Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

7 37 Many atmospheric organic compounds are long-lived enough to be transported from their sources
8 38 to polar regions and high mountain environments where they can be trapped in ice archives. While
9 39 inorganic components in ice archives have been studied extensively to identify past climate
10 40 changes, organic compounds have rarely been used to assess paleo-environmental changes,
11 41 mainly due to the lack of suitable analytical methods. This study presents a new method of direct
12 42 injection HPLC-MS analysis, without the need of pre-concentrating the melted ice, for the
13 43 determination of a series of novel biomarkers in ice-core samples indicative of primary and
14 44 secondary terrestrial and marine organic aerosol sources. Eliminating a preconcentration step
15 45 reduces contamination potential and decreases the required sample volume thus allowing a
16 46 higher time resolution in the archives. The method is characterised by limits of detections (LODs)
17 47 in the range of 0.01-15 ppb, depending on the analyte, and accuracy evaluated through an
18 48 interlaboratory comparison. We find that many components in secondary organic aerosols (SOA)
19 49 are clearly detectable at concentrations comparable to those previously observed in replicate
20 50 pre-concentrated ice samples from the Belukha glacier, Russian Altai Mountains. Some
21 51 compounds with low recoveries in preconcentration steps are now detectable in samples with this
22 52 new direct injection method significantly increasing the range of environmental processes and
23 53 sources that become accessible for paleo-climate studies.

1. Introduction

The analysis and quantification of non-anthropogenic marine and terrestrial organic compounds in ice cores is a developing field presenting a new suite of compounds potentially applicable to palaeoenvironmental reconstruction ¹. A small selection of studies obtaining new records of various novel organic compounds in ice has proven the concept; Kawamura et al. ² detected lipid compounds in snow layers dating back 450 years at Site J, Greenland, using gas chromatography – mass spectrometry (GC-MS), Pokhrel et al. ³ detected oxidation products of isoprene and monoterpenes in ice up to 350 years old in Alaska using GC-MS on rotary evaporation-preconcentrated samples, and Muller-Tautges et al. ⁴ detected carboxylic acids and inorganic ions between 1942-1993 from Grenzgletscher (Monte Rosa Massif) in the southern Swiss Alps using high performance liquid chromatography-mass spectrometry (HPLC-MS) on stir-bar preconcentrated samples. Following this, King et al. ⁵ developed a method of HPLC-MS analysis for rotary evaporation-preconcentrated ice samples. We quantified concentrations of a wide range of novel organic compounds in ice core samples which had shown good potential for survival during transport to, and preservation within, ice core records, and relationships to environmental conditions ¹. These included a range of fatty acids, secondary oxidation aerosol compounds, and primary biogenic molecules at both detectable and reproducible concentrations.

Adaptation of methods towards those not requiring preconcentration has been previously successfully applied to levoglucosan, an organic compound produced by combustion of cellulose and used to indicate past biomass burning trends from ice core analysis. In order to both circumnavigate the need for preconcentration and to avoid more time consuming GC-MS methods, Gambaro et al. ⁶ developed the first method of direct injection HPLC-triple quadrupole mass spectrometry (HPLC/ESI-MS/MS) for quantification of levoglucosan in Antarctic ice samples, where concentrations are expected to be very low. They achieved detection limits as low as 0.003ppb in samples as small as 1mL, reproducible at 20-50%, while lowering analysis time and contamination risk, demonstrating the potential benefits of this process.

In this study we compare our previous method ⁵ for preconcentrated samples with a similar one for use on non-preconcentrated snow and ice samples, i.e. direct injection HPLC-MS, for an identical compound list (Table 1).

While preconcentration is still needed in many cases due to the very low levels of organic compounds in polar and alpine ice samples (typically parts per trillion (ppt, equivalent to ng/L) –

1
2
3 95 parts per billion (ppb, equivalent to $\mu\text{g/L}$), some samples closer to source location may contain
4 96 higher compound concentrations detectable without requiring such a step. Alternatively, new
5 97 instrumentation presents the opportunity to analyse samples at detection levels as low as ppt,
6 98 thus removing the need for preconcentration. The elimination of a preconcentration step would
7 99 be beneficial for several reasons; reducing the processing steps of samples reduces the
8 100 possibility for introduction of contamination, especially in the case of fatty acids where background
9 101 contamination is generally high compared to SOA compounds ⁵. Additionally, for some of the
10 102 compounds on our target list, preconcentration has been ineffective, due to very low recovery.
11 103 For example, the rotary evaporation method previously applied in King et al. (2018) showed very
12 104 low recovery for oxidised biogenic aerosol markers such as MBTCA. Direct injection, if suitable
13 105 detection limits can be achieved, opens up these additional compounds to ice core analysis, and
14 106 therefore offers an enhanced suite of compounds for paleo-environmental reconstruction. Finally,
15 107 the required sample volume for direct injection is also much smaller, in this case approximately
16 108 100 μL per sample rather than 10 mL for a sample requiring preconcentration, thus improving the
17 109 depth and time resolution that can be attained from the ice core. As an example, this will often
18 110 allow seasonally-resolved samples to be analysed, as opposed to annual or multi-annual records,
19 111 which will be invaluable to develop an understanding of the processes and sources these novel
20 112 organic paleo-environmental markers represent. This may also be particularly useful when
21 113 evolving the method to analyse much older ice than currently tested, where annual ice layers are
22 114 much thinner, due to ice flow, than those in younger, shallower counterparts. As a long-term
23 115 perspective, methods requiring low sample volume may be amenable to adaptation for coupling
24 116 with continuous flow analysis systems (e.g Kaufmann *et al.* 2008). Finally, the use of high-
25 117 resolution MS without sample preconcentration would allow retrospective non targeted analysis,
26 118 whereas the sample preconcentration step invariably alters the samples representatively.

125 **Table 1:** Target compound list for this study (adapted from King et al. ⁵), by compound group and
 126 in order of increasing number of carbon atoms.

Compound Source	Neutral Formula	Name
Isoprene-derived SOA	C ₄ H ₁₀ O ₄	Meso-erythritol*
Isoprene-derived SOA	C ₅ H ₁₂ O ₄	Methyl-tetrols
Monoterpene-derived SOA	C ₇ H ₁₂ O ₄	Pimelic acid*
Monoterpene-derived SOA	C ₇ H ₁₀ O ₆	1,2,4-butanetricarboxylic acid (BTCA)*
Monoterpene-derived SOA	C ₈ H ₁₂ O ₆	3-methyl-1,2,3-butanetricarboxylic acid (MBTCA)
Monoterpene-derived SOA	C ₇ H ₁₀ O ₄	Terebic acid
Monoterpene-derived SOA	C ₁₀ H ₁₈ O ₃	Pinolic acid
Monoterpene-derived SOA	C ₁₀ H ₁₆ O ₃	<i>Cis</i> -pinonic acid
Monoterpene-derived SOA	C ₁₀ H ₁₄ O ₃	Keto-pinonic acid
Sesquiterpene-derived SOA	C ₁₄ H ₂₂ O ₄	β-caryophyllinic acid
Sesquiterpene-derived SOA	C ₁₅ H ₂₄ O ₃	β-caryophyllonic acid
Sesquiterpene-derived SOA	C ₁₄ H ₂₂ O ₄	β-nocaryophyllonic acid
Biogenic SOA	C ₄ H ₆ O ₅	D-malic acid
Primary biogenic	C ₇ H ₆ O ₃	Salicylic acid
Low molecular weight fatty acids (LFA) (<C24); marine / microbial sources	C ₁₂ H ₂₄ O ₂	Lauric acid
	C ₁₄ H ₂₈ O ₂	Myristic acid
	C ₁₇ H ₃₄ O ₂	Heptadecanoic acid
	C ₁₈ H ₃₄ O ₂	Oleic acid
	C ₁₉ H ₃₈ O ₂	Nonadecanoic acid
	C ₂₀ H ₃₂ O ₂	Arachidonic acid
	C ₂₂ H ₄₄ O ₂	Behenic acid
	C ₂₃ H ₄₆ O ₂	Tricosanoic acid
High molecular weight fatty acids (HFA) (>C24); terrestrial biomass	C ₂₇ H ₅₄ O ₂	Heptacosanoic acid
	C ₂₈ H ₅₆ O ₂	Octacosanoic acid
	C ₃₀ H ₆₀ O ₂	Melissic acid

2. Materials and methods

Sample analysis was carried out by direct injection ultra-high performance liquid chromatography (UHPLC) electrospray ionisation (ESI) high-resolution mass spectrometry (HRMS) with a post-column injection of ammonium hydroxide in methanol.

2.1 Standard solutions and eluents

Bulk standard solutions were prepared in dichloromethane (>99.9%, Optima™, HPLC/MS, Fisher Chemical), and acetonitrile (>99.9%, Optima™ HPLC/MS, Fisher Chemical), and then combined into a diluted standard mixture of all analytes at a concentration of 1 ppm in acetonitrile. Details of the sources and purities of each compound standard can be found in King et al.⁵. Final standards for instrument calibration, quantification of detection limits, and quantification of matrix effects were made at concentrations of 10 ppt, 100 ppt, 1 ppb, 10 ppb and 100 ppb by dilutions with water (>99.9%, Optima™ UHPLC/MS, Fisher Chemical).

2.2 Decontamination protocols

All glassware was baked at 450°C for 8 hrs using the method of Müller-Tautges et al. (2014). Glassware was capped with PTFE lined lids. Solvents were also cleaned using ozonation following the method of King et al.⁵, which has been shown to reduce background contamination of unsaturated fatty acids.

2.3 Instrumental analysis

Analysis was carried out using an UltiMate3000 UHPLC coupled with a Thermo Scientific™ Q Exactive™ Hybrid Quadrupole-Orbitrap MS at the Department of Chemical Sciences, University of Padua, Italy. We utilise this more sensitive instrument than that used in the methodological development of the previous study. The interlaboratory comparison described in the previous study shows how this instrument lowered detection limits to the range of ppt for many compounds, in comparison to the HPLC-ESI-HRMS (with Accela system HPLC (Thermo Scientific, Bremen, Germany) coupled to an LTQ Velos Orbitrap (Thermo Scientific, Bremen, Germany)) at the University of Cambridge, UK, which did not achieve detection limits below ppb concentrations (Table 2). Given that concentrations of compounds detected in preconcentrated samples in King et al.⁵ were in the order of ppb, this more sensitive instrument should allow detection not only of these compounds without preconcentration but may allow detection of previously undetected

1
2
3 163 compounds. This is due in part to the different detectors in the two instruments, which gives the
4 164 Q-Exactive a better sensitivity and thus lower detection limits. Similarly, a triple quadrupole mass
5 165 analyser may provide better sensitivity for SOA compounds while it would not give reliable
6 166 determination of unsubstituted fatty acids when using HPLC with an ESI source. This is because
7 167 the fragmentation used in the single and multiple reaction monitoring when using triple quadrupole
8 168 mass analysers cannot be exploited for the determination of unsubstituted fatty acids which would
9 169 lose the only functional group that can be easily ionised (the carboxylic group). Further factors
10 170 giving the Q-Exactive better sensitivity are that the ionic path is much shorter than for the Velos,
11 171 resulting in less ion scattering, and that the Q-Exactive has an enhanced vacuum, increasing the
12 172 electronic performance. There are also factors which are unique to every instrument set-up and
13 173 specific laboratory environment: the contamination introduced into the instrument is dependent
14 174 on the working environment in which the instrument sits, the previous samples analysed and also
15 175 the age of the instrument. Beside these, removing a sample pre-concentration procedure may
16 176 reduce potential contaminations introduced during sample handling. In this study we account for
17 177 these factors by repeating some optimisation steps applied to the previously used instrument, as
18 178 discussed further in section 3.1.

19 179 The optimised settings of the instrument were those developed by King et al. ⁵ and were as
20 180 follows; the LC injected sample volumes of 20 μ L and used a Waters XBridge™ C18 (3.5 μ m,
21 181 3.0x150 mm) column with the mobile phases (A) water with 0.5 mM NH_4OH and (B) methanol
22 182 with 0.5 mM NH_4OH . The gradient programme was 0–3 min 0% B, 3–4 min linear gradient from
23 183 0% to 30% B, 4–9 min 30% B, 9–10 min linear gradient from 30% to 100% B, 10–25 min 100%
24 184 B, 25–26 min linear gradient from 100% to 0% B, 26–35 min 0% B, with a 250 μ L/min flow rate at
25 185 20°C. We applied a post-column injection of methanol with 5 mM NH_4OH at a flow rate of
26 186 100 μ L/min. MS analysis was performed in negative ionisation using the following ESI source
27 187 parameters: 400°C source temperature, 40 arbitrary units (a.u.) sheath gas flow rate, 20 a.u.
28 188 auxiliary gas flow rate, 3.5 kV needle voltage, 350°C transfer capillary temperature, S-Lens RF
29 189 Level 50%. MS spectra were collected in full scan, with a resolution of 70 000 at m/z 400, in the
30 190 mass range m/z 80–600 and in MS/MS for all target compounds with a collision-induced
31 191 dissociation (CID) energy of 30 (normalized collision energy). Instrumental calibration was carried
32 192 out routinely to within an accuracy of \pm 2 ppm, using Pierce LTQ Velos ESI Positive Ion Calibration
33 193 Solution and a Pierce ESI Negative Ion Calibration Solution (Thermo Scientific, Bremen,
34 194 Germany).

1
2
3 195 Calibration for quantification of target analytes was carried out at the start of each sample series,
4 196 for which analysis took approximately 60 continuous hours, using standard solutions of 10 ppt, 100
5 197 ppt, 1 ppb, 10 ppb and 100 ppb. Deuterated internal standards d3-malic acid, d10-pimelic acid and
6 198 d31-palmitic acid at a concentration of 10 ppb were used as internal standards to adjust
7 199 concentrations accounting for methodological and instrumental variability. Quality check
8 200 standards solutions at a concentration of 10 ppb have also been analysed every 10 samples to
9 201 ensure no changes in detection sensitivity throughout the sequence of analysis.
10
11
12
13
14
15

16 202 **2.4 Sample preparation**

17 203 Ice samples analysed were from the Belukha glacier ice core, Russian Altai mountains, for which
18 204 details on drilling, transportation and cutting can be found in Olivier et al. ⁸. A total of 18 samples
19 205 were tested representing ice from a range of ice-core ages, accounting for differences in ice
20 206 chemistry and physical ice properties which may affect analysis. These were 12 samples from
21 207 1866-1869, and 6 samples from 1821-1823.
22
23
24
25

26 208 Sample sections were cut to avoid the outer-most ice of the core, which has been exposed to
27 209 potential contamination. Additionally, once cut, samples for the analysis of organic compounds
28 210 were scraped with a metal scalpel to remove cut surfaces and placed directly in pre-cleaned
29 211 amber glass vials with PTFE lined caps. Samples were stored at -25°C before melting in sealed
30 212 vials inside a class 100 clean room, at approximately 16°C. Each sample represented 10 cm ice
31 213 core resolution, equivalent to sub-annual resolution. 1 mL of the well-mixed sample was
32 214 transferred to a glass LC-MS vial and spiked with 10 ppb deuterated standards for immediate
33 215 analysis.
34
35
36
37
38
39
40

41 216 **3. Results and discussion**

42 217 **3.1 Methodological optimisation**

43 218 While the HPLC-MS method was optimised in our previous study (⁵), some parameters were re-
44 219 tested to ensure the methodology was appropriate for the new instrument (i.e. the Q Exactive™
45 220 Orbitrap MS). This particularly included steps in reducing background contamination, which can
46 221 be different for individual compounds depending on the instrument and lab environment being
47 222 used.
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 223 The repeated tests were: testing of non-ozonated and ozonated solvents, testing of the inclusion
4 224 of a post-column injection, and the application of MS-MS analysis to ensure correct identification
5 225 of peaks in the mass spectra.
6
7

8
9 226 On average, the application of a post column injection of 5 mM NH₄OH in methanol increased
10 227 peak areas by 1.5 to 2 times compared to peak areas without a post-column injection. The use of
11 228 ozonated solvents was again shown to be effective at reducing background contamination of
12 229 unsaturated fatty acids which break down during ozonolysis; in non-ozonated solvents these
13 230 compounds were present at contamination levels of ≥ 10 ppb, while ozonated solvents allowed
14 231 detection at as low as 10 ppt.
15
16
17
18

19 232 Instrumental analysis showed that the retention time of some compounds shifted when comparing
20 233 preconcentration/direct injection analysis. This is because the solvent of the final sample (and
21 234 standard solutions) is different in the two cases; in the preconcentrated samples the solvent is
22 235 methanol, used to re-dissolve the compounds from the rotary evaporation vial. In direct injection,
23 236 the solvent is the snow melt water of the sample or LC-MS water for the standard solutions. The
24 237 retention times for the direct injection, aqueous sample are presented in Table 2. In general, the
25 238 retention times of SOA compounds are slightly shorter while retention times of fatty acids are
26 239 longer for samples and standard solutions in water compared with methanol ⁵.
27
28
29
30
31
32
33

34 240 **3.2 Methodological validation**

35 241 Instrumental LODs were evaluated on standard solutions prepared in water to match the matrix
36 242 of the ice samples. Calculation used the Hubaux-Vos method, following IUPAC recommendations
37 243 ^{9,10}. Limits of quantifications (LOQs) are $10/3 \times \text{LODs}$. Sensitivity (slope of the calibration line) and
38 244 linearity range were tested using both the r-Pearson correlation test and the F-test to compare
39 245 linear and quadratic fits. Results showed a good linearity in the tested range (10 ppt-100 ppb) for
40 246 all compounds. Method/instrumental repeatability was evaluated in real ice core samples.
41 247 Validation parameters are reported in Table 2.
42
43
44
45
46

47 248 Matrix effects of direct-injection samples were tested by comparing the linear calibration lines of
48 249 two different sets of prepared standards, each analysed in triplicate; one set of 1 ppb, 10 ppb,
49 250 and 100 ppb concentrations diluted with water (external calibration), and another of the same
50 251 concentrations diluted with ice-sample melt made by pooling together aliquots of the different ice
51 252 samples analysed in this study (internal calibration). Comparison of the slopes of the lines, using
52 253 a t-test, was used to evaluate the difference in values quantified between the two standard types.
53
54
55
56
57
58
59
60

1
2
3 254 This approach was used instead of the post-column infusion and post-extraction addition
4 protocols ¹¹ due to unavailability of blank samples (i.e. melted ice samples free from target
5 255 analytes). Results show (Table 2) the presence of a small but significant matrix effect for most of
6 256 the analytes. Analytes with lower background contaminations are generally also less affected by
7 257 matrix effects while compounds with higher background contaminations are more affected by
8 258 matrix effects (e.g. fatty acids). Isotopically labelled (deuterated) standards do not compensate
9 259 for matrix effects, probably due to slight differences in lipophilicity and ion suppression effects, as
10 260 observed in previous studies ^{12,13}.

294 3.3. Method comparison

295 A method comparison was done to assess the accuracy of the direct injection UHPLC-ESI-HRMS
296 method, comparing ice samples from the Belukha glacier ice core measured both with the method
297 developed in this study and with the method developed by King et al. ⁵. The method of King et al.
298 ⁵ used rotary-evaporation to preconcentrate the samples before analysis with HPLC-ESI-HRMS
299 using an Accela system HPLC (Thermo Scientific, Bremen, Germany) coupled to an LTQ Velos
300 Orbitrap (Thermo Scientific, Bremen, Germany) ⁵. An inter-laboratory comparison has already
301 been carried in King et al. ⁵ showing that sample concentrations measured on the previously used
302 instrument are reliably reproduced on the instrument used in this study, and therefore our sample
303 concentrations of the preconcentrated method are accurate and may be reliably compared to the
304 direct injection samples.

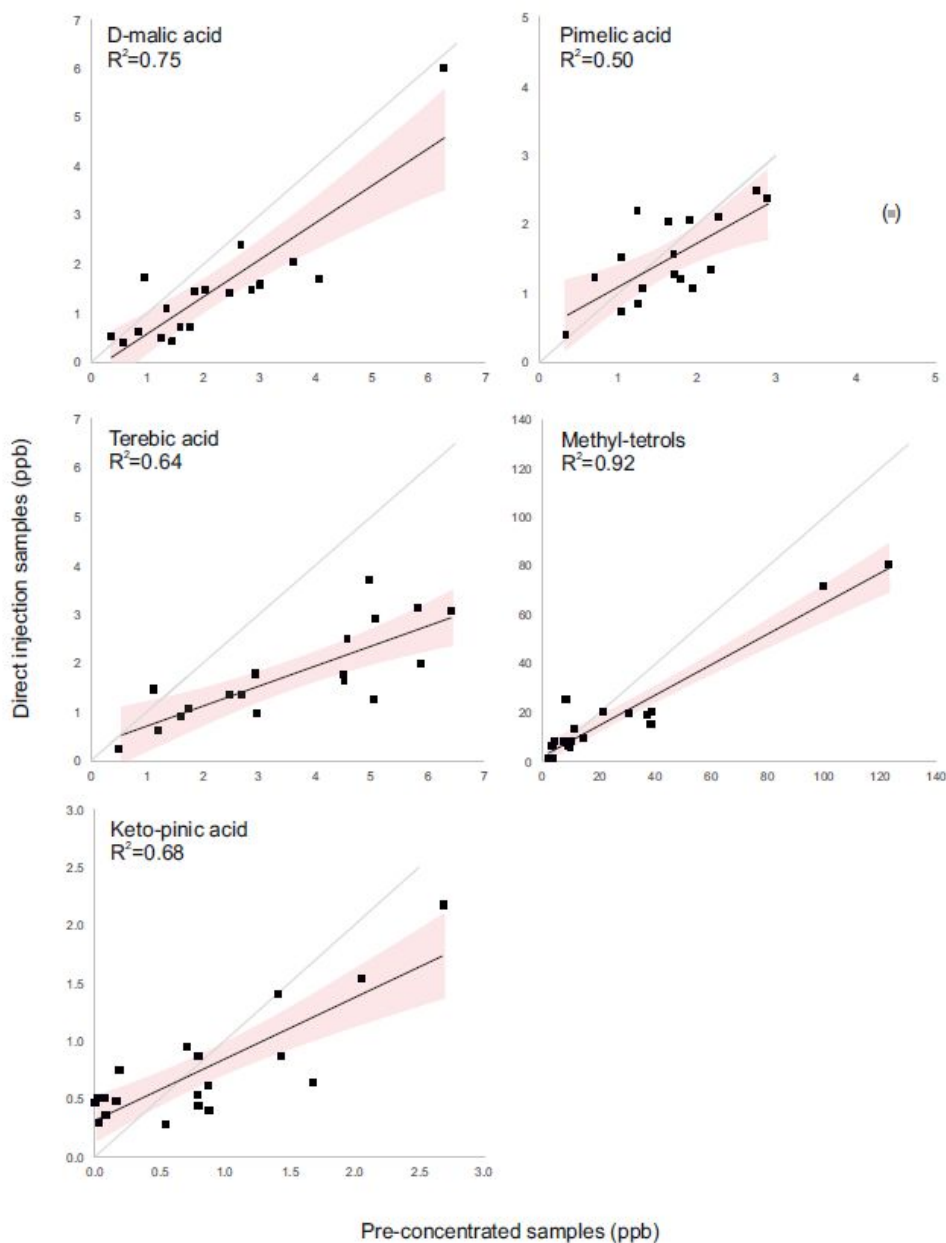

305 Compounds detected in the preconcentrated Belukha samples were as follows; D-malic acid,
306 terebic acid, methyl-tetrols, pimelic acid, keto-pinonic acid, cis-pinonic acid, heptacosanoic acid,
307 octacosanoic acid, and melissic acid. MBTCA was detected in a very few samples above
308 detection limits. In the direct injection method compounds detected were MBTCA, D-malic acid,
309 terebic acid, methyl-tetrols, pimelic acid and keto-pinonic acid. BTCA and cis-pinonic acid were
310 detected in some of the direct injection samples, but in others were below LODs. In comparison,
311 the direct injection promoted BTCA and MBTCA detection, as recovery percentage for both
312 compounds in preconcentrated samples was only 3%, the lowest value observed for all
313 compounds [5], which results in values falling below LOD in these samples. Avoiding this
314 drawback, the direct injection method successfully detects MBTCA in all samples well above
315 LODs.

316 All of the fatty acids detected with the pre-concentration technique were below detection limits in
317 the direct injection samples; this is because background contamination levels were high in these
318 experiments, and consequently so are LODs.

319 The results of the comparison between the preconcentrated and direct injection samples are
320 shown in Figure 1, as scatterplots representing the reproducibility of final concentration values in
321 the samples. The scatterplots show good linearity for all compounds, indicating that trends in the
322 sample timeseries are reliably reproduced. For some compounds, the linear trend lines deviate
323 from the 1:1 ratio line, for example terebic acid. This difference is not accounted for by matrix
324 effects evaluated using a test ice-sample melt (see section 3.2 for details). However, each

1
2
3 325 individual ice sample would be characterized by a different matrix composition, which may affect
4 326 quantification differently from one sample to another. In each case, the deviation from the 1:1 ratio
5 327 line suggests either a lower-than-expected sample concentration in the direct injection samples,
6 328 or higher-than-expected concentration in the pre-concentrated samples. This may be because
7 329 pre-concentrated samples are finally analysed in methanol, used to re-dissolve the samples from
8 330 the dried vial following rotary evaporation, whereas direct injection samples are measured in the
9 331 original snow melt. It would be expected that methanol is an overall cleaner sample as the lower
10 332 solubility discourages the presence of inorganics in the sample which may otherwise interfere
11 333 with the ionisation of the analytes in the ESI source. Ideally, matrix effects could be accounted for
12 334 by using an internal calibration. However, this is not a viable alternative for this application due to
13 335 limited amount of sample available for the analysis.

14
15
16
17
18
19
20
21 336 The observed offset, where large enough to be significant such as for terebic acid, may be
22 337 quantified and accounted for in further analysis.

339 **Figure 1:** Scatterplots representing comparisons between final sample concentrations of each of
340 direct injection and preconcentration methods of analysis of replicate environmental samples.
341 Linear trendlines and associated R^2 values are presented to assess reproducibility, and error
342 bands at 95% confidence intervals shown in pink. The bracketed outlying point in the pimelic acid
343 plot is shown but not included in the trend line and R^2 value. Compounds shown are those with a
344 complete dataset (i.e. no sample concentrations below detection limits).

1
2
3 345 Because of the poor detection of MBTCA in the pre-concentrated samples, we cannot assess the
4 346 reproducibility of this compound compared to direct injection. We instead compare to previously
5 347 reported ions in the ice core ¹⁴ to see if overall trends detected in the sample series appear
6 348 reasonable. Figure 2 compares MBTCA to sulfate. Sulfate was chosen for comparison as it
7 349 showed the most significant correlation to MBTCA of all other measured ions in the core
8 350 ($R^2=0.55$). We display only the corresponding sample numbers since environmental interpretation
9 351 is outside the scope of this study. The record shows that both compounds display similar trends
10 352 over time, with peaks coinciding with mid-year summertime. Therefore MBTCA measured by
11 353 direct injection produces results that are reasonable with previous findings. Indeed, this is also
12 354 the case for all other new organic compounds detected i.e. trends match those of previously
13 355 detected ions. However we save presentation of these results for future work alongside
14 356 environmental interpretation.

357

358

359 **Figure 2:** MBTCA and sulfate concentrations measured in a time series of ice core samples.

360 4. Conclusions

361 A method for analysing a series of organic compounds in ice core samples by direct injection
362 UHPLC-ESI/HRMS is presented. This method is beneficial in reducing the required sample
363 volume and the potential for contamination generated by sample pre-concentration steps. The
364 method provides LODs of 0.01-3.02 ppb for SOA compounds, and 0.44-15.75 ppb for fatty acids,
365 with average instrumental repeatability of 7%. Small, but significant, matrix effects (~10% on
366 average) were determined.

1
2
3 367 This direct injection analytical method is particularly suitable for SOA compounds which showed
4 368 low recoveries in pre-concentrated samples, e.g. MBTCA, and which are significantly above
5 369 detection limits only with direct injection analysis. Other SOA compounds, detected more clearly
6 370 than MBTCA in pre-concentrated samples, were also detected with similar sensitivity in direct
7 371 injection samples. Many of the studied tracers showed good reproducibility in final sample
8 372 concentrations in both analytical methods, while others showed a lower-than-expected
9 373 concentration in direct injection samples compared with pre-concentrated samples. This can be
10 374 accounted for by differences in sample matrices or ionisation efficiency in samples analysed with
11 375 the two techniques, and can be adjusted for in final sample concentrations.

12
13
14 376 Direct injection is less suitable for fatty acid compounds; their high background contamination
15 377 results in high detection limits, and thus these compounds are more suited to analyses after a
16 378 pre-concentration. Alternatively, detection limits for these compounds require new, tailored,
17 379 cleaning protocols to reduce background contaminations in the solvents and in the instrument
18 380 itself before direct injection analysis.
