Vibration Induced to the Cyclist

ABSTRACT

Apollo

Improving comfort in road bicycle design is a paramount concern for cyclists, who are affected by the vibrations caused by constant contact with the road surface. The cycling community has deployed many efforts in the attempt to understand and improve bicycle comfort. However, these attempts have been focused on specific components such as the fork, frame and wheels without knowing their relative influence on vibration induced to the bicyclist (VIB). The objective of this paper is to assess the relative contribution of bicycle components on the VIB at the cyclist's hands and buttocks. A factorial design test comparing the VIB in acceleration, force and power of different bicycle components has already shown that the handlebar and fork are the preponderant components for the VIB measured at the cyclist's hands. At the buttocks, the preponderant components are the wheels and frame.

Keywords: Bicycle Dynamic Comfort, Bicycle Testing, Factorial Design, Vibration Measurement,

1. INTRODUCTION

Road cycling is a sport in which equipment design has a major impact on the cyclist's overall performance and experience. As this sport has progressed over the years, most of improvements in bicycle design have been focused on reducing the bicycle's mass and aerodynamic drag, and on increasing stiffness. More recently however, the ride quality of road bicycles has become a more desirable characteristic for users as well as an important design issue for bicycle manufacturers. If we want the cyclist to "fit" properly on the bicycle, then we need to consider that the quality of the ride is most closely related to the level of vibration transmitted from the road to the cyclist via the various components of the bike.

In the process of increasing the quality of the ride and improving cyclist comfort, the assessment of the vibrations induced to the bicyclist (VIB) is an essential step and an active research topic in sports engineering. This research topic is divided into three parts: (1) developing force transducers, (2) developing excitation techniques, and (3) investigating the characteristics of a bicycle that reduce the VIB.

An important part of research on VIB is the development of bicycle force transducers such as instrumented pedals, stems and seat posts. These transducers measure loads at the contact interface between the cyclist and the bicycle ¹⁻⁶. They also enable us to assess a metric to quantify VIB with the ultimate goal of reducing it. Richard et al. ⁷ used force and energy transmitted to the cyclist measured by an instrumented stem to investigate comfort. Vanwallenghem et al. ⁸ also used an instrumented handlebar and seat post to measure the absorbed power as a metric for cyclist comfort.

Embedded force transducers and accelerometers have been incorporated on instrumented bicycles to measure VIB with different excitation techniques. The most common excitation technique for a bicycle is to ride on a road ⁸⁻¹². The VIB has also been measured using different excitation techniques in the controlled environment of the laboratory. Hastings et al. ¹³ compared the VIB among three bicycle frames mounted by a cyclist on a treadmill. Thite et al. ¹⁴ compared the VIB between two different mountain bike frames and a dummy cyclist excited by a shaker. Lépine et al. ¹⁵ developed a test rig that mimics the road excitation in a laboratory in order to compare the VIB between different bicycles. Bicycle component vibration transmissibilities were also compared using an incomplete bicycle assembly. For example, wheel transmissibility was studied via different test rigs; one developed by Petrone et al. ¹⁶ and the other developed by Lépine et al. ¹⁷.

Force transducers and excitation techniques allowed some research on the bicycle's characteristics that could reduce VIB. The fork and frame structural damping effect on bicycle vibrational behaviour and VIB were studied ^{14,18,19}. The modal proprieties and mode shapes of bicycles were also studied in order to provide a better understanding of bicycle dynamic response to improve comfort ^{20,21}. The relationship between VIB and wheel set characteristics such as tire pressure, number of spokes, rim material, radial stiffness, etc. has also been studied and discussed in the literature ^{10,11,16,17,22}.

Several attempts have thus been made to understand the effect of a bicycle's characteristics on vibrational behaviour and to ultimately increase cyclist comfort. However, these studies have been focused on specific components such as the fork, frame and wheels without knowing their relative influence on VIB on a fully assembled bicycle. The objective of this paper is to assess the relative contribution of bicycle components on the VIB at the cyclist's hands and buttocks. This will draw the cycling community's attention to the VIB preponderant components during the selection and assembly of components in order to design more comfortable bicycles.

2. METHODOLOGY

The relative contribution of road bicycle components on VIB is determined via a factorial design experiment. This factorial design investigates the effect of all possible combinations of the factor levels on the VIB. In this case, the factors represent the bicycle component categories and are separated into two levels: the lowest (-) and the highest (+) vibration transmitting component. In other words, the bicycle assembly is divided into 5 factors (bicycle component categories): wheels, fork, frame, stem and handlebar. As well, each factor has two different levels (component selection): the components with the lowest (-) and the highest (+) VIB level. The seat post and the brake hood are used as transducers; consequently they were not included in these factors. The method used to measure and compare VIBs between component categories is presented in part (a) of this paper. Part (b) presents how the factor levels are selected to finally perform the factorial design experiments used to quantify the relative contribution of road bicycle component categories on VIB detailed in part (c).

a) VIB measurement method

In this paper, VIBs are measured on a bicycle in the controlled environment of the laboratory. The bicycle is vertically excited by a road simulator composed of two hydraulic shakers positioned under the wheels (Fig. 1). These shakers reproduce a 30 second excitation simulation of a bicycle at 26 km/h on a granular road as described by Lépine et al. ¹⁵. A cyclist is seated on the bicycle during the measurement. The cyclist's position is controlled by the static force applied by the hands on the handlebar. The hands are resting (not grasping) on the brake hoods and the pedals are set at a horizontal position.

Fig. 1 Bicycle excitation setup: the road simulator

VIBs are measured at three different cyclist contact points on the bicycle depending on the test performed: (1) the vertical force and acceleration transmitted via the saddle and to the cyclist's buttocks is measured with a strain gauge instrumented seat post and a PCB 352C65 accelerometer (Fig. 2); (2) the force and the acceleration transmitted via the handlebars to the cyclist's hands is measured with a strain gauge instrumented stem and a PCB 352C68 accelerometer (Fig. 3); (3) the force and the acceleration transmitted to the cyclist's hands is measured with a strain gauge instrumented brake hood and a PCB 352C68 accelerometer under the hands (Fig. 4).

Using instrumented bicycle components, three measurands are used to quantify the level of VIB: (1) the acceleration a_{VIB} , (2) the force F_{VIB} and (3) the absorbed power P_{VIB} . Seat post a_{VIB} and F_{VIB} are calculated using the RMS value of the transducer signal filtered with the 2631 ISO standard vertical frequency-weighting curves for whole body transmitted vibrations ²³. The stem and brake hoods a_{VIB} and F_{VIB} are

calculated at all contact points with the combination of the force and velocity. The velocity is calculated from the integration of the accelerometer time signal.

Fig. 3 Instrumented stem: (a) transducers position; (b) applied position of the measured force

Fig. 4 Instrumented brake hood: (a) transducers position; (b) applied position of the measured force

b) Factor levels selection

To define the levels of each factor (bicycle component category) used in the factorial design, the VIB level of several components available on the market were compared and ranked. The ranking was done by swapping the component on the same bicycle and measuring the VIB variation in acceleration, force and power. The component with the highest VIB level will be the (+) in its respective category (factor) and vice versa. The list of components and the characteristics of each factor are presented in Table 1-6. The dimensions of the components were selected to keep the cyclist's position as constant as possible.

The wheel set transmission ranking was done by comparing the VIB variation between different front wheels (Table 1). Identical clincher or tubular tires were installed on the rim, i.e. Vittoria Rubino Pro Slick 700x23c with Vittoria inner tube for the clincher tire and Vittoria Corsa CX 21-28' for the tubular tire. The width is the axial length of the rim and the depth is the radial length of the rim. The total mass includes the wheel and the tire but not the skewer.

The Fulcrum 7 rear wheel was installed on the bicycle frame during every comparison. Each wheel was tested 5 times in a random order. The VIBs were measured in force, acceleration and power at the brake hoods for wheel rankings. The same cyclist, frame, fork, stem and handlebar were used for all tests. The tire pressure was set at 8 bars.

Only the front wheels were compared due to wheel set availability. Nevertheless, the factorial design includes both the front and the rear wheels as one factor. The hypothesis is that the front and rear wheel dynamic is similar; the lowest or highest transmitting front wheel should also be the lowest or highest transmitting rear wheel.

Name	Tire	Number	Spoke	Spoke	Rim	Rim	Rim	Total

FACT			

The frame transmission ranking was obtained by comparing the VIB variation at the brake hoods and the seat post using different frames (Table 3). The frame size is the size given by the frame manufacturer. The top

tube length is the horizontal distance between the head tube and top tube junction to the seat tube (or its prolongation). The total mass included the bottom bracket and the seat post clamp.

Each frame was tested 7 times in a random order. The VIBs were measured in force, acceleration and power at the stem and the seat post. The same cyclist, fork, wheel set, stem and handlebar were used for all tests. The tire pressure was set at 8 bars.

Name	Material	Size	Top tube length	Total mass

Cervelo R5ca	Carbon	56	56.4	800	

Table 3. Components tested for the frame factor

The stem transmission ranking was done by comparing the VIB variation at the brake hoods using different stems (Table 4). The stem length is the distance between the center of the fork and the handlebar attachment. The total mass includes all the stem's screws. Each stem was tested 6 times in a random order. The same cyclist, frame, fork, wheel set and handlebars were used for all tests. The tire pressure was set at 8 bars.

3T ARX-PRO	Aluminum	110	132
3T ARX-LTD	Carbon	110	126
FSA OS-99 CSI	Aluminum wrapped with Carbon	110	141

The handlebar transmission ranking was done by comparing the VIB variation at the brake hoods between different handlebars (Table 5). The width is the overall dimension of the handlebar. Every handlebar was tested 5 times in a random order. The same cyclist, frame, fork, wheel set and stem were used during these tests. The tire pressure was set at 8 bars.

c) Factorial design plan

Once the (-) and (+) levels of each factor (bicycle component) were defined, the factorial design was conducted. To assess the relative contribution of the bicycle components, the VIB level for each factor combination is measured. A sample combination is: wheels (-) with the fork (-), frame (+) and handlebar (-). Even though five factors were considered in the selection, only four are included in the factorial design:

wheels, fork, frame and handlebar. The stem is excluded from the factorial design because no significant difference was measured between the tested stems. This exclusion is explained in the factor selection results and analysis (presented in Section 3.a-b).

The factorial design used was a 2^4 factorial performed in 4 blocks (measurement session) with 2 replicates completely randomized for a total of 32 combinations (Table 6-7). The experiment design is made of blocks of 8 combinations to ensure that testing can be performed in a relatively short timeframe (about 2 hours including assembly and disassembly). Dividing up the test in this way minimizes the tester's level of fatigue, as well as any natural variations in dynamic behaviour and other time-dependent phenomena that could alter the measurements.

Two techniques are used to increase the degree of freedom of the analysis and therefore increase the statistical power: the combinations are replicated twice and only the main factor and two-factor interactions effect are included in the analysis²⁵.

3. RESULTS AND ANALYSIS

The experimental results are separated in two parts. Part (a) presents the results from the factor level selection tests and these results are analysed in part (b). Part (c) presents the results of the factorial design based on the factor level selection made in part (b). The factorial design results are analysed in Part (d).

a) Factors levels selection results

The significant levels (*p*-value) of the three measurands are calculated by means of an ANOVA (analysis of variance) at the measurement points for each factor levels selection test (Table 8). When the *p*-value is below 0.05, a significant difference of VIB between the bicycle's components tested is concluded.

Factor	Measurement point	<i>p</i> -value for a_{VIB}	<i>p</i> -value for F_{VIB}	<i>p</i> -value for P_{VIB}
Wheel	Left Brake Hood	0.164	0.115	0.000
	Right Brake Hood	0.208	0.084	0.000
Fork	Left Brake Hood	0.280	0.017	0.000
	Right Brake Hood	0.201	0.263	0.000
Frames	Stem	0.000	0.007	0.000
	Seat Post	0.000	0.016	0.003
Stem	Left Brake Hood	0.967	0.644	0.282

	Right Brake Hood	0.038	0.000	0.000

Table 8 *p*-value of the factor levels selection tests

The key results of Table 8 and Figures 5-10 are:

VIB comparison between the front wheels at the right and the left brake hoods (Fig. 5)

- A significant difference is measured for P_{VIB} at both measurement points.
- Wheel ranking is similar for both brake hoods.

VIB comparison between the forks at the right and left brake hoods (Fig. 6)

- A significant difference is measured for F_{VIB} and P_{VIB} at the left brake hood but at the right brake hood, a significant difference for only P_{VIB} is measured.
- Fork ranking is similar for both brake hoods.

VIB comparison between the frames at the stem and seat post (Fig. 7 and Fig. 8.)

• A significant difference is measured with all three measurands at both measurement points.

VIB comparison between the stems made at the right and the left brake hoods (Fig. 9)

• No significant difference is measured at either brake hoods.

VIB comparison between the handlebars made at the right and the left brake hood (Fig. 10)

• A significant difference is measured with all three measurands at both measurement points except for $a_{\rm VIB}$ measured at the left brake hood.

b) Factors levels selection analysis and discussion

The objective of this section is to select the lowest and highest transmitting component for each factor. These selected components will be respectively the (-) and (+) level. The selection is summarised in Table 9.

The wheel level selection is based on P_{VIB} values because it is the only measurand that has a significant impact on both measurement points (Table 8). The lowest transmitting wheel is the Zipp 202 and the highest is the Fulcrum 7 (Fig. 5 c).

Like the wheel selection, the fork level selection is based on absorbed power P_{VIB} values because it is the only measurand that has a significant impact on both measurement points (Table 8). The lowest transmitting fork is the Specialized Roubaix Fact and the highest transmitting fork is the Easton EC90SL (Fig. 6 c).

The frame level selection is based on all three measurands and both measurement points because they all present significant differences (Table 8). As seen on Fig. 7 and Fig. 8, the Cervélo R5ca is the lowest transmitting frame at 4 measurands out of a total of 6 and the Masi Gran Criterium is the highest transmitting frame at 4 measurands out of a total of 6. These frames are therefore the (-) and (+) level for the frame factor.

No significant difference can be made between the tested stems (Table 8). The stem factor is therefore excluded from the factorial design.

The handlebar level selection is based on the measurands presenting a significant difference on both measurement points, i.e. a_{VIB} , F_{VIB} and P_{VIB} at the right brake hood and F_{VIB} and P_{VIB} at the left brake hood (Table 8). The 3T Ergonova LTD and the 3T Ergonova Pro are respectively the lowest and highest transmitting handlebars except for the a_{VIB} at the right brake hood. They will be respectively the (–) and (+) level for the handlebar factor.

The power absorbed by the cyclist (P_{VIB}) seems to be the most consistent measurand because it allows the lower *p*-value in the factor levels selection (Table 8). It is also the only measurand that presents the same result at the left and right brake hoods in the factorial design.

Factor	(-) level	(+) level		
Wheels	Zipp 202	Fulcrum 7

Table 9. Factors level selection

c) Factorial design results

The standardized effect of each factor (bicycle component) and component interaction are represented with Pareto charts for each measurand. In these charts it is also possible to assess the VIB variation percentage explained by the sum of the more influent components and their interaction. Discrepancies between the effect of the factors' ranking at the left and right brake hoods are explained by the asymmetric dynamic behaviour of the cyclist. These discrepancies are mainly seen on factors with a lower effect on the VIB.

Table 10. Component ranking contribution explaining at least 80 % of the VIB variations at 5 % significance for each measurement point

The key results of Table 10 and Figures 11-16 are:

Regarding *a*_{VIB} at the brake hoods (Fig. 11)

- The fork and wheels are the 2 factors with the most influence.
- At the left brake hood, the handlebars, wheels/fork and wheels/handlebar interactions do not have a significant effect on *a*_{VIB}.
- The effects of the first 6 factors and interactions (from fork to fork/handlebar, Table 10) account for 82 % of the *a*_{VIB} variation measured at the left brake hood.
- At the right brake hood, in addition to the fork and wheels, the wheel/fork interaction and the handlebar have a significant effect on a_{VIB} .
- These first 4 factors and interaction effects (Table 10) account for 66 % of the a_{VIB} variation measured at the right brake hood.

Regarding *F*_{VIB} at the brake hoods (Fig. 12)

- The handlebars and fork are the 2 factors with the greatest influence.
- All factors have a significant effect on F_{VIB} the interactions do not except for the wheels/fork interaction at the left brake hood and the fork/frame interaction at the right brake hood, which have an effect on F_{VIB} .
- The effects of the first 4 factors and interaction (from handlebars to wheels/fork, Table 10) account for 80 % of the *F*_{VIB} variation measured at the left brake hood.
- The effects of the first 5 factors and interactions (from handlebar to wheels, Table 10) account for 82 % of the F_{VIB} variation measured at the left brake hood.

Regarding *P*_{VIB} at the brake hoods (Fig. 13)

- The handlebars and fork are also the 2 most influential factors followed by the other factors.
- At the left brake hood, only the handlebar interactions (fork/handlebar, wheels/handlebar and frame/handlebar) do not have a significant effect on P_{VIB} .

- The effects of the first 5 factors and interaction (from handlebar to wheels/fork, Table 10) explain 83 % of the P_{VIB} variation measured at the left brake hood.
- At the right brake hood, the wheels/fork, frame/handlebar and fork/handlebar interactions do not significantly effect *P*_{VIB}.
- The effects of the 4 factors (from handlebar to frame, Table 10) account for 81 % of the P_{VIB} variation measured at the right brake hood.

Regarding *avib* at the seat post (Fig. 14)

- The wheels and frame are the 2 factors with the greatest effect.
- In addition to these factors, only the wheels/frame and fork/frame interactions have a significant effect on *a*_{VIB}.
- The effects of the 3 first factors and interactions (from wheels to wheels/frame, Table 10) account for 87 % of the *a*_{VIB} variation measured at the seat post.

Regarding *F*_{VIB} at the seat post (Fig. 15)

- Wheels and wheels/frame interactions are the 2 factors with the most influence and the only ones with a significant effect on F_{VIB} .
- The effects of the two factors account for 48 % of the F_{VIB} variation measured at the seat post (Table 10).

Regarding PVIB at the seat post (Fig. 15)

- The wheels and frame are the two factors with the greatest effect.
- In addition to these, the wheel/frame interaction is the only other factor with a significant effect on P_{VIB} .
- The effects of these first 3 factors account for 81 % of the P_{VIB} variation at the seat post (Table 10).

d) Factorial design analysis and discussion

Determining the predominant factors (bicycle components) on the VIB is not trivial because these depend on the measurement point and the measurand considered. At the brake hoods, for example, the fork and wheels are the most influential factors for a_{VIB} , but for F_{VIB} and P_{VIB} it is the handlebar and the fork. Only the fork is one of the most influential factors for each measurand at the brake hoods.

For F_{VIB} and P_{VIB} at the brake hoods, the handlebar and the fork account for approximately 50 % of all the variations. This shows their predominance on these measurands. It is only for P_{VIB} that all 4 factors explain at least 80 % of the variation on P_{VIB} . This enables us to assume that component interactions can be neglected when the power absorbed by the cyclist is used to measure VIB.

For a_{VIB} and P_{VIB} at the seat post, the wheels are always the most influential factors following by the frame. For F_{VIB} , the wheels/frame interaction is the second most influential factor and this interaction is the third factor for the other measurands.

For a_{VIB} and P_{VIB} at the seat post, the wheels and frame account for approximately 70 % of the VIB variation and the wheels/frame interaction only account for 17 % and 10 %, respectively, of the VIB variation. That indicates that the wheels and frame are the predominant factors for these measurands.

Regarding the P_{VIB} which was the most consistent measurand in the factor selection, two main conclusions can be made: the handlebar and the fork are the predominant bicycle components for the VIB level at the hands (brake hoods); and the wheels and frame are the predominant bicycle components for the VIB level at

the buttocks (seat post). This means it is important to select a lower-transmitting pair of wheels and frame to reduce the VIB at the seat post. But this does not mean that the other bicycle components do not have any effect. It only means that considering the components tested in this study, it is the wheels and the frame that have the greatest effect on the P_{VIB} at the seat post. The same statement can be made with regard to the brake hood results.

Therefore, to reduce the P_{VIB} at the brake hoods, it is not useful to change the frame if the bicycle is not already equipped with a lower-transmitting fork and handlebar mount, because changing these two components should have a more significant effect on P_{VIB} than changing the frame.

4. CONCLUSION

The aim of this study was to investigate the relative contribution of the bicycle components on the VIB. To achieve this objective, the bicycle was divided into its 5 main components. Four of these bicycle components were used as factors for a factorial design experiment.

For each bicycle component, the lowest and highest transmitting components were defined and used to establish the level for the factors in the factorial design. The selection and factorial analysis were based on 3 measurement points (left and right brake hood and seat post) and 3 different measurands (acceleration, force and power).

The factor levels selection and factorial design results show that the power absorbed by the cyclist is the most consistent of the three measurands to quantify the VIB. According to the P_{VIB} it is the handlebar and the fork that have the greatest effect on VIB at the brake hoods whereas the wheels and frame have the greatest effect on the VIB at the seat post. These results provide valuable insight as to which components must be evaluated in order to improve dynamic comfort.
