulating cellular excitability (142,143). Additionally, K2P channel activity is influenced by many physicochemical factors including extra- and intracellular pH, temperature, membrane stretch, as well as being modulated by membrane lipids and volatile anaesthetics, i.e. like ASICs and TRP channels, K2P channels integrate a number of external and internal signals. In mammals, 15 different K2P subunits have been identified and grouped into 6 different subclasses (TWIK, TREK, TASK, TALK, THIK and TRESK) based on their sequence similarity and functional properties (142), however, transcript processing and post-translational modifications further increase their diversity (144,145). Nevertheless, K2P channels are not restricted to mammals, being highly conserved during evolution. The first ion channel presenting two pore-forming domains per subunit was identified in the yeast *Saccharomyces cerevisiae* and named TOK1 (YORK), however, this channel differs from the mammalian K2P channels by having eight TMs (146), rather than the four observed in mammalian K2Ps. Furthermore, K2P channels with a 2P/4TM architecture have been identified in a range of different animal species, including: the marine sponge *A. queenslandica* (147), the marine opisthobranch *Aplysia californica* (148), *D. rerio* (149), *D. melanogaster* (150), *C. elegans* (151), *M. musculus* (152), *R. norvegicus* (153) and *H. sapiens* (139), i.e. K2P channels are an ancient ion channel family.

Most mammalian K2P channels are modulated by extra- and intracellular acidification. In particular, the inhibition of proton-sensitive K2Ps by extracellular acidic pH reduces constitutive K⁺ efflux produced by these channels, thus contributing to membrane depolarisation and acid-induced

1 nociception. Within the K2P channel family, TASK1 and TASK3 channels from human, mouse, rat and
2 guinea pig (TASK3) (153–156) are markedly sensitive to extracellular acidification. The protonation of
3 H98 (Fig. 1), immediately following the K⁺ selectivity filter sequence (GYG) in the P1 loop, primarily
4 confers proton sensitivity to these channels (155–157), although mutation of this residue does not
5 completely abolish proton sensitivity and the participation of other residues in the extracellular domain
6 (H72 and K210: mTASK1 numbering) has also been demonstrated (158). Moreover, TASK1 and
7 TASK3 can form heteromeric channels, presenting intermediate properties in terms of proton
8 sensitivity (159). In *D. melanogaster*, 10 putative K2P channels have been identified by homology
9 screening, but only two of them share a significant sequence identity with mammalian K2P. dTASK6
10 (52–57% identity with hTASKs (160)), appears to be proton-sensitive, however, mutation of conserved
11 histidines (H98 and H72 in hTASKs) does not produce proton-insensitive channels, and it has been
12 suggested that other residues in the M1-P1 loop are involved in this process (161). Moreover, dTASK7
13 (49–55% identity with hTASKs (160)) does not form homomeric functional channels due to two non-
14 conserved residues (A92 and M93) in the P1 domain and although mutation of these residues to
15 conserved threonines produces functional channels, they are still proton-insensitive, even though
16 dTASK7 presents the conserved histidines (H98 and H72) in its sequence (161), reaffirming the
17 involvement of other residues/regions in the proton sensitivity of these channels. In *C. elegans*, forty-
18 seven genes encode K2P channels (160,162,163). Among them, SUP-9 and TWK-20 exhibit
19 significant sequence identity with hTASKs (43–57%) (160), however, their proton sensitivity has not
20 yet been tested. Members of the TALK family are mainly activated in the alkaline pH range; however,
21 they are markedly inhibited by protons, being less active (TASK2), largely inhibited (TALK1) or
22 completely inhibited (TALK2) at pH 7.4 (164,165). Similarly, zebrafish TASK2 (zTASK2) displays a
23 comparable proton sensitivity profile as its mouse homologue (166). Human TWIK1 channels are also
24 inhibited by extracellular acidosis due to the protonation of a homologous histidine (H122) in the P1
25 domain (167), nonetheless, TWIK1 produce only a very small current in heterologous systems and
26 native conditions due to post-translational modifications (sumoylation) (167,168). In addition, it has
27 been shown that during extracellular acidification, TWIK1, TASK1 and TASK3 become permeable to
28 Na⁺ (169,170), a trait also observed in TWIK1 in hypokalaemic conditions (171). TRESK, another
29 member of the K2P family regulated by intracellular Ca²⁺ (172), is also sensitive to extracellular
30 acidosis, however, whereas mouse/rat TRESK are inhibited by extracellular low pH due to a
31 homologous histidine (H132 in mTRESK), the presence of tyrosine in the same position makes
32 hTRESK proton-insensitive (173,174); an arginine residue in the zebrafish TRESK homologue might
33 result in proton-insensitivity, but this has not been tested (175). With regard to TREKs, mutation of a
34 different histidine in the M1P1 extracellular loop of murine TREK1 (H126), TREK2 (H151) and TRAAK
35 (H85) channels demonstrated its involvement in their pH sensitivity. However, whereas TREK1 and
36 TRAAK are inhibited by extracellular acidification, TREK2 is activated, this differential pH modulation
37 involved other charged residues in the P2M4 domain (176). Moreover, both TREK1 and TREK2 are
38 activated by intracellular acidification, with residues in the C-terminus responsible for this activation
39 (177,178). Interestingly, another study showed that the proton sensitivity of hTREK1 follows a different
40 mechanism (C-type inactivation), involving two different surfaced-exposed histidines (H87 and H141;
41 not conserved in mTREK1 and TREK2) in the turret loop (179). Altogether, K2P channel proton
42 sensitivity is common to most subfamilies, involving protonatable histidine residues in the extracellular
43 domain (Fig.1), a trait conserved across mammalian species and in *D. melanogaster*, however, the
44 lack of functional data with regard to the proton sensitivity of K2P channels in other species, including
45 model organisms such as *C. elegans*, prevents a more extensive evolutionary analysis of K2P channel
46 proton sensitivity.

57
58 When considering physiological roles of K2P channels, their key role in setting neuronal excitability
59 has resulted in attempts to elucidate their participation in nociception (143,180), largely through
60 manipulation of gene expression due to the lack of specific K2P channel agonists and antagonists.
For instance, TASK1^{-/-} and TASK3^{-/-} mice have altered thermal perception, whereas TASK1^{-/-} display

1 an increased sensitivity to hot temperatures (181), TASK3^{-/-} mice are hypersensitive to cold
2 temperatures (182), suggesting roles for both channels in thermosensation. Moreover, TASK3 is
3 enriched in TRPM8-positive cold-sensitive neurones, which display a decreased thermal threshold
4 after TASK3 silencing and in neurones from TASK3^{-/-} mice (182), and expression of TASK3 in Na_v1.8-
5 negative neurones has been shown to be involved in innocuous and acute noxious cooling (183).
6 During inflammation, the mRNA levels of TASK1 and TASK3 are reduced and this reduction has been
7 correlated to spontaneous pain behaviours (184). Furthermore, after spared sciatic nerve injury,
8 TASK3 and TWIK1 are downregulated in lumbar 4 and 5 DRG, whilst TASK1 expression remains
9 constant, however, TASK3 expressions return to baseline levels in weeks, whereas downregulation
10 of TWIK1 persisted for months (185). In a similar fashion, TRESK, the most highly expressed K²P
11 channel in DRG neurones, which together with TREK2 mediates most of the background K⁺ current
12 in small- and medium-sized DRG neurones, i.e. likely nociceptors (173), is downregulated in
13 inflammation partially underlying spontaneous pain behaviour observed in rats (184). In addition, it
14 has been shown rat TRESK (rTRESK) is inhibited by arachidonic acid and hypertonic medium
15 (174,186), as well as protons, all mediators found in the inflammatory soup, and these effects appear
16 to be additive (174), highlighting the role of TRESK on neuronal excitability during inflammation.
17 Corroborating the idea of TRESK being important in sensory neuronal excitability, overexpression of
18 TRESK in trigeminal neurones reduces neuronal excitability (187) and TRESK overexpression in DRG
19 and spinal cord after nerve injury alleviates neuropathic pain in rats (188). Moreover, analysis of
20 migraine genetics supports a role for TRESK. The dominant negative mutation F139WfsX24 (TRESK-
21 MT) downregulates TRESK wildtype channels, inducing hypersensitivity of trigeminal neurones (189)
22 and occurs in patients experiencing familial migraine with aura (190). Intriguingly, a further TRESK
23 mutation (C110R), found in control and migraine patients (191) that produces a complete loss of
24 TRESK function, does not however induce trigeminal neurone hyperexcitability (192). A recent study
25 has described a novel transcriptional mechanism, frameshift mutation-induced alternative translation
26 initiation (fsATI), that resolves the role of TRESK. During TRESK-MT transcription, fsATI leads to the
27 production of a second protein fragment (MT2) that inhibits TREK1/TREK2 activity increasing sensory
28 neuronal excitability in trigeminal neurones, i.e. both non-functional TRESK-MT and inhibition of
29 TREK1/TREK2 are required to induce migraine-like pain states in mice (193). Lastly, members of the
30 TREK channel family are modulated by a wide range of physicochemical factors, including
31 temperature and mechanical stretch, and they have been implicated in polymodal pain perception.
32 TREK1^{-/-} mice are more sensitive to painful heat near the threshold between warmth and noxious
33 heat, exhibit greater mechanical sensitivity and enhanced inflammatory hypersensitivity, suggesting a
34 role for TREK1 in peripheral nociceptor sensitisation in inflammation (194). Moreover, extracellular
35 acidosis and lysophosphatidic acid, two inflammatory mediators, inhibit TREK1 activity (195). TREK2^{-/-}
36 mice show enhanced sensitivity to warmth and cool temperatures and reduced mechanical threshold
37 in normal conditions and additionally display an absence of nocifensive behaviours in response to
38 hypertonic saline injections after PGE₂ sensitization (196).

46
47
48
49 In summary, the role of K²P in different aspects of nociception and pain pathophysiological states has
50 been clearly confirmed by the use of animal models, however, their specific role in acid nociception
51 has yet to be tested.

52 53 **Proton-Sensing G Protein-Coupled Receptors**

54 Rather than binding complex extracellular ligands, proton-sensing G protein-coupled receptors (PS-
55 GPCRs) engage heterotrimeric G-proteins in response to mild increments in the extracellular proton
56 concentration. To date, four mammalian PS-GPCRs have been identified: the proton sensitivity of
57 GPR68 was described first, quickly followed by GPR4, GPR65 and GPR132, which were studied due
58 to high sequence similarity (197–199). Homologous genes for PS-GPCRs have been identified across
59 vertebrate subphyla, all of which exhibit strong conservation of histidine residues in extracellular
60 portions of the receptor, amino acids that confer proton sensitivity (Fig. 1) (197–200). PS-GPCRs

1 exhibit widespread tissue distribution (201) and are expressed in mammalian sensory neurones
2 (22,23), thus they likely evolved as sensors of the extracellular environment, being engaged in
3 response to local pH perturbations and functioning to maintain homeostasis. This has been reaffirmed
4 by studies of knockout mice, which are in the most part phenotypically normal (202), however issues
5 regarding autoimmunity have been reported, implicating these receptors in immune cell function
6 (203,204). Many PS-GPCRs have also been shown to respond to various lipids, such as GPR65 which
7 responds to psychosine (205), whether the receptors first arose as proton sensors or receptors for
8 lipids is also unknown, but may be addressed by studying evolutionary older variants. PS-GPCRs are
9 expressed throughout the central and peripheral nervous systems. Importantly, a high degree of co-
10 expression with peripherin and TRPV1, both markers of small diameter nociceptors has been
11 observed (201), suggesting a role of these receptors in acid nociception. Further to this, expression
12 of GPR4, GPR65 and GPR132 has been shown to be upregulated at the transcriptional level in various
13 rodent models of inflammation (206). Indeed, a body of evidence exploring the roles of PS-GPCRs in
14 inflammation has started to amass in recent few years.

15
16
17
18
19
20 Taking each PS-GPCR in turn, GPR4 preferentially couples to G_{α_s} proteins following acidic challenge,
21 resulting in the accumulation of cAMP, half maximal activation of this pathway occurs in response to
22 pH 7.55 in HEK293 cells transiently expressing GPR4 (197). Although unlikely to result in acute
23 nociceptor activation, downstream signalling from G_{α_s} plays a key role in nociceptor sensitisation
24 (207,208), i.e. proton-induced activation of GPR4 can sensitise nociceptor function, which may be
25 important to sensitisation process during chronic pathological conditions associated with tissue
26 acidosis. Elevated GPR4 mRNA has been detected in a murine model of inflammatory pain (206), as
27 well as in the colon and intestinal tissues of human ulcerative colitis and Crohn's disease patients.
28 Moreover, GPR4^{-/-} mice responded less severely to the colitis model in terms of weight loss,
29 histological damage and leukocyte infiltration (209,210). Accordingly, acid-induced activation of GPR4
30 coordinates increased expression of pro-inflammatory genes and enhances immune cell recruitment
31 following acidosis (211). Miltz and colleagues have recently developed a novel antagonist of GPR4,
32 which as well as preventing proton-induced cAMP accumulation in cell lines, was found to be orally
33 active and could reduce swelling and prevent joint damage in an arthritis model as well as reduce
34 mechanical hyperalgesia following complete Freund's adjuvant (CFA)-induced inflammation (212).

35
36
37
38
39 GPR65, also referred to as the T cell death-associated gene 8 (TDAG8) receptor, is activated by
40 protons, as well as the glycosphingolipid psychosine and the synthetic compound BTB09089. While
41 protons and BTB09089 cause GPR65-mediated accumulation of cAMP (198,213) and thus could lead
42 to nociceptor sensitisation as described above, psychosine inhibits adenylate cyclase and mobilises
43 intracellular Ca^{2+} (205) suggesting an inherent G-protein bias; mobilisation of intracellular Ca^{2+} both
44 depolarises neurones and activates PKC and thus proton-mediated GPR65 activation could both
45 activate and sensitise nociceptors. Genome wide association studies have reported correlation
46 between single nucleotide polymorphisms in GPR65 and the inflammatory conditions chronic
47 obstructive pulmonary disease-asthma overlap and ankylosing spondylitis (214,215). GPR65^{-/-} mice
48 are more susceptible to developing colitis, which has been linked to an influence of GPR65 on
49 lysosomal function and pathogen clearance (216), however, no link between the gene and
50 inflammatory bowel disease was observed in a Chinese population (217). Neuronal expression of
51 GPR65 has been shown to increase in murine models of bone cancer pain and following carrageenan-
52 or CFA-induced inflammation, and when siRNA targeting GPR65 is administered to animals before
53 the induction of these models less mechanical hyperalgesia is observed (218,219). Direct activation
54 of GPR65 with BTB09089 also produces mechanical allodynia (219). Studies of cultured DRG and
55 HEK293T cells have also shown that GPR65 is able to enhance capsaicin-induced Ca^{2+} fluxes through
56 TRPV1, indicative of a pro-inflammatory role of the receptor (206,220). A study of TRPV1, ASIC3 and
57 GPR65 knockout animals has shown that while all three receptors are important for the manifestation
58 of chronic inflammation following injection of CFA, only loss of GPR65 prevented the acute phase,
59
60

1 suggesting that different acid sensors play different roles in inflammatory hyperalgesia (132). Despite
2 the associations between GPR65 and inflammatory conditions, studies of GPR65 and immune cells
3 have reported decreases in the production of pro-inflammatory cytokines and upregulation of
4 protective factors, following proton-induced activation (213,221,222). Similarly, the expression of pro-
5 inflammatory cytokines was elevated in GPR65^{-/-} mice compared to wildtypes in a colitis model, the
6 same was observed for a T-cell transfer colitis model when the T-cells were harvested from GPR65^{-/-}
7 mice, however, the differential expression of inflammatory mediators between GPR65^{-/-} and wildtype
8 animals did not ameliorate the disease pathology (223). Taken together there appears to be a paradox
9 surrounding the role of GPR65 in inflammation with the role of GPR65 as pro- or anti-inflammatory
10 being highly dependent on the cellular context. GPR65 thus represents an interesting receptor for
11 studying the neuroimmune axis of inflammation.
12
13
14

15
16 GPR68, or the ovarian cancer G protein-coupled receptor 1 (OGR1), so called as it was first cloned
17 from an ovarian cancer cell line (224), stimulates the accumulation of inositol phosphates and
18 mobilisation of intracellular Ca²⁺ in response to extracellular acidosis within the range of pH 7.6 – 6.8
19 (225). This suggests a G_q coupling, which would both directly activate nociceptors (through Ca²⁺
20 mobilisation and depolarisation) and coordinate sensitisation (through PKC activation). More recently,
21 GPR68 has also been shown to be activated by benzodiazepines and physical stress (226,227).
22 GPR68 has been implicated in the production of pro-inflammatory cytokines by a number of cell types
23 in response to extracellular acidification, including pancreatic β -cells, osteoblasts and aortic smooth
24 muscle cells (228–230). Fittingly, GPR68 has been postulated to be the molecular mediator behind
25 asthma-associated inflammation due to its coordinating role in the production of interleukin-6 in
26 response to bronchial acidosis (231). Additionally, GPR68 has been highlighted as a potential target
27 in the treatment of heartburn associated pain given the high expression of this receptor compared to
28 other PS-GPCRs within oesophageal C-fibres (232). Hypoxia has been reported to contribute to
29 increased expression of GPR68 by intestinal macrophages and colonic tissue (233) and further to this,
30 elevated GPR68 mRNA was observed in intestinal mucosa from ulcerative colitis and Crohn's disease
31 patients (234). Studies of GPR68^{-/-} mice have identified several genes whose expression is dependent
32 on activation of GPR68 by extracellular acidosis. Loss of GPR68 was also shown to be protective in
33 a murine model of spontaneous colitis, with less inflammation and myeloperoxidase activity as well as
34 a lower incidence of colonic prolapse being observed (234).
35
36
37
38
39

40 The last of the PS-GPCRs is GPR132, also referred to as G2A, shows more restricted expression
41 than other PS-GPCRs and is comparatively less studied. Following acidic challenge cells expressing
42 GPR132 can activate Rho GTPases, however minimal activity in cAMP and inositol phosphate
43 accumulation assays has been reported (199,235) and thus proton-induced GPR132 activation has
44 the potential to both activate and sensitise nociceptors. Enhanced Ca²⁺ signals in response to acid
45 challenge have been described for cells co-expressing GPR132 and GPR68, suggesting the PS-
46 GPCRs may form oligomers to increase signalling diversity (236). In a neuropathic pain model, G2A^{-/-}
47 mice exhibit less mechanical hypersensitivity, however oxaliplatin, the drug used to manifest the
48 model, was shown to increase levels of oxidised lipids which could sensitise TRPV1 via G2A and PKC
49 dependent mechanisms (237). In contrast, overexpression of G2A in mice reduced mechanical
50 hypersensitivity following CFA-induced inflammation, while knockdown prolonged hyperalgesia (238).
51 Given that we have recently reported that the CFA model does not result in acidosis, this suggests
52 protons are not agonising G2A to confer the observed pain relief (55). The role of G2A in acid
53 nociception thus remains elusive.
54
55
56
57

58 While less is known about the nociceptive roles of PS-GPCRs compared to the other proton-sensitive
59 receptors, the associations between the genes encoding these receptors and conditions associated
60 with pain, as well as observations that loss of PS-GPCRs leads to reduced pain phenotypes in various

1 animal models, shows that PS-GPCRs are rightfully of considerable interest in understanding the
2 molecular mechanisms underpinning nociception.
3

4 **Other Acid Sensors**

5 In this review, we have focused on the main proton sensors with regard to nociceptor function.
6 However, numerous ion channels are modulated by pH that we have not discussed here, such as
7 inhibition of NMDA receptors, voltage-gated Ca^{2+} channels, the voltage-gated proton channel H_v1 and
8 ionotropic purinergic receptors but these have been reviewed elsewhere (97,239).
9

10 **Integrating Nociceptor Acid Sensitivity**

11 As mentioned earlier, the naked mole-rat does not respond to acid as a noxious stimulus, despite a
12 comparable expression pattern of ASICs to mice (75), functional ASIC-like and TRPV1-like currents
13 being recorded from isolated naked mole-rat sensory neurones (58,74) and similar proton-sensitivities
14 of cloned mice and naked mole-rat ASICs and TRPV1 (58), with the exception of ASIC3 (74); the
15 proton-sensing properties of K2Ps and PS-GPCRs remain unknown in this species. Recent RNA-
16 sequencing analysis has also demonstrated that proton-sensitive ASIC3 and TWIK1 (as well as
17 sepiapterin reductase) are both commonly downregulated in the naked mole-rat and the other proton-
18 insensitive rodents, the Cape mole-rat and East African root rat) (47). Downstream of proton-detection,
19 the transducer channel has to mediate sufficient depolarisation to reach the activation threshold for
20 Na_v subunits to initiate an action potential. However, protons can negatively regulate Na_v subunits,
21 blocking the channel pore and altering the voltage-sensor movement that changes gating, as has
22 been extensively reviewed (240), and thus Na_v modulation can also play a role in nociceptor acid-
23 sensitivity. In naked mole-rat DRG neurones, macroscopic voltage-gated inward currents are
24 significantly more susceptible to proton inhibition than those in mouse DRG neurones (58), attributed
25 to a difference in the amino acids involved in proton inhibition, EKE replacing the relatively conserved
26 KKV, and thus enhancing proton block. Swapping KKV for EKE in human $\text{Na}_v1.7$ enhanced the degree
27 of proton block and thus acid acts like an anaesthetic in naked mole-rat acid-sensing nociceptors to
28 prevent action potential firing (58). This EKE motif is also found in the proton-insensitive Cape mole-
29 rat, whereas EKD (which has a similar $-+ -$ charge constellation) is present in other, proton-sensitive
30 mole-rats suggesting that additional factors are likely involved in determining proton-induced
31 nociceptor excitability and further negative charges in $\text{Na}_v1.7$ have been identified as common only to
32 the naked and Cape mole-rats (47). The selection of $\text{Na}_v1.7$ variants likely results from the
33 evolutionary pressure of living in a hypercapnic, but relatively safe, environment and thus the change
34 in $\text{Na}_v1.7$ may represent an adaptation to prevent somatic nociceptor activation by hypercapnia-
35 induced acidosis. Indeed, recent computational analysis has identified evidence of convergent
36 evolution in the $\text{Na}_v1.7$ amino acid variation associated with naked mole-rat acid-insensitivity in
37 hibernating (but not closely related, non-hibernating) species (241) such that selection for this motif
38 has occurred at least 6-times independently i.e. the change in the $\text{Na}_v1.7$ sequence may represent a
39 form of convergent evolution to enable resistance to acid-induced nociceptor activation in species
40 living in hypercapnic environments. However, the proton-insensitive East Africa root rat has $\text{Na}_v1.7$
41 motifs common to proton-sensitive rodents, suggesting that in addition to selective pressure on $\text{Na}_v1.7$
42 that there are further, divergent mechanisms responsible for proton-insensitivity in this species (47).
43 It should also be noted that acid nociception has usually been measured in response to subcutaneous
44 acid administration, but responses observed are perhaps unrepresentative of a whole organism's
45 proton sensitivity. For example, in the naked mole-rat, subcutaneous acid administration fails to induce
46 nociceptive behaviour and skin-innervating nociceptors are proton-insensitive (42) and yet in the same
47 species, sensory nerves innervating the distal colon are both activated and sensitised by acid (whether
48 this correlate with visceral acid nociception is unknown) (242). This finding correlates with the fact that
49 whilst $\text{Na}_v1.7$ is vital for somatic pain, it is not required for visceral pain in mice (243). Therefore, it
50 might well be that divergent evolutionary pressures have led to differential proton sensitivity within a
51 single species, in the case of the naked mole-rat, life in a safe, but hypercapnic environment has
52
53
54
55
56
57
58
59
60

1 resulted in loss of somatic proton-induced nociception, but the homeostatic role of acidification in the
2 gastrointestinal tract (e.g. pathogen elimination) has led to maintained sensory neurone proton
3 sensitivity.
4

5
6
7 Overall, the co-expression of different proton-sensitive receptors by nociceptors allows integration of
8 localised acidosis to a number of intracellular signalling events within nociceptors. For example, in
9 response to a decrease in extracellular pH both ASICs and TRPs coordinate cation influx, contributing
10 to depolarisation. The permeance of TRPs to Ca^{2+} also allows them to coordinate release of
11 neuropeptides which may act on other receptors to increase nociceptor excitability, as well as
12 promoting inflammation. Similarly, several K2Ps expressed in nociceptors are inhibited by
13 extracellular protons and thus constitutive K^+ efflux is reduced, further contributing to membrane
14 depolarisation and increasing the likelihood of action potential firing. In addition to this, activation of
15 PS-GPCRs has been shown to sensitise certain TRP channels and the role of GPCRs in
16 transcriptional regulation may also serve to increase expression of proton-sensitive ion channels or
17 expression of other proteins that may positively modulate nociceptor activity. The combined effect of
18 this nociceptor priming is greater action potential discharge and heightened sensitivity to harmful
19 stimuli, which likely manifests in pain. An overview of the integration of nociceptor acid-sensation is
20 depicted in Figure 3.
21
22
23
24

25 Conclusion

26 Detection of acid as a noxious stimulus is present in a wide variety of phyla in the Animalia kingdom,
27 thus demonstrating that evolutionary pressure has maintained selection for this facet of nociceptor
28 function. A wide variety of proton-sensitive receptors are expressed by sensory neurones to enable
29 detection of the environmental pH. The range across which these different receptors are activated, as
30 well as their modulation by a variety of other inflammatory mediators, enables sensory neurones to
31 integrate information regarding tissue pH in both physiological and pathophysiological conditions and
32 the hope is that by studying the evolution of nociceptor proton sensitivity the key molecular players
33 can be identified resulting in therapeutic interventions for conditions associated with tissue acidosis
34 and pain. It is most likely this requirement of detecting a pH range that has led to the evolution of a
35 variety of different proton-sensitive receptors, but at the same time, it is clear that many proton-
36 sensitive receptors are modulated by other stimuli. Therefore, it could be that proton sensitivity is a
37 remnant of a precursory role of that particular receptor, but alternatively it could be that proton
38 sensitivity is the key role and that sensitivity to other stimuli is a feature that has remained, but with
39 limited selection pressure, e.g. ASIC precursors are activated by peptides, whereas mammalian
40 ASICs are proton sensors whose function is modulated by peptides.
41
42
43
44
45

46 As much as our understanding of how protons regulate nociceptors has accelerated dramatically in
47 recent years, certain questions remain to be answered:

48 • Many proton-sensors are activated/modulated by other stimuli, what is the physiological role
49 of such sensors *in vivo* – detection of protons or different stimuli and what evolutionary pressures
50 drove this dual sensitivity?
51

52 • Are the 'proton-sensitive' residues identified in certain proton sensor families common to all
53 proton-sensitive receptors of that family throughout evolution?
54

55 • What evolutionary pressure(s) maintained selection for the variety of acid sensors
56 nociceptors express and how does an individual nociceptor integrate their signals?
57

58 • What is the molecular basis of nociceptor proton sensitivity in those species where no
59 pharmacology or genetics has yet been applied, e.g. frogs and leeches, and does this help to explain
60 the evolution of proton-sensor function?

Figure Legends

Figure 1. Membrane topologies of proton-sensitive receptor subunits. Schematic diagram of the basic structure of proton-sensitive receptors, with residues or regions important for proton sensitivity annotated (yellow – highly conserved among family members; white – less conserved or important in some, but not all, family members). Functional ASICs, K2Ps and TRPs are multimeric, but for simplicity only one subunit of each receptor is shown.

Figure 2. Phylogeny of general nociception and acid nociception. Annotated phylogenetic tree indicating the presence of general nociceptors, observation of acid nociception and functional expression of proton sensitive receptors. Annotation is limited by the rarity of molecular studies focussing on lower-order species. Expression of proton sensitive receptors is only acknowledged for those species where proton sensitivity of at least one member of the group in question has been empirically proven. For simplicity only species addressed in this review are shown.

Figure 3. Proton-sensation at the peripheral terminal of a typical nociceptor. Following localised acidosis, the increased extracellular concentration of protons is sensed by several receptors which act in concert to increase neuronal excitability and release mediators which may sensitise other neurones. Increased extracellular proton concentration induces the activation of proton-sensitive depolarising channels (ASICs and TRPs) causing cation influx and membrane depolarisation. Simultaneously, proton-induced inhibition of K2P channels reduces constitutive K⁺ efflux further facilitating membrane depolarisation. Activation of PS-GPCRs can drive changes in gene expression and coordinate phosphorylation and sensitisation of TRP channels. Altogether, nociceptor membrane depolarisation activates Na_v subunits resulting in generation of action potentials that transmit nociceptive signals to the spinal cord (*Amino acid variations in Na_v1.7 of some species renders the channel hypersensitive to proton-block resulting in an absence of proton-induced nociception).

For Review Only

Figure 1. Membrane topologies of proton-sensitive receptor subunits. Schematic diagram of the basic structure of proton-sensitive receptors, with residues or regions important for proton sensitivity annotated (yellow – highly conserved among family members; white – less conserved or important in some, but not all, family members). Functional ASICs, K2Ps and TRPs are multimeric, but for simplicity only one subunit of each receptor is shown.

338x190mm (117 x 117 DPI)

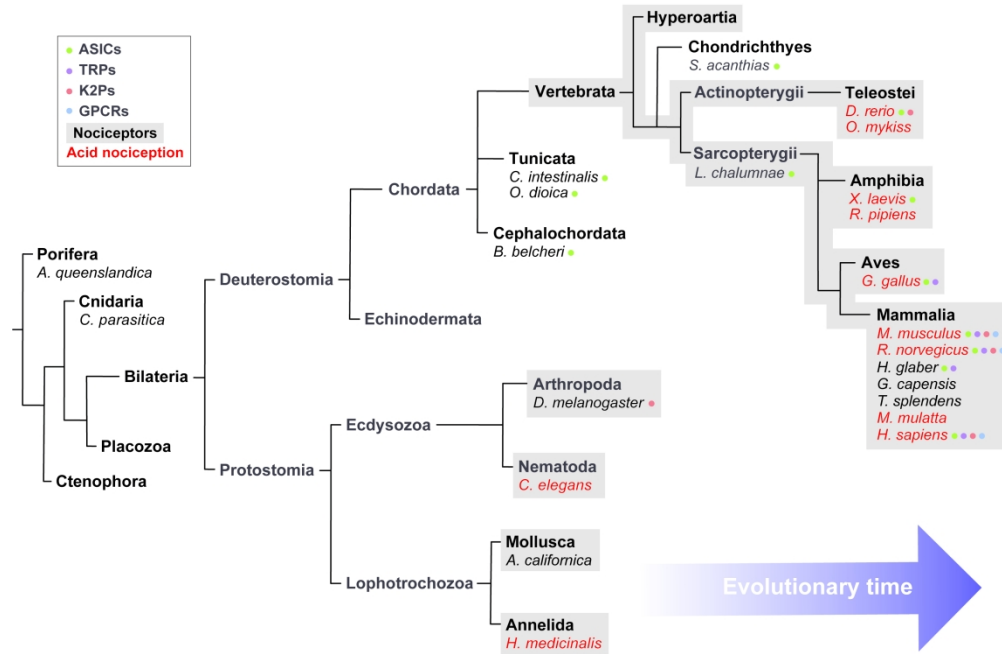

Figure 2. Phylogeny of general nociception and acid nociception. Annotated phylogenetic tree indicating the presence of general nociceptors, observation of acid nociception and functional expression of proton sensitive receptors. Annotation is limited by the rarity of molecular studies focussing on lower-order species. Expression of proton sensitive receptors is only acknowledged for those species where proton sensitivity of at least one member of the group in question has been empirically proven. For simplicity only species addressed in this review are shown.

Figure 3. Proton-sensation at the peripheral terminal of a typical nociceptor. Following localised acidosis, the increased extracellular concentration of protons is sensed by several receptors which act in concert to increase neuronal excitability and release mediators which may sensitise other neurones. Increased extracellular proton concentration induces the activation of proton-sensitive depolarising channels (ASICs and TRPs) causing cation influx and membrane depolarisation. Simultaneously, proton-induced inhibition of K₂P channels reduces constitutive K⁺ efflux further facilitating membrane depolarisation. Activation of PS-GPCRs can drive changes in gene expression and coordinate phosphorylation and sensitisation of TRP channels. Altogether, nociceptor membrane depolarisation activates NaV subunits resulting in generation of action potentials that transmit nociceptive signals to the spinal cord (*Amino acid variations in NaV1.7 of some species renders the channel hypersensitive to proton-block resulting in an absence of proton-induced nociception).

338x190mm (117 x 117 DPI)
