(Received 26 January 2018; accepted 8 May 2018; published online 22 May 2018)

In this work, we test graphene electrodes in nanometric channel n-type Organic Field Effect Transistors (OFETs) based on thermally evaporated thin films of the perylene-3,4,9,10-tetracarboxylic acid diimide derivative. By a thorough comparison with short channel transistors made with reference gold electrodes, we found that the output characteristics of the graphene-based devices respond linearly to the applied bias, in contrast with the supralinear trend of gold-based transistors. Moreover, short channel effects are considerably suppressed in graphene electrode devices. More specifically, current on/off ratios independent of the channel length ( $L$ ) and enhanced response for high longitudinal biases are demonstrated for  $L$  down to  $\sim 140$  nm. These results are rationalized taking into account the morphological and electronic characteristics of graphene, showing that the use of graphene electrodes may help to overcome the problem of Space Charge Limited Current in short channel OFETs. *Published by AIP Publishing.* <https://doi.org/10.1063/1.5023659>

Organic electronics has gathered a great deal of attention due to the possibility of fabricating flexible and low cost devices for several applications.<sup>1–4</sup> Despite considerable advances in understanding and controlling the fundamental mechanisms, several bottlenecks still restrict the miniaturization of Organic Field Effect Transistors (OFETs) towards the nanometric scale. In particular, in short-channel architectures, the transport mechanism is often dominated by non-linear Space Charge Limited Current (SCLC)<sup>5–8</sup> in which the current is mostly given by charge carriers directly injected from the contacts to the bulk of the organic thin film. This spurious effect reduces the overall performances of the devices at the nanometric scale despite the fact that the maximization of the output currents, switching frequencies, and minimum supply voltages are directly related to the reduction of the active channel length ( $L$ ).<sup>9,10</sup> Short-channel effects are primarily due to the highly intense electric fields building up at the channel. They hinder charge accumulation at the dielectric interface and manifest in the form of parabolic current-voltage characteristics for channel lengths already at the micrometric scale<sup>11</sup> and high off-state currents due to drain-induced barrier lowering, commonly encountered in inorganic devices as well.<sup>12,13</sup> In this scenario, contact effects at the organic semiconductor/electrode junctions play a key role. Charge carrier injection and extraction mechanisms in OFETs are indeed dictated by the interplay between the net alignment of the Fermi level of the metallic electrodes with the LUMO (HOMO) level of the organic semiconductor and the energetic and morphological order of

the organic thin film nearby the contacts.<sup>14–16</sup> Careful choice of materials or chemical treatment of contact electrodes is therefore needed in order to optimize the OFET response,<sup>17</sup> especially in nanometric architectures. Graphene and graphene-based materials have been recently considered as a novel electrode material in field-effect devices based on conventional organic semiconductors,<sup>18–22</sup> graphene nano-ribbons,<sup>23</sup> and single molecule junctions,<sup>24</sup> taking advantages from their work function tunability,<sup>25</sup> permeability to the transversal electric field, and overall chemical stability.<sup>26,27</sup>

In this work, we report on the fabrication and characterization of short channel n-type OFETs with graphene electrodes and with channel length  $L$  ranging from 140 nm to 1  $\mu\text{m}$ , with a fixed channel width ( $W = 2 \mu\text{m}$ ). For direct comparison, devices with an analogous architecture have been fabricated using standard gold contacts in the same  $L$  interval. As the organic semiconductor, we used a perylene-3,4,9,10-tetracarboxylic acid diimide derivative, also known as PDIF-CN<sub>2</sub> (Polyera ActiveInk™ N1100), which has gained great attention in the last few years due to its enhanced air stability and excellent n-type transporting properties,<sup>28–30</sup> yielding field-effect mobility values largely exceeding  $1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  in state of the art single crystal devices.<sup>31</sup>

As the electrode material, we employed polycrystalline monolayer CVD graphene grown and transferred with a wet-approach, as reported in Ref. 32, on a 300 nm-thick SiO<sub>2</sub>/doped-Si substrate. Graphene sheets under analysis are found to be heavily p-type doped, as it can be seen from the transport characteristics of micrometric strips ( $W = 2 \mu\text{m}$ ,  $L = 4 \mu\text{m}$ ) used as a benchmark (Fig. S1 in the [supplementary material](#)). Graphene doping was further investigated via Scanning Kelvin Probe Microscopy (Park-XE-100) in ambient conditions.

Using a grounded gold pad as the reference for the gold-coated AFM cantilever, an average work function of about 4.9 eV for the graphene was determined (Fig. S2). Unintentional doping effects in CVD-graphene are commonly encountered and are usually related to substrate surface treatments prior to the graphene transfer<sup>33</sup> or to contamination due to environmental exposure.<sup>34</sup> Devices have been realized starting from the large area graphene sheet by means of Electron-Beam Lithography (EBL) and oxygen plasma Reactive Ion Etching (RIE), employing the underlying doped-Si as the gate in the bottom contact-bottom gate (BC-BG) architecture. A micrometric pattern of gold tracks and probe pads (3/30 nm and 5/50 nm of thermally evaporated Cr/Au, respectively) is over imposed on the nanopatterned graphene, obtaining the structure depicted in Figs. 1(a) and 1(b). An analogous fabrication procedure has been used for the devices with gold electrodes. After the lithographic processes, the samples have been cleaned via an N-methylpyrrolidone-solvent bath at 65 °C for 4.5 h, then left in acetone for 2 h at room temperature, and rinsed in isopropanol. This was done in order to eliminate resist contaminants and improve the organic thin film morphology especially on the graphene electrodes. Finally, the SiO<sub>2</sub> substrate has been functionalized by a self-assembled monolayer (SAM) of

FIG. 1. (a) Sketch depicting the bottom contact-bottom gate architecture used for the n-type short channel OFETs under analysis. (b) SEM image of a short-channel FET based on graphene electrodes ( $L = 400 \pm 30$  nm). The channel width ( $W$ ) is fixed at  $2 \mu\text{m}$  for every channel length  $L$ . Enhanced-color AFM topographies of the graphene-based transistor (c) and gold-based device (d) with  $L = 400 \pm 30$  nm. Dashed lines in (c) highlight the graphene/channel interfaces. From AFM analysis, root-mean-square roughnesses ( $\sigma$ ) of  $\approx 1.4$  nm and  $\approx 1.8$  nm are estimated in the channel and on the graphene electrodes, respectively, while  $\sigma \approx 1.2$  nm and  $\approx 1.6$  nm are observed in the channel and on the electrodes in gold-based transistors. The scales in (a)–(c), indicated by the white bars, are of  $1 \mu\text{m}$ .

hexamethyldisilazane (HMDS) by vapor priming (1 h at 160 °C), enhancing in such a way the growth of the organic thin film and the overall performances of the devices.<sup>29</sup>

PDIF-CN2 has been deposited via Organic Molecular Beam Deposition (OMBD) on the substrates kept at 100 °C with a deposition rate of about 0.3 nm/min in high vacuum conditions, resulting in a 25 nm thick polycrystalline thin film [Figs. 1(c) and 1(d)]. The electrical characterization has been performed in a Janis probe station, in vacuum and dark conditions, employing a Keithley-2612A SourceMeter.

Output curves for three of six different channel lengths under analysis are reported in Fig. 2 (refer to Figs. S3 and S4 for the whole set of  $L$ ). A comparative analysis shows substantial differences between the gold-based and graphene-based nanodevices. Focusing on the graphene electrodes [Figs. 2(a)–2(c)], the drain-source current ( $I_{\text{ds}}$ ) responds linearly to the drain-source bias ( $V_{\text{ds}}$ ) in the range  $0 \text{ V} < V_{\text{ds}} < 20 \text{ V}$ . An obvious current modulation is observed in the case of graphene electrodes for increasing the gate-source bias ( $V_{\text{gs}}$ ), independently of the channel length  $L$ . Increasing  $L$  from  $140 \pm 30$  nm to  $1000 \pm 30$  nm, the maximum  $I_{\text{ds}}$  values are observed to decrease accordingly. Conversely, in the case of gold electrodes [Figs. 2(d)–2(f)], a supralinear behavior is evident in the same  $V_{\text{ds}}$  interval, while the  $V_{\text{gs}}$  current-modulation deteriorates for  $L$  approaching the minimum value of 140 nm [Fig. 2(d)]. It should be pointed out that in both architectures, current saturation is not achieved for any  $L$  due to the relatively thick gate dielectric (300 nm) and its effective charge accumulation. Moreover, despite that PDIF-CN2 organic thin films show similar morphologies inside the active channel of graphene and gold-based transistors [Figs. 1(c) and 1(d)], maximum  $I_{\text{ds}}$  values were observed to differ of nearly one order of magnitude, indicating a major contribution of the contact resistance for the case of graphene electrodes. Contact effects are indeed known to be not uniquely dictated by the energetic alignment at the electrode/organic Schottky interface, but morphological and geometrical contributions must be considered too. In fact, the correlation between the molecular crystal domain orientation on the electrodes and the resulting work function and injection barrier has been studied for different configurations, in particular pentacene on graphene<sup>19,35</sup> and n-type P-(NDI2OD-T2) on gold electrodes.<sup>36</sup> It turns out that different crystalline orientations, namely, when the molecules sit on the substrate with the edge (stand-up) or the face (lay-down), play a major role in the final properties of the system. In the case of n-type P-(NDI2OD-T2) thin films, it is observed that the injection barrier for electrons is higher in the edge-on than in the face-on devices. In our case, when one-atom thick graphene is used as the electrode, charges are likely to be injected perpendicularly with respect to the molecular layer in contrast with the 30 nm thick gold contacts where the transport of the charge carriers takes place mostly in the parallel direction, resulting in lower contact resistances, as schematically depicted in Figs. 2(g) and 2(h), respectively. It is important to underline that our result is clearly different from the case of pentacene OFETs with graphene electrodes,<sup>19</sup> where the beneficial orientation of the interfacial dipole layer is responsible for improved performances. Moreover, it must be stressed also that the pentacene films

FIG. 2. Output curves obtained in vacuum for different channel lengths  $L$  for (a)–(c) the graphene-based devices ( $-80 \text{ V} \leq V_{\text{gs}} \leq +40 \text{ V}$  with  $+20 \text{ V}$  steps) and (c), (d), and (f) the gold-based devices ( $-60 \text{ V} \leq V_{\text{gs}} \leq +60 \text{ V}$  with  $+20 \text{ V}$  steps). (g) and (h) Schematic depiction of charge injection for graphene and gold electrodes, respectively.

have the same polarity (p-type) of the graphene electrodes. Nevertheless, the high resistive but still-ohmic region at the electrodes can be considered as a healing factor that hinders the creation of an intense electric field (of the order of MV/cm in  $\sim 100 \text{ nm}$  long channels for  $V_{\text{ds}} = +20 \text{ V}$ ), limiting the space charge transport in the bulk of the organic channel.

To further check this hypothesis, in Fig. 3(a), we plot the output curves in ln-ln scale in order to investigate in deeper details the power-law characteristics  $I_{\text{ds}} \approx V_{\text{ds}}^n$ , describing the charge transport in both the architectures. For graphene-based transistors, the results show that, even in the case of our shortest channel ( $L = 140 \text{ nm}$ ),  $I_{\text{ds}}$  has a quasi-linear dependence on the entire drain-source voltage interval with  $n \approx 1.2$ . On the other hand, the power law for the gold-based devices with a comparable channel length appears to be characterized by two distinct regimes depending on the applied drain-source bias (that is equivalent to say the magnitude of the longitudinal electric field) with a slope value  $n \approx 1.5$  diverging from the linearity for  $V_{\text{ds}} > 2 \text{ V}$ . This is a typical signature from a SCLC contribution that becomes more evident for decreasing  $V_{\text{gs}}$  [Fig. 3(b)]. The exponent  $n$  for  $V_{\text{ds}} > 2 \text{ V}$  approaches values exceeding 2 for gate-source bias near  $-60 \text{ V}$  where punch-through currents appear to dominate the charge carrier transport, as we will further discuss below. For  $V_{\text{ds}} < 2 \text{ V}$ , gold-based devices show slope values similar to those obtained for graphene-based transistors, with  $n$  asymptotically approaching 1.2 for increasing  $V_{\text{gs}}$  biases.

In Figs. 4(a) and 4(b), we report the transfer curves ( $I_{\text{ds}}-V_{\text{gs}}$ ) for both architectures. As a common feature, highly negative onset voltages ( $V_{\text{on}}$ ) are observed with values of about  $-60 \text{ V}$  in the case of gold electrodes and  $-80 \text{ V}$  for graphene electrodes. Large negative threshold values are commonly observed for perylene diimides and especially for PDIF-CN2 when deposited on “bare” (i.e., not passivated)  $\text{SiO}_2$  substrates, where the presence of charge traps also induces hysteresis in the current characteristics and affects negatively the overall morphology of the organic thin film. These issues are usually overcome by the HMDS functionalization.<sup>29</sup>

The effectiveness of our functionalization procedure is confirmed by the ordered polycrystalline morphology of the organic thin film and the absence of the hysteresis phenomena in the electrical characteristics. Therefore, we ascribed the highly negative onset voltages to a partially unpassivated surface, where, likely, a fixed parasitic surface charge density at the  $\text{SiO}_2/\text{HMDS}$  interface is still present.<sup>37</sup> Importantly, the negative threshold values do not influence the direct

FIG. 3. (a) Ln-Ln plot of the output curves for  $V_{\text{gs}} = +20 \text{ V}$  of the graphene-based device (red squares) and for the gold-based transistor (black circles) with  $L = 140 \pm 30 \text{ nm}$ . The  $n$  values indicate the slope of the ln-ln curves extracted from the linear best fit. (b) Slopes  $n$  extracted as a function of the applied gate-source bias in both the architectures for  $L = 140 \pm 30 \text{ nm}$ . For gold electrode devices, the responses for  $V_{\text{ds}} < 2 \text{ V}$  (empty circles) and  $V_{\text{ds}} > 2 \text{ V}$  (filled circles) are reported.

FIG. 4. Transfer curves acquired in vacuum for a fixed drain source bias ( $V_{ds} = +5$  V), at different channel lengths for (a) gold and (b) graphene based devices. (c) Comparison of on/off ratios for the two architectures as a function of the channel length ( $L$ ) and (d) as a function of the applied drain-source voltage  $V_{ds}$  for  $L = 140$  nm. In (c) and (d), equal  $V'_{gs} = V_{gs} - V_{on} = 100$  V has been considered.

comparison between the graphene and gold-based devices. The advantages in terms of the overall performances in short-channel transistors based on graphene electrodes can be observed comparing the transfer curves reported in Figs. 4(a) and 4(b). In particular, punch-through currents due to drain-induced barrier lowering are evidently suppressed in graphene-based devices. Indeed, in the case of gold-electrode devices, approaching  $V_{gs}$  values near to the onset voltages ( $V_{on}$ ) and off-state currents ( $I_{off}$ ) for a fixed  $V_{ds}$  bias deteriorate progressively for decreasing  $L$ , with increasing  $I_{off}$  values from  $\approx 10^{-9}$  A for  $L = 140$  nm to  $\approx 10^{-6}$  A for channel lengths approaching  $1 \mu\text{m}$  [Fig. 4(a)]. Conversely, off-state currents in graphene based devices appear to sustain the shrinking of the channel length down to  $L = 140$  nm with values fixed in the nA scale [Fig. 4(b)]. This obviously affects the on/off ratio ( $R_{ON/OFF}$ ) trends plotted in Fig. 4(c) as a function of  $L$  where  $R_{ON/OFF}$  has been evaluated considering similar device polarizations for both architectures, i.e., considering on-state currents for equivalent effective bias  $V'_{gs} = V_{gs} - V_{on}$ . Graphene-based transistors essentially show constant  $R_{ON/OFF}$  values of the order of  $10^2$  in contrast with gold-based devices for which  $V_{gs}$  current-modulation decreases towards  $10^1$  for  $L < 400$  nm [Fig. 4(c)]. These results can be explained taking into account the gate-tunability of the work function in monolayer graphene. In particular, considering the measured work function of p-doped graphene at zero bias ( $W_F \approx -4.9$  eV) and the LUMO level of PDIF-CN2 ( $-4.5$  eV),<sup>38</sup> a theoretical barrier of  $\approx 0.4$  eV builds up at the heterointerface. This value depends directly on the applied  $V_{gs}$  since  $W_F$  for graphene decreases (i.e., becomes more negative) for negative gate voltages, as it was shown by means of Kelvin Probe measurements.<sup>25</sup> As a result, an increasing barrier is expected for

decreasing gate-source voltages towards negative onset threshold values, counterbalancing in such a way the drain-induced barrier lowering and suppressing the punch through currents otherwise observed in gold-based transistors. This is further supported by the results reported in Fig. 4(d) where  $R_{ON/OFF}$  as a function of the applied  $V_{ds}$  is plotted for the shortest channel devices ( $L = 140$  nm) and for comparable  $V'_{gs} = 100$  V. Graphene-based transistors take advantage of the aforementioned barrier modulation with an increasing  $R_{ON/OFF}$  for increasing  $V_{ds}$ , as a consequence of the steadily low  $I_{off}$  values, while, on the other hand, drain-induced barrier lowering degrades  $R_{ON/OFF}$  for increasing longitudinal electric fields in gold-based transistors [Fig. 4(d)]. For the sake of completeness, the full set of transfer curves for different  $V_{ds}$  values are reported in Fig. S5 of the [supplementary material](#).

In conclusion, p-doped CVD-graphene has been employed as an electrode in bottom-contact/bottom-gate n-type OFETs with a channel length at the sub-micrometric scale. Experimental results suggest that graphene suppresses short-channel effects thanks to its morphological and electronic properties. A minor contribution of SCLC on the overall response and remarkable improvements in terms of off-state currents are observed when compared to transistors with gold electrodes and equivalent channel lengths. The use of CVD-graphene as an electrode is a valuable choice for the development of highly dense support circuitry in all-organic electronic devices, with possible applications for active-matrix-driven Organic Light Emitting Diode (OLED) panels or Organic Light Emitting Transistor (OLET) arrays where mechanical flexibility and low optical absorption are mandatory.

See [supplementary material](#) for further details on the estimation of the work function of graphene and electric characterization of the nanodevices.

The authors thank Dr. Mario Barra and Dr. Fabio Chiarella for the helpful discussions on the experimental results.

Dr. Claudia Menozzi is gratefully acknowledged for the support during the fabrication of the devices.
