**A Tabu Search Methodology for Spacecraft Tour
Trajectory Optimization**

by

Gregory Phillip Johnson, B.S.AS.E., M.S.E.

Dissertation

Presented to the Faculty of the Graduate School of

The University of Texas at Austin

in Partial Fulfillment

of the Requirements

for the Degree of

Doctor of Philosophy

The University of Texas at Austin

December 2014

To my wife Angie, and to my parents Don and Sharon.

Acknowledgments

First and foremost, I want to thank my advisor, Dr. Cesar Ocampo. His guidance and unending support have been invaluable throughout my studies. His enthusiasm was inspiring, and he gave me the freedom to explore many different topics. I am grateful to my committee members: Dr. Wallace Fowler, Dr. David Morton, Dr. Ryan Russell and Dr. Juan Senent, for all of their support and valuable feedback. I would also like to thank Dr. J. Wesley Barnes for introducing me to tabu search and for the discussions along the way.

I have been lucky to develop many long-lasting friendships during my time at the university. I wish to thank Paul Bauman and Victor Calo for helping me to always stay positive, and in particular for their feedback during the dissertation writing process. I would also like to thank Sebastian Munoz and Divya Thakur; it was a pleasure going through the undergraduate and graduate programs with them. I also thank my research group, Mark Jesick, Ricardo Restrepo, Noble Hatten, Drew Jones and Nick Bradley, for the many discussions and the exchange of ideas.

I owe a huge debt of gratitude to my colleagues at the Texas Advanced Computing Center, especially to Kelly Gaither, Paul Navratil and Jay Boisseau, for their support during my graduate studies.

To conclude, and most importantly, I would like to thank my wife Angie and my parents Don and Sharon. None of this would have been possible without their unfailing support and patience.

A Tabu Search Methodology for Spacecraft Tour Trajectory Optimization

Publication No. _____

Gregory Phillip Johnson, Ph.D.
The University of Texas at Austin, 2014

Supervisor: Cesar A. Ocampo

A spacecraft tour trajectory is a trajectory in which a spacecraft visits a number of objects in sequence. The target objects may consist of satellites, moons, planets or any other body in orbit, and the spacecraft may visit these in a variety of ways, for example flying by or rendezvousing with them. The key characteristic is the target object sequence which can be represented as a discrete set of decisions that must be made along the trajectory. When this sequence is free to be chosen, the result is a hybrid discrete-continuous optimization problem that combines the challenges of discrete and combinatorial optimization with continuous optimization. The problem can be viewed as a generalization of the traveling salesman problem;

such problems are NP-hard and their computational complexity grows exponentially with the problem size. The focus of this dissertation is the development of a novel methodology for the solution of spacecraft tour trajectory optimization problems.

A general model for spacecraft tour trajectories is first developed which defines the parameterization and decision variables for use in the rest of the work. A global search methodology based on the tabu search metaheuristic is then developed. The tabu search approach is extended to operate on a tree-based solution representation and neighborhood structure, which is shown to be especially efficient for problems with expensive solution evaluations. Concepts of tabu search including recency-based tabu memory and strategic intensification and diversification are then applied to ensure a diverse exploration of the search space. The result is an automated, adaptive and efficient search algorithm for spacecraft tour trajectory optimization problems. The algorithm is deterministic, and results in a diverse population of feasible solutions upon termination. A novel numerical search space pruning approach is then developed, based on computing upper bounds to the reachable domain of the spacecraft, to accelerate the search. Finally, the overall methodology is applied to the fourth annual Global Trajectory Optimization Competition (GTOC4), resulting in previously unknown solutions to the problem, including one exceeding the best known in the literature.

List of Figures

2.1	A single trajectory segment and its associated initial conditions and decision variables. $\mathbf{z}_{i-1}(t_{i-1})$ represents the state at the initial time. s_i denotes the target object, and \mathbf{y}_i gives the continuous decision variables of the segment including the segment duration Δt_i	15
2.2	A tour trajectory and its associated decision variables. \mathbf{z}_0 represents the initial state at time t_0 . $s_1 \dots s_{n_s} \in O$ denote the sequence of objects visited in the tour, and $\mathbf{y}_1 \dots \mathbf{y}_{n_s}$ give the continuous decision variables of each segment. The tour consists of n_s trajectory segments visiting n_s target objects.	16
2.3	A finite burn trajectory segment. An initial maneuver causes the spacecraft to intercept the target object, and an optional final maneuver causes a rendezvous.	21
2.4	An impulsive trajectory segment. An initial impulse $\Delta \mathbf{V}_{int}$ maneuvers the spacecraft to intercept the target object, and an optional final impulse $\Delta \mathbf{V}_{ren}$ maneuvers the spacecraft to rendezvous with the target.	25
2.5	The impulsive trajectory segment shown in Figure 2.4 with all spacecraft states and discontinuities shown.	26

2.6	A valid finite burn representation of an impulsive $\Delta\mathbf{V}$ maneuver The finite burn begins at time t_{fb_0} , thrusts over a period of time and matches position and velocity with the post-impulse trajectory at time t_{fb_f} [50].	28
2.7	An impulsive trajectory segment with estimates for finite burn maneuvers replacing the impulses.	30
2.8	The finite burn characteristic velocity and duration ratios are shown for the case where gravity losses are considered and for the ideal case. 50 consecutive maneuvers are made for an impulsive ΔV of 1 km/s. The spacecraft parameters correspond to the GTOC4 problem described in Chapter 5.	35
3.1	k tour trajectories are shown with final states $\mathbf{z}_{n_s}^1 \dots \mathbf{z}_{n_s}^k$. Each trajectory shares the previous $n_s - 1$ segments in common. The state \mathbf{z}_{n_s-1} can be used in the computation of the k final segments.	43
3.2	A group of trajectories. Colors identify different objects. The final bright green object is visited with three different segments corresponding to different segment decision variables \mathbf{y}	46
3.3	A detailed view of the tree representation of Figure 3.2 is shown. Children of nodes are numbered in ascending order starting at 0. Paths can be defined with ordered lists of node numbers starting at the root of the tree. States and decision variables are annotated for two paths, corresponding to the superscripts 1 and 2.	47
3.4	All possible tour sequences shown in the tree solution representation for $N_o = 5$ candidate objects and sequence lengths of $n_s = 5$	49
3.5	Number of tours and tree solution representation speedup for total enumeration of $N_o = 100$ candidate objects and segment discretizations of $K = 1, 2, 4, 8$	51

3.6	An annotated tree is shown for an incumbent solution \mathbf{x} . The root of the tree \mathbf{x}_{root} , children nodes $\mathcal{C}(\mathbf{x})$ and parent nodes $\mathcal{P}^k(\mathbf{x})$ are labeled.	55
3.7	The neighborhood definition $\mathcal{N}(\mathbf{x}) = \mathcal{C}(\mathbf{x})$ leads to a depth-first search. At each iteration the incumbent solution moves deeper in the tree.	56
3.8	The neighborhood corresponds to a breadth-first search. The search explores all nodes at the highest level of the tree before progressing deeper.	58
3.9	A group of tour trajectories represented in the tree solution representation. The best-first neighborhood is highlighted.	59
3.10	A group of tour trajectories represented in the tree solution representation. The restricted best-first neighborhoods corresponding to different h values are shown.	61
3.11	The guiding objective contains the objective defined in the problem statement evaluated on the partial trajectory $J(\mathbf{x})$, and a heuristic term based on the parameter $\frac{dJ^*}{dt}$ estimating contributions over the remaining mission time.	64
3.12	The mass and ΔV time histories are shown for maximum continuous thrust until fuel exhaustion and the budgeted amount. The regions where penalties are added to the objective are highlighted. The infeasible regions for a finite burn model and for the final state constraints are shown. The spacecraft parameters correspond to the GTOC4 problem [12].	69
3.13	For the next target object s , a discretized grid of possible new children solutions over the range of allowed τ and Δt values. The set of solutions found to be feasible after evaluation is highlighted.	72

3.14	The tabu list \mathcal{T} is an array of solution attributes that are prohibited in the search. Its length is the tabu tenure $N_{\mathcal{T}}$ and determines how many iterations attributes are considered tabu. As attributes of new incumbent solutions $A(\mathbf{x}_i)$ are added to the list, the oldest tabu attributes are forgotten.	78
3.15	An example search history. The incumbent solution lengths are shown along with the stall condition evaluated for $N_{stall} = 25$ and $\underline{R} = 5$	83
4.1	The values for ΔV_{max} are shown over varying spacecraft initial mass and values of Δt_{max} . The spacecraft parameters correspond to the fourth annual global trajectory optimization competition (GTOC4) summarized in Table 5.2.	97
4.2	Discretization of all possible impulsive maneuvers for a magnitude of ΔV_{max} . The maneuver direction is discretized over the spherical angles α and β for a total of $K_{\Delta V} = K_{\alpha}K_{\beta}$ discretizations.	99
4.3	The trajectories forming a trajectory envelope are shown for $\Delta V_{max} = 1$ km/s and $\Delta t_{max} = 0.55$ years. The spherical angles α and β are each discretized over a 15 degree spacing.	100
4.4	An axis-aligned bounding box bounds a volume in the spatial region of $([x_{min}, x_{max}], [y_{min}, y_{max}], [z_{min}, z_{max}])$. We additionally constrain the bounding box with a time range $[t_{min}, t_{max}]$	102
4.5	$N_{BB} = 10$ bounding boxes are shown for the trajectory envelope of Figure 4.3 ($\Delta V_{max} = 1$ km/s).	105
4.6	The target object bounding box intersections are shown for the case in Figure 4.5.	105
4.7	The bounding boxes associated with trajectory envelopes from the results in Table 4.4.	111

5.1	The set of 1436 asteroids for the GTOC4 problem. The highlighted regions show combinations of semimajor axis and eccentricity for Atiras, Atens, Apollos and Amors near-Earth asteroids [45].	116
5.2	Base case: Best partial and complete solutions found for 1024 runs over launch dates from 2015 to 2025.	124
5.3	Base case: run #409/1024. The objective history for the incumbent solution and best found partial and complete solutions are shown.	126
5.4	Base case: run #409/1024. The trajectory is shown for a $J = -45$ solution rendezvousing with asteroid 2006BZ147.	128
5.5	The best solutions found for the base case and the case ignoring finite burn constraints.	130
5.6	The number of trajectory families found for complete solutions in the base case and the case ignoring finite burn constraints.	131
5.7	Performance of base case (search space pruning) versus case with space pruning disabled for 1024 runs. The run time is constrained to 2 hours. A median of $10.5\times$ more iterations are computed with space pruning enabled, with 95% of runs seeing at least a $5\times$ improvement.	133
5.8	Results of base case (search space pruning) versus case with space pruning disabled for 1024 runs. The run time is constrained to 2 hours. The best partial and complete solutions are shown.	134
5.9	Performance of base case (search space pruning) versus case with space pruning disabled for 1024 runs. 1000 iterations are computed and the run time is unconstrained. The median runtime speedup is $11.0\times$ with 99% of the runs seeing at least a $5\times$ speedup.	135

5.10	The results of the base case are re-run with dynamic neighborhood selection disabled for various static values of the restricted best-first neighborhood parameter h . The best solutions found are shown for each case.	138
5.11	The best solutions found for the static neighborhood $h = \infty$ case and the dynamic neighborhood selection case.	139
5.12	The number of trajectory families found for complete solutions in the dynamic neighborhood selection case and the static neighborhood $h = \infty$ case.	140
5.13	The standard deviation of the incumbent solution length for all runs in the dynamic neighborhood selection case and the static neighborhood $h = \infty$ case.	141
5.14	Reduced spacecraft performance cases compared to base case: Best partial and complete solutions generated by 1024 runs over launch dates from 2015 to 2025.	144
5.15	Reduced spacecraft performance case A: run #622/1024. The objective history for the incumbent solution and best found partial and complete solutions are shown for (a) 2 hour run time and (b) 36 hour run time.	145
5.16	Reduced performance case A: run #622/1024. The trajectory is shown for a $J = -45$ solution rendezvousing with asteroid 2006QQ56.	147
5.17	Reduced spacecraft performance case B: run #402/1024. The objective history for the incumbent solution and best found partial and complete solutions are shown for (a) 2 hour run time and (b) 36 hour run time.	148

5.18	Reduced spacecraft performance case B: run #402/1024. The trajectory is shown for a $J = -43$ solution rendezvousing with asteroid 2006UB17.	150
5.19	Number of trajectory families found versus objective for the base case parameters and a launch epoch of 58676.40 MJD. The search is allowed to run for 12 hours. Only complete solutions are shown. . .	153
5.20	Number of trajectory families found versus objective for the increased spacecraft performance case and a launch epoch of 58676.40 MJD. The spacecraft's maximum allowed thrust T_{max} is increased by 5% from 0.135 N to 0.14175 N. The search is allowed to run for 12 hours. Only complete solutions are shown.	155
5.21	Increased spacecraft performance case: The trajectory is shown for a $J = -45$ solution rendezvousing with asteroid 2000SZ162.	157
5.22	Workflow for GTOC4 solution process. The impulsive search algorithm generates a population of impulsive trajectories. The user then selects specific impulsive trajectories, optimizes them impulsively, and passes them to the black-box finite burn conversion and optimization tool.	160
5.23	Low-thrust finite burn trajectory corresponding to the $J = -45$ impulsive trajectory of the reduced spacecraft performance case shown in Figure 5.16 and Table 5.12.	161
5.24	Low-thrust finite burn trajectory corresponding to the $J = -45$ impulsive trajectory of the reduced spacecraft performance case shown in Figure 5.16 and Table 5.12. The original impulsive trajectory is also shown.	162

Chapter 1

Introduction

1.1 Spacecraft Tour Trajectory Definition

A spacecraft tour trajectory can be defined as a trajectory in which a spacecraft visits a number of objects in sequence. The collection of target objects may consist of satellites, moons, planets or any other body in orbit. The spacecraft may visit these in a variety of ways, for example flying by or rendezvousing with the targets. The conditions that must be satisfied at each target are problem-specific, as are the dynamics of the trajectory and constraints on the spacecraft. The key characteristic however is the target object sequence: this is a discrete set of decisions that must be made along the trajectory. For some missions the sequence may be predetermined, while for others it may be designed to optimize mission objectives. This work focuses on the latter case. The sequence of a tour trajectory may be designed by hand; however, as mission complexity grows this quickly becomes challenging. For such problems there may be a vast number of potential sequences, and enumerating even a fraction of them is not practical. Further, for each single sequence there may exist a continuum of solutions. Developing an automated methodology for finding promising spacecraft tour trajectories, subject to problem-provided constraints and

objectives, is the subject of this work.

1.1.1 Optimization Problem

We can formulate the spacecraft tour trajectory design problem as an optimization problem. The decision variables of the optimization include two principal components: the target object sequence of the trajectory, and the remaining decision variables representing initial conditions, timing and maneuvering information, for example. The sequence decision variables are discrete, belonging to a finite (but potentially very large) set of possible values. Conversely, the remaining decision variables are continuous. The resulting problem is thus a hybrid discrete-continuous optimization problem combining the challenges of discrete and combinatorial optimization with continuous optimization.

We can examine the overall problem by considering its simplifications. First, consider the target object sequence to be predetermined and fixed. This eliminates the discrete decision variables and yields a continuous optimization problem that is treatable using optimal control methods. Numerical methods for continuous optimal control problems can be broadly classified as either indirect or direct methods [13]. Indirect methods are based on analytical necessary conditions from the calculus of variations, and usually require the solution of a nonlinear multipoint boundary value problem [33]. Direct methods instead introduce a parameterization for the control variables, transcribing the continuous optimal control problem into a parameter optimization problem. The control variables are then manipulated directly to optimize the objective function, resulting in a nonlinear programming problem (NLP) [48]. The general optimal control problem is a global optimization problem; however both the indirect and direct methods described so far only find locally optimal solutions. These formulations can be used in multi-stage workflows, for example executing the optimization for a variety of starting conditions [60] or in combination

with metaheuristic approaches [18, 67], to explore the global search space. Further, metaheuristic methods can be used on their own to find optimal solutions in the global search space [66, 61].

We can also simplify the problem by eliminating the continuous decision variables, either by fixing their values or disregarding the dynamics of the problem. The result is then a discrete optimization problem that only considers the target object sequence of the trajectory. If we represent the sequence with integer decision variables, the result is an integer programming problem (IP) [47]. Integer programming problems are NP-hard, and it is widely believed that no polynomial-time algorithms exist for their solution [53]. We can classify solution methods for integer programming problems as either exact or approximate. An exact method finds a provably optimal solution, while an approximate method finds good solutions with no guarantee of optimality. The commonly used exact method for solving integer programming problems is branch and bound. The algorithm systematically enumerates candidate solutions, discarding subsets of solutions based on estimates for upper and lower bounds on the objective being optimized. In the case of minimization, lower bounds are often found by solving relaxations of the original problem—for example by allowing integer decision variables to be continuously valued. Upper bounds representing worst-case best solutions are generated as integer-feasible solutions are found. Dynamic programming is another method applicable to integer programming problems that can be decomposed into simpler subproblems in a recursive manner. The method is based on Bellman’s principle of optimality [10]. Both branch and bound and dynamic programming find globally optimal solutions; however the required computational effort make them impractical for many larger-scale problems. In these cases approximate methods such as metaheuristics can be used. These include evolutionary and genetic algorithms, simulated annealing, particle swarm optimization and tabu search, among others [43]. These methods generally

do not find provably global optimal solutions; their purpose is instead to find good solutions in reasonable compute times. For both exact and approximate methods, space pruning approaches can be used to reduce the size of the search space and reduce the time to solution. For example, cutting plane methods use valid inequalities to prune the search space; when combined with branch and bound these form the basis for branch and cut algorithms [47]. Similarly, other space pruning procedures can be combined with approximate methods to achieve speedups [35].

When we combine both the discrete and continuous components of the optimization problem, we can form a mixed-integer nonlinear programming problem (MINLP) [22]. The focus of this work is on large-scale spacecraft tour trajectory problems, and thus we explore metaheuristic methods for their solution in this study.

1.1.2 Relation to Traveling Salesman Problem

The traveling salesman problem (TSP) is perhaps the most widely studied problem in discrete and combinatorial optimization, and can be considered as a basis for the spacecraft tour trajectory optimization problem [40]. The problem considers a salesman that departs his home city, visits each of a collection of cities, and then returns to his home city upon completion. The optimal tour minimizes the total distance traveled by the salesman. For N cities, there are a total of $(N - 1)!$ possible tours starting from the home city. If the distance between cities is the same regardless of direction, then the problem is symmetric and the search space can be reduced to $\frac{(N-1)!}{2}$ solutions. For $N = 10$, there are nearly 200,000 possible solutions; for $N = 100$, there are more than 10^{155} . Total enumeration is clearly not feasible except for the smallest problem instances. In 1954, Dantzig solved a 49-city TSP, establishing a record that held for 17 years [19]. As of this writing, the largest known solved instance of the traveling salesman problem consists of 85,900 cities, and was found by the Concorde solver using cutting plane methods [5].

We can adapt the TSP to fit the spacecraft tour trajectory optimization problem by considering the salesman to be the spacecraft, the cities to be target objects, and the objective to minimize fuel consumption or mission time, for example. Further, there exist variations of the TSP which can be mapped to other components of spacecraft tour trajectory problems [30]. While the standard TSP considers visiting the entire collection of cities, the orienteering problem instead requires visiting only a subset of the cities. Each city has an associated value or prize, and the objective is to find a tour maximizing the total collected prize. Travel between cities has an associated duration, and the tour must not exceed a problem-specified total duration. The duration constraint can be mapped to either a maximum time limit or fuel limit on a spacecraft trajectory, and the prize associated with each city can be mapped to mission value per target object, for example. Another variation is the time dependent TSP, which considers the cost of travel between cities to vary with each time period. The moving target TSP further complicates the problem by assuming all cities are moving at some fixed velocity. The combination of these latter two variations could be used to approximate the dynamics and maneuvering costs of a spacecraft trajectory, for example. The close relation of the TSP to the spacecraft tour trajectory optimization problem highlights the applicability of discrete and combinatorial optimization methods to the current work.

1.2 Motivation

The main purpose of this dissertation is the development of a novel methodology for solving spacecraft tour trajectory design and optimization problems. The search space for problems of this type is sufficiently large to make exact approaches impractical. Therefore, the focus of this work is the development of an efficient algorithm that finds promising, but not provably globally optimal, solutions quickly. We base our approach on the tabu search metaheuristic, adapting and extending the method

to the spacecraft tour trajectory optimization problem, and benchmark the method against known problems in the literature [27].

There are many examples of interplanetary missions that can be considered spacecraft tour trajectories. These include the Voyager 1 and 2, Cassini-Huygens, Messenger and Rosetta missions, among others. Each of these trajectories executes a sequence of gravitational flybys, and could therefore have been posed as a spacecraft tour trajectory optimization problem. However, the primary motivation for this work is problems with much larger design spaces. An example of practical importance is the Earth orbital debris problem: as the amount of debris in low Earth orbit increases, the collision risk to current and future space missions grows [37]. Even with no new satellite launches, in the absence of any mitigation strategy this population will continue to increase due to collisional cascading, a behavior known as the Kessler syndrome [38]. As a result, recent studies have emphasized the need for active debris removal (ADR) to control the orbital debris population [41, 42]. One concept for ADR is the design of missions to rendezvous with multiple debris objects for the purposes of mitigation [6, 14, 15]. This is a challenging problem, requiring the design of a trajectory that visits a subset of debris objects out of a population of thousands of potential targets. The methodology developed in this work is directly applicable to such problems.

The Global Trajectory Optimization Competition (GTOC) is another primary motivation for this study [1]. The GTOC is an international competition focusing each year on challenging global optimization problems in interplanetary trajectory design. Each of the past seven competition problems have belonged to the class of discrete-continuous optimization problems that is the focus of this work. The GTOCs have enjoyed wide participation, and the competition results serve as a useful set of benchmark solutions for testing new methodologies for spacecraft tour trajectory optimization. The fourth GTOC problem, a multiple asteroid intercept

and rendezvous mission, is specifically considered in this work [12].

1.3 Related Work

Recently there has been an increase in research related to the spacecraft tour trajectory problem, including applications of both exact and approximate methods for discrete-continuous optimization. At the time of Betts's survey paper, he made the claim that trajectory optimization problems do not fall into the class of problems with discrete decision variables, and therefore there was no reason to use such methods [13]. Although this was more true at that time, this is becoming no longer the case. Here we give a brief overview of some of the relevant contributions in this area.

Alemaný conducted a survey in 2007 on global optimization for low-thrust multiple asteroid tour missions [4]. At the time, there were no fully integrated methods in the literature for optimizing full tour trajectories, including the mission sequence. Instead, the sequences were predetermined using other approaches before passing them to a continuous optimization method. Alemany later developed a branch and bound approach that she combined with pruning techniques to systematically explore the asteroid sequences as well [3]. The pruning techniques were limited to rendezvous missions only, however, ignoring the possibility for flybys. Cerf later successfully applied branch and bound to a multiple space debris collection mission [15]. He points out, however, that the approach is limited to smaller problem sizes, and for large-scale problems it would be necessary to explore alternate approaches. A dynamic programming based approach was used by Grigoriev to generate the winning solution for the fourth Global Trajectory Optimization Competition (GTOC4) [29]. That method relied on a heuristic procedure to significantly prune the search space, and thus the final solution was not provably globally optimal. In general, the successful application of these exact procedures depends on either a small problem

size or a significant problem-specific pruning of the search space.

There have been various approaches to addressing tour problems using metaheuristics, many of which have been hybrid approaches. Sentinella developed a hybrid evolutionary algorithm for interplanetary trajectories with multiple impulses and gravity assists [61]. The method makes use of genetic algorithms, differential evolution and particle swarm optimization in parallel. The approach finds globally good solutions, but does not vary the discrete decision variables of the problem—the mission sequences are fixed. Izzo applies differential evolution, particle swarm optimization, and genetic algorithms to multiple gravity assist trajectories in a similar way [35]. Another hybrid approach by Woo uses a genetic algorithm for global search and refines solutions with an indirect calculus of variations based method [72], while Shan does the same but instead combines particle swarm optimization with a direct method [62]. Vinko benchmarks several global optimization metaheuristics on tour problems as well [69]. In all of these cases, the metaheuristic methods are used to find globally good solutions for fixed mission sequences, not treating the discrete decision variables of the problems.

Other approaches treat the combinatorial components of the tour problem serially in a multi-stage manner. Izzo presents a three-stage method to for an asteroid grand tour problem [36]. The first stage treats the combinatorial problem, finding promising sequences based on a generalized distance metric, while the latter two stages treat the global and local optimization of the problem for the given sequence. Olympio formulates the low-thrust multiple asteroid tour problem as an optimal control problem, utilizing an indirect method for its solution [52]. It takes as input an impulsive tour with a predetermined sequence to generate the low-thrust optimal result, and can thus be used as a final stage for other methods.

A limited number of approaches have varied the mission sequences directly in the metaheuristic search procedures. Vasile combined an evolutionary algorithm

with a systematic branching strategy [65]. In some of the results, the mission sequences were left free in the optimization, and promising results were found for flyby sequences to Jupiter. However, the author recommended that the combinatorial components of the problem be treated separately. Morimoto implements a basic genetic algorithm for multiple asteroid sample return missions [46]. In that work the asteroid sequence was left free (but of fixed length), and missions visiting sequences of up to three asteroids were found.

Finally, custom approaches not based on a particular metaheuristic have been used. Barbee created the series method for finding promising tours of multiple small bodies, considering both rendezvous and flyby, and applied the methodology to the fourth Global Trajectory Optimization Competition [7]. The method iteratively constructs the tour, at each step generating a population of additional trajectory segments and choosing the next segment in a greedy nearest-neighbor manner. The method therefore does not explore the global search space, but executes with a reduced computational complexity. Later, he applied the same method for designing missions to remove multiple orbital debris objects [6]. In both cases, both the sequence of target objects and continuous decision variables were allowed to vary simultaneously. However, the optimality of the series method has not been determined.

The methods surveyed span exact and approximate methods in discrete and combinatorial optimization, global optimization, as well as direct and indirect methods in continuous trajectory optimization. However, few methods treat both the mission sequence and continuous decision variables in a unified approach. The author notes however that there are undoubtedly other approaches not documented in the literature that have been developed and applied to the several Global Trajectory Optimization Competition problems [1].

1.4 Dissertation Organization and Contributions

The current dissertation describes an overall methodology for the solution of spacecraft tour trajectory optimization problems for the purposes of preliminary and conceptual mission design. The work focuses on large-scale problems, and applies many of the tenets of tabu search. The resulting method is intended to be broadly applicable to spacecraft tour trajectory optimization problems.

Chapter 2 develops a general model for tour trajectories that visit a collection of target objects in sequence. Cases are modeled where both the agent and target objects move with time according to some set of prescribed dynamics. This general model defines the parameterization and decision variables that are used in subsequent models and the development of the global search methodology. A model for spacecraft tour trajectories subject to two-body dynamics utilizing impulsive maneuvers is then developed for use in later applications. Chapter 3 develops the global search methodology, based on the tabu search metaheuristic, for finding promising solutions to tour trajectory optimization problems. It first describes a tree-based solution representation for tour trajectories, and then defines neighborhoods that operate on that representation. It then presents guiding objective functions for use in the search, and describes the use of recency-based tabu memory as well as strategic intensification and diversification. The result is an algorithm based on the tabu search metaheuristic, which is the first known application of tabu search to spacecraft trajectory optimization. Chapter 4 then develops a novel numerical method for search space pruning which can be used to accelerate the tabu search algorithm. The approach efficiently computes an upper bound to the reachable domain of the spacecraft that is used to prune the search space and reduce the number of infeasible trajectories explored during the search. Finally, Chapter 5 applies all of the components of the methodology to the fourth annual Global Trajectory Optimization Competition (GTOC4). It combines the impulsive spacecraft tour trajectory

model, the tabu search algorithm and the search space pruning method. A sensitivity analysis is conducted to study the effect of each component of the algorithm. Selected solutions are converted to optimal finite burn trajectories, generating new previously unknown solutions to GTOC4. Chapter 6 then draws general conclusions and presents possibilities for future work.

Chapter 2

Tour Trajectory Modeling

This chapter develops models for tour trajectories that visit a collection of target objects in sequence. We model cases where both the agent and target objects are allowed to move with time according to some set of prescribed dynamics. These tour trajectories therefore represent complications of simpler models such as that of the traveling salesman problem. A general model is first developed; this defines the parameterization and decision variables for use in subsequent models and the global search methodology discussed in Chapter 3, “Global Search Methodology”. We then develop a model for spacecraft tour trajectories considering their specific dynamics that is used for applications in Chapter 5, “Application to Fourth Global Trajectory Optimization Competition”.

2.1 General Model

We develop a general model for tour trajectories that represents all of the decision variables applicable to the types of tour problems we will consider. Like the traveling salesman problem, it must first represent the sequence of target objects the agent must visit. However, now we assume that the agent and target objects

move with time, and therefore may be visited at different times resulting in different costs. There are a continuum of ways with associated costs to move from one target to another, rather than the singular static costs of moving between objects in the traveling salesman problem. The tour problem thus has both discrete decision variables to represent the sequence and continuous decision variables that determine the properties of the specific path taken.

2.1.1 Initial Conditions

The tour begins with the initial conditions of the agent. This includes the time at which the tour starts, t_0 , and the initial state of the agent at that time. Since the agent moves according to some dynamics, the state contains the velocity in addition to the position. Specific problems may include additional elements in the state such as the agent's mass or available fuel, for example. The components of the state are given in the state vector \mathbf{z} . Thus, the decision variables for the initial conditions are

$$t_0 \qquad \text{initial time} \qquad (2.1)$$

$$\mathbf{z}_0(t_0) = \begin{pmatrix} \mathbf{r}(t_0) \\ \mathbf{v}(t_0) \end{pmatrix} \qquad \text{agent state at initial time} \qquad (2.2)$$

The initial conditions may be free or constrained in the problem statement. For example, they may be constrained to match the state of an initial target object at t_0 .

2.1.2 Target Objects

We have a collection of target objects that the agent may visit during the tour. We define these target objects with the set O ,

$$O = \{O_1, O_2, O_3, \dots, O_{N_O}\} \qquad (2.3)$$

In the traveling salesman problem, these target objects represented cities with fixed positions and therefore fixed distances between them. We now allow them to move with time and assume that their position and velocity are known for all time. Their state can be computed according to known dynamics or retrieved by some other means such as an ephemeris. We define the state of a target object O_i with its position and velocity as

$$\mathbf{X}_{O_i}(t) = \begin{pmatrix} \mathbf{r}_{O_i}(t) \\ \mathbf{v}_{O_i}(t) \end{pmatrix} \quad (2.4)$$

With the addition of the velocity to the state, there are now two ways that we may visit a target object. We say that the agent intercepts the target if it matches the target's position at a specified time. The agent rendezvouses with the target if it additionally matches the target's velocity. If we visit a target object O_i at time t_k , then the conditions for an intercept and rendezvous are

$$\mathbf{r}(t_k) = \mathbf{r}_{O_i}(t_k) \quad (\text{intercept}) \quad (2.5)$$

$$\begin{pmatrix} \mathbf{r}(t_k) \\ \mathbf{v}(t_k) \end{pmatrix} = \begin{pmatrix} \mathbf{r}_{O_i}(t_k) \\ \mathbf{v}_{O_i}(t_k) \end{pmatrix} \quad (\text{rendezvous}) \quad (2.6)$$

2.1.3 Trajectory Segments

We define a trajectory segment for each target object in a tour sequence. A segment begins at a given time and state t_{i-1} and \mathbf{z}_{i-1} and ends at a target object specified by the discrete decision variable $s_i \in O$. We also associate continuous decision variables \mathbf{y}_i with the segment; at a minimum this contains the segment duration Δt_i , but can also have elements to represent maneuvers or other properties of the trajectory to s_i . We then have

$$\mathbf{y}_i = \begin{pmatrix} \Delta t_i \\ \vdots \end{pmatrix} \quad (2.7)$$

Figure 2.1: A single trajectory segment and its associated initial conditions and decision variables. $\mathbf{z}_{i-1}(t_{i-1})$ represents the state at the initial time. s_i denotes the target object, and \mathbf{y}_i gives the continuous decision variables of the segment including the segment duration Δt_i .

The time at the end of the segment t_i is found from the known initial time t_{i-1} and the segment duration Δt_i as

$$t_i = t_{i-1} + \Delta t_i \quad (2.8)$$

Given the initial conditions \mathbf{z}_{i-1} at t_{i-1} and the segment decision variables s_i and \mathbf{y}_i , we can compute the state at the end of the segment \mathbf{z}_i according to the prescribed dynamics functionally as

$$\mathbf{z}_i(t_i) = \mathbf{z}_i(t_{i-1}, \mathbf{z}_{i-1}, s_i, \mathbf{y}_i) \quad (2.9)$$

This assumes that any required maneuvers can be computed for either intercepting or rendezvousing with the target object. This is dependent on the dynamics of the specific problem; we consider specific cases for spacecraft tour trajectories in later sections. Figure 2.1 shows a single trajectory segment.

2.1.4 Tour Trajectory

We can patch multiple trajectory segments together to form a complete tour trajectory, where the final state of one segment corresponds to the initial conditions of

Figure 2.2: A tour trajectory and its associated decision variables. \mathbf{z}_0 represents the initial state at time t_0 . $s_1 \dots s_{n_s} \in O$ denote the sequence of objects visited in the tour, and $\mathbf{y}_1 \dots \mathbf{y}_{n_s}$ give the continuous decision variables of each segment. The tour consists of n_s trajectory segments visiting n_s target objects.

Name	Description
t_0	Initial time of the tour
\mathbf{z}_0	Initial state of the tour at time t_0
$s_1 \dots s_{n_s}$	Sequence of objects (from the set O) visited in the tour
$\mathbf{y}_1 \dots \mathbf{y}_{n_s}$	Continuous decision variables of each trajectory segment (contains the duration of each segment Δt_i)

Table 2.1: Decision variables for the general tour trajectory model.

the next. A tour begins at the initial conditions \mathbf{z}_0 at time t_0 and continues for n_s trajectory segments visiting n_s target objects. Figure 2.2 shows a tour trajectory, and Table 2.1 summarizes the decision variables. We can combine all of the decision variables into a solution vector \mathbf{x} as

$$\mathbf{x} = [t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}] \quad (2.10)$$

Given a solution \mathbf{x} , we can compute the state \mathbf{z} at any time according to the problem-provided prescribed dynamics as

$$\mathbf{z}(t) = \mathbf{f}(t, \mathbf{x}) \quad (2.11)$$

A tour trajectory optimization problem can then be written in terms of a scalar objective function $J(\mathbf{x})$, dynamics \mathbf{f} and inequality constraints \mathbf{C} as.

$$\text{Determine } \mathbf{x} = [t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}] \quad (2.12)$$

$$\text{minimizing } J(\mathbf{x}) \quad (2.13)$$

$$\text{subject to } \mathbf{z}(t) = \mathbf{f}(t, \mathbf{x}) \quad (2.14)$$

$$\mathbf{C}_{initial}(t_0, \mathbf{z}_0) \leq \mathbf{0} \quad (2.15)$$

$$\mathbf{C}_{sequence}(s_1 \dots s_{n_s}) \leq \mathbf{0} \quad (2.16)$$

$$\mathbf{C}_{segment}(s_i, \mathbf{y}_i) \leq \mathbf{0} \quad \text{for } i = 1 \dots n_s \quad (2.17)$$

$$\mathbf{C}(\mathbf{x}) \leq \mathbf{0} \quad (2.18)$$

Note that equality constraints can be expressed as two inequality constraints in the above formulation. The definitions of the objectives, dynamics and constraints above are problem specific. Separable constraints of the initial conditions, tour sequence, or segment decision variables may exist (Equations (2.15) through (2.17)). Constraints coupling all of the decision may also exist (Equation (2.18)). This model is general in the sense that it encompasses problems of simpler types. For example, when the dynamics vanish and the objective is to minimize the total travel cost visiting all target objects, it represents a traveling salesman problem. Alternatively, when the object sequence is fixed, we have a continuous trajectory optimization problem. The objective, dynamics and constraints in the model may be nonlinear, and the sequence decision variables $s_1 \dots s_{n_s}$ can be represented as a set of integer decision variables. The model is therefore a mixed-integer nonlinear programming problem [54, 22].

m_0	Initial mass (with fuel)
m_{dry}	Dry mass (fuel exhausted)
T_{max}	Maximum thrust magnitude
I_{sp}	Specific impulse

Table 2.2: Spacecraft parameters and descriptions.

2.2 Spacecraft Tour Trajectories

We now implement the general tour model described in the previous section for the specific case of spacecraft tour trajectories. The agent of the model is now a spacecraft, and the target objects are now objects in space such as satellites, asteroids or other celestial objects. We treat the spacecraft and target objects as point masses throughout the development.

2.2.1 Spacecraft Dynamics

We define the spacecraft with a propulsion system and a corresponding mass of fuel onboard with which to make maneuvers. We limit our development to a constant specific impulse propulsion system with a maximum thrust magnitude [16]. Table 2.2 gives the parameters of the spacecraft. We extend to the state vector \mathbf{z} to now include the spacecraft's mass as

$$\mathbf{z}(t) = \begin{pmatrix} \mathbf{r}(t) \\ \mathbf{v}(t) \\ m(t) \end{pmatrix} \quad (2.19)$$

Then, at the initial time of the tour the spacecraft's mass is

$$m(t_0) = m_0 \quad (2.20)$$

and it is constrained for all time by the limited fuel mass as

$$m(t) \geq m_{dry} \quad (2.21)$$

The spacecraft may thrust in any direction and with any magnitude up to the limit of T_{max} as long as fuel is available. We define the spacecraft's thrusting over time with $\mathbf{T}(t)$ such that $T(t) \leq T_{max}$. The spacecraft is subject to a gravitational acceleration $\mathbf{g}(\mathbf{r})$, and its motion is governed by

$$\mathbf{z}_0(t_0) = \begin{pmatrix} \mathbf{r}(t_0) \\ \mathbf{v}(t_0) \\ m(t_0) \end{pmatrix} \quad \dot{\mathbf{z}}(t) = \begin{pmatrix} \mathbf{v}(t) \\ \mathbf{g}(\mathbf{r}(t)) + \frac{\mathbf{T}(t)}{m(t)} \\ -\frac{T(t)}{I_{sp} g_0} \end{pmatrix} \quad (2.22)$$

where g_0 is the standard gravitational acceleration on Earth's surface. This initial value problem can be numerically integrated given a definition of $\mathbf{g}(\mathbf{r})$ and a thrust history $\mathbf{T}(t)$. If we have Keplerian two-body motion about a central body with gravitational parameter μ , then the spacecraft's equations of motion are

$$\mathbf{z}_0(t_0) = \begin{pmatrix} \mathbf{r}(t_0) \\ \mathbf{v}(t_0) \\ m(t_0) \end{pmatrix} \quad \dot{\mathbf{z}}(t) = \begin{pmatrix} \mathbf{v}(t) \\ -\frac{\mu}{r(t)^3} \mathbf{r}(t) + \frac{\mathbf{T}(t)}{m(t)} \\ -\frac{T(t)}{I_{sp} g_0} \end{pmatrix} \quad (2.23)$$

This ignores any effect of target objects on the spacecraft's motion. We will assume Keplerian two-body motion for the rest of the development. The spacecraft is in ballistic motion when $\mathbf{T}(t) = \mathbf{0}$; in that case it is only subject to the gravitational acceleration of the central body. The ballistic motion can then be found as the solution to Kepler's problem [8].

2.2.2 Target Object Dynamics

The motion of the target objects O_i is assumed to be known such that their state \mathbf{X}_{O_i} at any time t can be represented as

$$\mathbf{X}_{O_i}(t) = \begin{pmatrix} \mathbf{r}_{O_i}(t) \\ \mathbf{v}_{O_i}(t) \end{pmatrix} \quad (2.24)$$

The state $\mathbf{X}_{O_i}(t)$ may be provided in the form of a pre-computed ephemeris and retrieved directly, or may be computed according to prescribed dynamics. For example, if the objects O_i move according to a gravitational acceleration $\mathbf{g}(\mathbf{r})$, then their states may be found at any time as the solution of the initial value problem

$$\mathbf{X}_{O_i}(t_0) = \begin{pmatrix} \mathbf{r}_{O_i}(t_0) \\ \mathbf{v}_{O_i}(t_0) \end{pmatrix} \quad \dot{\mathbf{X}}_{O_i}(t) = \begin{pmatrix} \mathbf{v}_{O_i}(t) \\ \mathbf{g}(\mathbf{r}_{O_i}(t)) \end{pmatrix} \quad (2.25)$$

which can be numerically integrated. If we further assume that the target objects O_i are in two-body Keplerian motion about a central body as we did with the spacecraft, then we have

$$\mathbf{X}_{O_i}(t_0) = \begin{pmatrix} \mathbf{r}_{O_i}(t_0) \\ \mathbf{v}_{O_i}(t_0) \end{pmatrix} \quad \dot{\mathbf{X}}_{O_i}(t) = \begin{pmatrix} \mathbf{v}_{O_i}(t) \\ -\frac{\mu}{r_{O_i}(t)^3} \mathbf{r}_{O_i}(t) \end{pmatrix} \quad (2.26)$$

This motion may also be integrated numerically, but can also more simply be solved as the solution to Kepler's problem [8].

2.2.3 Finite Burn Trajectory Segments

We can model the thrust history of the spacecraft $\mathbf{T}(t)$ directly as a series of finite burn maneuvers. A single finite burn maneuver models a continuous thrust over a non-zero period of time, and is therefore a realistic model for low-thrust spacecraft.

Figure 2.3: A finite burn trajectory segment. An initial maneuver causes the spacecraft to intercept the target object, and an optional final maneuver causes a rendezvous.

Here we will define trajectory segments using finite burns for use in constructing tour trajectories.

Figure 2.3 gives one possible parameterization for a finite burn segment. There are two finite burn maneuvers: $\mathbf{T}_{int}(t)$ intercepting the target object and $\mathbf{T}_{ren}(t)$ completing an optional rendezvous to match its velocity. The τ decision variables give time bounds on the finite burn maneuvers and are constrained such that

$$0 \leq \tau_{int_0} < \tau_{int_f} \leq \tau_{ren_0} < 1 \quad (2.27)$$

The rendezvous maneuver ends at the final time of the segment. In order to parameterize the thrust histories, let us decompose the thrust vector $\mathbf{T}(t)$ into its

magnitude $T(t)$ and a unit thrust direction $\hat{\mathbf{u}}(t)$, such that

$$\mathbf{T}(t) = T(t) \hat{\mathbf{u}}(t) \quad (2.28)$$

$$0 \leq T(t) \leq T_{max} \quad (2.29)$$

$$\|\hat{\mathbf{u}}(t)\| = 1 \quad (2.30)$$

The unit thrust direction can be further parameterized by spherical angles $\alpha(t)$ and $\beta(t)$ as

$$\hat{\mathbf{u}}(t) = \begin{pmatrix} \cos \alpha(t) \cos \beta(t) \\ \sin \alpha(t) \cos \beta(t) \\ \sin \beta(t) \end{pmatrix} \quad (2.31)$$

If we assume a quadratic steering model [49], then we have

$$\alpha(t) = \alpha_0 + \dot{\alpha}_0(t - t_{fb_0}) + \frac{\ddot{\alpha}_0(t - t_{fb_0})^2}{2} \quad (2.32)$$

$$\beta(t) = \beta_0 + \dot{\beta}_0(t - t_{fb_0}) + \frac{\ddot{\beta}_0(t - t_{fb_0})^2}{2} \quad (2.33)$$

where t_{fb_0} is the beginning time of the maneuver. Finally, we can fix the thrust magnitude to its maximum value such that

$$T(t) = T_{max} \quad (2.34)$$

The continuous decision variables for a finite burn trajectory segment intercepting a target object are then

$$\mathbf{y}_i^{int} = \left(\Delta t_i \quad \tau_{int_0} \quad \tau_{int_f} \quad (\alpha_0 \quad \dot{\alpha}_0 \quad \ddot{\alpha}_0 \quad \beta_0 \quad \dot{\beta}_0 \quad \ddot{\beta}_0)_{int} \right)_{1 \times 9}^T \quad (2.35)$$

and for the rendezvous case they are

$$\mathbf{y}_i^{ren} = \begin{pmatrix} \Delta t_i & \tau_{int_0} & \tau_{int_f} & (\alpha_0 & \dot{\alpha}_0 & \ddot{\alpha}_0 & \beta_0 & \dot{\beta}_0 & \ddot{\beta}_0)_{int} & \cdots \\ \tau_{ren_0} & (\alpha_0 & \dot{\alpha}_0 & \ddot{\alpha}_0 & \beta_0 & \dot{\beta}_0 & \ddot{\beta}_0)_{ren} & & & \end{pmatrix}_{1 \times 16}^T \quad (2.36)$$

The segment decision variables \mathbf{y}_i must then be chosen to intercept or rendezvous with the target object s_i , given the initial conditions \mathbf{z}_{i-1} at t_{i-1} . For each segment in a tour then, the segment conditions that must be satisfied for the intercept case are

$$\mathbf{C}(\mathbf{y}_i^{int}) = \left(\mathbf{r}(t_{i-1} + \Delta t_i) - \mathbf{r}_{s_i}(t_{i-1} + \Delta t_i) \right)_{3 \times 1} = \mathbf{0} \quad (2.37)$$

and for the rendezvous case are

$$\mathbf{C}(\mathbf{y}_i^{ren}) = \begin{pmatrix} \mathbf{r}(t_{i-1} + \Delta t_i) - \mathbf{r}_{s_i}(t_{i-1} + \Delta t_i) \\ \mathbf{v}(t_{i-1} + \Delta t_i) - \mathbf{v}_{s_i}(t_{i-1} + \Delta t_i) \end{pmatrix}_{6 \times 1} = \mathbf{0} \quad (2.38)$$

In both cases we have an underdetermined system of nonlinear equations. Multiple feasible solutions may be possible, or a feasible solution may not exist. If multiple feasible solutions are possible, then a single solution can be found by defining an objective function and computing an optimal solution. However, multiple locally optimal solutions may also exist. In general this is a challenging the problem, and constructing a tour trajectory composed of multiple of these segments only increases the difficulty. Existing systems such as Copernicus can be used to find such solutions given a fixed sequence $s_1 \dots s_{n_s}$ [51, 71]. Olympio provides an optimal control formulation of the tour problem for fixed sequences as well [52].

2.2.4 Impulsive Trajectory Segments

We can alternatively develop trajectory segments in terms of impulsive maneuvers, ignoring the spacecraft's limited maximum thrust magnitude. An impulsive maneuver occurs instantaneously and imparts a change in velocity denoted as $\Delta \mathbf{V}$. This is a discontinuous change in the spacecraft's state, and is thus a less realistic model for spacecraft, especially those with low-thrust propulsion systems where the thrust durations are long. However, this approach has advantages compared to the finite burn approach especially in the context of tour trajectories.

The states immediately before and after the maneuver are $\mathbf{z}(t^-)$ and $\mathbf{z}(t^+)$ and can be expressed as

$$\mathbf{z}(t^-) = \begin{pmatrix} \mathbf{r}(t^-) \\ \mathbf{v}(t^-) \\ m(t^-) \end{pmatrix} \quad \mathbf{z}(t^+) = \begin{pmatrix} \mathbf{r}(t^+) \\ \mathbf{v}(t^+) \\ m(t^+) \end{pmatrix} \quad (2.39)$$

The change in velocity $\Delta \mathbf{V}$ defines the maneuver. There is also a corresponding change in mass Δm corresponding to fuel used during the maneuver. The states instantaneously before and after the maneuver satisfy the relation

$$\mathbf{z}(t^+) = \mathbf{z}(t^-) + \begin{pmatrix} \mathbf{0} \\ \Delta \mathbf{V} \\ \Delta m \end{pmatrix} \quad (2.40)$$

Only the position of the spacecraft is the same across the impulse. Given the magnitude of a maneuver ΔV , the change in mass Δm may be determined using the Tsiolkovsky rocket equation that relates the magnitude of the maneuver to the propellant mass consumed [59].

$$\Delta V = I_{sp} g_0 \ln \left(\frac{m(t^-)}{m(t^+)} \right) \quad (2.41)$$

Figure 2.4: An impulsive trajectory segment. An initial impulse $\Delta \mathbf{V}_{int}$ maneuvers the spacecraft to intercept the target object, and an optional final impulse $\Delta \mathbf{V}_{ren}$ maneuvers the spacecraft to rendezvous with the target.

Manipulating the rocket equation we then have

$$\Delta m = m(t^+) - m(t^-) = m(t^-) \left(e^{-\Delta V / (I_{sp} g_0)} - 1 \right) \quad (2.42)$$

The state change that occurs for an impulsive maneuver is therefore completely determined by the $\Delta \mathbf{V}$ maneuver as

$$\mathbf{z}(t^+) = \mathbf{z}(t^-) + \begin{pmatrix} \mathbf{0} \\ \Delta \mathbf{V} \\ m(t^-) \left(e^{-\Delta V / (I_{sp} g_0)} - 1 \right) \end{pmatrix} \quad (2.43)$$

Figure 2.4 shows an impulsive trajectory segment. The segment begins at a given initial state \mathbf{z}_{i-1} at t_{i-1} and has a total duration Δt_i . An intercept maneuver

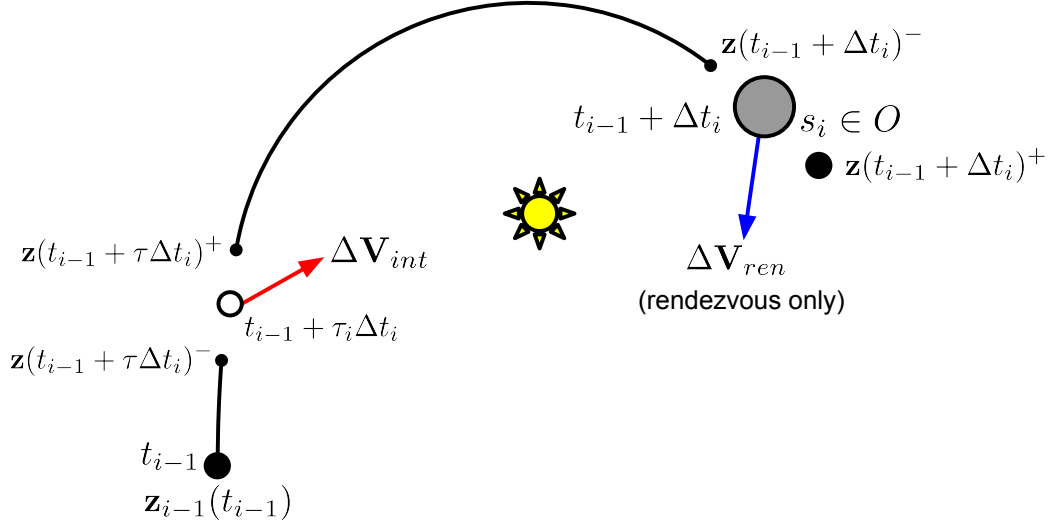

Figure 2.5: The impulsive trajectory segment shown in Figure 2.4 with all spacecraft states and discontinuities shown.

occurs at time $t_{i-1} + \tau_i \Delta t_i$, where $0 \leq \tau_i \leq 1$. Finally, an optional maneuver to rendezvous with the target object occurs at $t_{i-1} + \Delta t_i$. The states of the spacecraft are discontinuous across the maneuvers, and are shown schematically in Figure 2.5.

Recall that the initial state of the spacecraft $\mathbf{z}_{i-1}(t_{i-1})$ is known, and the states of the target objects are known for all time. The targeting problem is therefore to determine the $\Delta \mathbf{V}$ maneuvers such that

$$\mathbf{r}(t_{i-1} + \Delta t_i) - \mathbf{r}_{O_i}(t_{i-1} + \Delta t_i) = \mathbf{0} \quad (\text{intercept}) \quad (2.44)$$

$$\begin{pmatrix} \mathbf{r}(t_{i-1} + \Delta t_i) - \mathbf{r}_{O_i}(t_{i-1} + \Delta t_i) \\ \mathbf{v}(t_{i-1} + \Delta t_i) - \mathbf{v}_{O_i}(t_{i-1} + \Delta t_i) \end{pmatrix} = \mathbf{0} \quad (\text{rendezvous}) \quad (2.45)$$

For two-body Keplerian motion, these maneuvers may be computed as a solution to Lambert's problem [9, 64]. Concisely, given two positions and the elapsed time between them, the solutions of Lambert's problem provide the velocities at the

endpoints.

$$\text{LAMBERT}(\mathbf{r}_1, \mathbf{r}_2, \Delta t) \implies \mathbf{v}_1, \mathbf{v}_2 \quad (2.46)$$

These computed velocities allow for the determination of $\Delta \mathbf{V}_{int}$ and $\Delta \mathbf{V}_{ren}$ in the impulsive trajectory segment. It is important to note that in general there are multiple solutions to Lambert’s problem corresponding to “short way”, “long way”, and multiple revolution solutions [28]. It is assumed that the solution corresponding to the minimum total maneuver magnitude is used. Thus, for the intercept we only need to know when the maneuver occurs; a rendezvous maneuver occurs at the time of intercept to match velocity with the target.

We can now define the parameters for the impulsive trajectory segment as the segment duration and intercept maneuver time

$$\mathbf{y}_i = \begin{pmatrix} \Delta t_i \\ \tau_i \end{pmatrix} \quad (2.47)$$

These uniquely determine the maneuvers and trajectory to the target object s_i . The segment can be fully computed given its initial conditions, target object and segment decision variables. The resulting computation gives the values for any intercept and rendezvous maneuvers as

$$\mathbf{z}_i(t_i) = \mathbf{z}_i(t_{i-1}, \mathbf{z}_{i-1}, s_i, \mathbf{y}_i) \implies \Delta \mathbf{V}_{int_i}, \Delta \mathbf{V}_{ren_i} \quad (2.48)$$

2.2.5 Impulsive Maneuver to Finite Burn Maneuver Conversion

The use of impulsive maneuvers simplifies the generation of tour trajectories. We are able to parameterize an impulsive trajectory segment with only one additional decision variable: the time at which the intercept maneuver occurs. We can then compute the resulting intercept and optional rendezvous maneuvers by solving the corresponding Lambert’s problem. In contrast, a finite burn trajectory segment is

Figure 2.6: A valid finite burn representation of an impulsive $\Delta \mathbf{V}$ maneuver. The finite burn begins at time t_{fb_0} , thrusts over a period of time and matches position and velocity with the post-impulse trajectory at time t_{fb_f} [50].

more difficult; parameterizations require many more decision variables that must be chosen to satisfy intercept or rendezvous conditions. This can be an iterative procedure, and there is no guarantee that a feasible solution will be found. Finite burn trajectory segments, however, realistically model low-thrust trajectories and are therefore more useful for practical applications. This section describes the conversion of impulsive maneuvers to equivalent finite burns and develops constraints on impulsive maneuvers such that the conversion is likely to be feasible. This in turn allows us to use impulsive trajectory segments in the search for optimal tour trajectories and then later convert an impulsive solution to an equivalent finite burn solution if necessary.

Figure 2.6 shows a finite burn maneuver representation of an impulsive maneuver [50]. The impulsive $\Delta \mathbf{V}$ occurs at $t_{\Delta V}$ and instantaneously changes the spacecraft's trajectory from the pre-impulse trajectory $\mathbf{X}_{pre}(t_{\Delta V})$ to the post-impulse trajectory $\mathbf{X}_{post}(t_{\Delta V})$. A valid finite burn representation instead maneuvers from the pre-impulse spacecraft trajectory to the post-impulse trajectory over a non-zero period of time. The finite burn begins at time t_{fb_0} and continues until it matches

position and velocity with the post-impulse trajectory at time t_{fb_f} . Determining such a finite burn maneuver requires finding values for t_{fb_0} , t_{fb_f} and the thrust time history $\mathbf{T}(t)$ such that $\mathbf{X}(t_{fb_f}) = \mathbf{X}_{post}(t_{fb_f})$. Rather than treating the full conversion process, we instead attempt only to find constraints on the impulsive maneuvers such that the conversion may be feasible. For the above finite burn to be valid, its burn time must not fall outside of the prescribed bounds t_0 and t_f .

$$t_0 \leq t_{fb_0} < t_{fb_f} \leq t_f \quad (2.49)$$

So far the time bounds t_0 and t_f are arbitrary. We could define them to correspond to the bounds of a trajectory segment in a tour, or define them in relation to other proximal finite burn maneuvers.

We can estimate the duration a finite burn representation of an impulsive $\Delta\mathbf{V}$ based on the rocket equation. If we assume the spacecraft thrusts at T_{max} for the duration of the finite burn, then the predicted burn time is

$$\Delta t_{\Delta V} = -\frac{\Delta m}{T_{max}/(I_{sp} g_0)} = \frac{m(t^-) (1 - e^{-\Delta V/(I_{sp} g_0)})}{T_{max}/(I_{sp} g_0)} \quad (2.50)$$

For both impulsive and finite burn trajectory segments, we have described two types of maneuvers: intercepts and rendezvous. For the intercept case, we assume the impulse to be at the midpoint of the corresponding finite burn. For the rendezvous case, we assume that the finite burn ends at the time of the impulse. The impulsive maneuvers and their corresponding finite burn representations are shown in Figure 2.7. The estimated start times for finite burn representations of intercept and

Figure 2.7: An impulsive trajectory segment with estimates for finite burn maneuvers replacing the impulses.

rendezvous maneuvers are then

$$t_{fb_0} = t_{\Delta V} - \frac{\Delta t_{\Delta V}}{2} \quad (\text{intercept}) \quad (2.51)$$

$$t_{fb_0} = t_{\Delta V} - \Delta t_{\Delta V} \quad (\text{rendezvous}) \quad (2.52)$$

In both cases, the end time is

$$t_{fb_f} = t_{\Delta V} + \Delta t_{\Delta V} \quad (2.53)$$

We can add constraints on impulsive tours that prevent the finite burn estimates of their impulsive maneuvers from overlapping in time. This additionally restricts the feasible solution space so that the solutions found are more likely to have corresponding feasible finite burn trajectories. The constraints are in terms of the time bounds of Equations 2.51 through 2.53. If we have a set of $N_{\Delta V}$ maneuvers in a tour trajectory (intercepts and/or rendezvouses), then the additional constraints are

$$(t_{fb_0})_0 \geq t_0 \quad (2.54)$$

$$(t_{fb_f})_{N_{\Delta V}} \leq t_{n_s} \quad (2.55)$$

$$(t_{fb_f})_i \leq (t_{fb_0})_{i+1} \quad \text{for } i \in 1 \dots N_{\Delta V} - 1 \quad (2.56)$$

Equations (2.54) and (2.55) constrain the finite burn maneuvers from occurring outside of the initial and final times of the full tour trajectory, respectively. Equation (2.56) constrains the finite burn maneuvers from overlapping each other. Constructing an initial guess for the thrust histories $\mathbf{T}(t)$ is beyond the scope of the current work, but is addressed by Ocampo [50].

Gravity Losses

The estimate for the duration of a finite burn given in Equation 2.50 is based on the Tsiolkovsky rocket equation, and is thus only exact in the absence of external forces. We now consider performance penalties associated with the replacement of impulsive maneuvers with finite burns in the presence of gravity, following the analysis of Robbins [57]. Adjusting our finite burn estimates for these penalties will tighten the associated constraints on the impulsive maneuvers and improve the feasibility of the impulsive to finite burn conversion.

We define the characteristic velocity of a finite burn maneuver as the integral of the thrust acceleration magnitude over the duration of the maneuver. Assuming continuous maximum thrust, we have

$$\Delta V_{fb} = \int_{t_{fb_0}}^{t_{fb_f}} \frac{T_{max}}{m(t)} dt \quad (2.57)$$

When gravity (or more generally a gravity gradient) is absent and the thrust direction is constant, the characteristic velocity ΔV_{fb} is equal to the total velocity change achieved, and thus the finite burn estimate is an exact replacement for the corresponding impulsive maneuver. However, in realistic cases where a gravity gradient exists there is a performance penalty associated with the use of finite thrust such that

$$\Delta V_{fb} > \Delta V \quad (2.58)$$

That is, the characteristic velocity of the finite burn maneuver must be higher than the corresponding impulsive ΔV to achieve the same result. The finite burn maneuver must then thrust over a longer period of time using a larger mass of fuel. Robbins provides an analytical upper bound for this penalty as

$$\Delta V_{fb} \leq \Delta V + \frac{1}{24}(\omega_s \Delta t_{\Delta V})^2 \Delta V \quad (2.59)$$

where $\Delta t_{\Delta V}$ is our original rocket equation estimate for the finite burn duration, and ω_s is the Schuler frequency defined as

$$\omega_s^2 = \frac{\mu}{r^3} \quad (2.60)$$

This approximate upper bound is valid for mass-optimal impulsive maneuvers and cases where the dimensionless quantity $\omega_s \Delta t_{\Delta V}$ does not exceed unity. For a spacecraft orbiting the sun at 1 AU, the approximation is therefore valid for finite burn durations up to approximately 60 days. We see that the penalty grows rapidly with the duration of the finite burn maneuver as expected.

We now use this upper bound in our impulsive trajectory segment computations. We use

$$\Delta V_{fb} = \Delta V + \frac{1}{24} (\omega_s \Delta t_{\Delta V})^2 \Delta V \quad (2.61)$$

We replace the change in mass across the impulsive maneuver with the estimated mass use of the representative finite burn,

$$\Delta m_{fb} = m(t^-) \left(e^{-\Delta V_{fb}/(I_{sp} g_0)} - 1 \right) \quad (2.62)$$

The new change in mass corresponds to a longer finite burn time which we compute as

$$\Delta t_{fb} = -\frac{\Delta m_{fb}}{T_{max}/(I_{sp} g_0)} \quad (2.63)$$

We now modify the state change across an impulsive maneuver to correspond to the finite burn estimate's mass usage as

$$\mathbf{z}(t^+) = \mathbf{z}(t^-) + \begin{pmatrix} \mathbf{0} \\ \Delta \mathbf{V} \\ \Delta m_{fb} \end{pmatrix} \quad (2.64)$$

and update the estimated bounds on intercept and rendezvous finite burn maneuvers as

$$t_{fb_0} = t_{\Delta V} - \frac{\Delta t_{fb}}{2} \quad (\text{intercept}) \quad (2.65)$$

$$t_{fb_0} = t_{\Delta V} - \Delta t_{fb} \quad (\text{rendezvous}) \quad (2.66)$$

$$t_{fb_f} = t_{\Delta V} + \Delta t_{fb} \quad (2.67)$$

Compensating for gravity losses yields higher characteristic velocities for the finite burn maneuvers and a corresponding increase in fuel mass usage. It is interesting to note however that the effects are greater on earlier maneuvers in a trajectory. The increased fuel mass usage (and therefore reduced mass) makes the spacecraft more efficient for later maneuvers. In fact, the timing constraints on the finite burn maneuvers can actually be less restrictive later in a tour than the ideal case ignoring gravity losses. Figure 2.8 shows the ratios of the characteristic velocities and finite burn durations with gravity losses versus the ideal case for 50 sequential maneuvers. While the finite burn characteristic velocity always exceeds the impulsive value, we see that after a number of maneuvers the estimated maneuver duration becomes less than when gravity losses are not considered. The associated timing constraints would then be less restrictive than the ideal case where gravity losses are ignored.

Finally, we note that these finite burn estimates and their associated constraints are only valid for mass-optimal impulses and short finite burn durations. The additional constraints therefore do not guarantee feasible finite burn conversions. However, they do restrict the feasible solution space to improve the likelihood that such a conversion is possible.

Figure 2.8: The finite burn characteristic velocity and duration ratios are shown for the case where gravity losses are considered and for the ideal case. 50 consecutive maneuvers are made for an impulsive ΔV of 1 km/s. The spacecraft parameters correspond to the GTOC4 problem described in Chapter 5.

2.2.6 Augmented Impulsive Tour Model

We implement the general tour trajectory model of Section 2.1.4 for spacecraft tour trajectories. The state of the spacecraft includes its mass such that

$$\mathbf{z}(t) = \begin{pmatrix} \mathbf{r}(t) \\ \mathbf{v}(t) \\ m(t) \end{pmatrix} \quad (2.68)$$

We use the impulsive model for trajectory segments and maneuvers. The continuous segment decision variables are

$$\mathbf{y}_i = \begin{pmatrix} \Delta t_i \\ \tau_i \end{pmatrix} \quad (2.69)$$

The required impulsive maneuvers are computed by solving Lambert's problem, and the ballistic motion is found by solving Kepler's problem. The final state of each segment and the impulsive maneuvers can be found as

$$\mathbf{z}_i(t_i) = \mathbf{z}_i(t_{i-1}, \mathbf{z}_{i-1}, s_i, \mathbf{y}_i) \implies \Delta \mathbf{V}_{int_i}, \Delta \mathbf{V}_{ren_i} \quad (2.70)$$

The final mass of the tour is restricted by the available fuel so that $m(t) \geq m_{dry}$.

We augment the model to consider the feasibility of converting the impulsive maneuvers to finite burns. The state change of the spacecraft across impulsive maneuvers is then

$$\mathbf{z}(t^+) = \mathbf{z}(t^-) + \begin{pmatrix} \mathbf{0} \\ \Delta \mathbf{V} \\ \Delta m_{fb} \end{pmatrix} \quad (2.71)$$

where Δm_{fb} is the change in mass for a representative finite burn corrected for gravity losses given in Equation 2.62. Further, we add time constraints for each

impulsive maneuver such that the corresponding finite burn maneuvers do not overlap in time. These constraints are given by Equations 2.54 through 2.56 where the finite burn time bounds are given by Equations 2.65 through 2.67. The augmented impulsive tour model is thus

$$\text{Determine } \mathbf{x} = [t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}] \quad (2.72)$$

$$\text{minimizing } J(\mathbf{x}) \quad (2.73)$$

$$\text{subject to } \mathbf{z}(t) = \mathbf{f}(t, \mathbf{x}) \implies \Delta \mathbf{V}_1 \dots \Delta \mathbf{V}_{N_{\Delta V}} \quad (2.74)$$

$$m(t_{n_s}) \geq m_{dry} \quad (2.75)$$

$$(t_{fb_0})_0 \geq t_0 \quad (2.76)$$

$$(t_{fb_f})_{N_{\Delta V}} \leq t_{n_s} \quad (2.77)$$

$$(t_{fb_f})_i \leq (t_{fb_0})_{i+1} \quad \text{for } i \in 1 \dots N_{\Delta V} - 1 \quad (2.78)$$

$$\mathbf{C}_{initial}(t_0, \mathbf{z}_0) \leq \mathbf{0} \quad (2.79)$$

$$\mathbf{C}_{sequence}(s_1 \dots s_{n_s}) \leq \mathbf{0} \quad (2.80)$$

$$\mathbf{C}_{segment}(s_i, \mathbf{y}_i) \leq \mathbf{0} \quad \text{for } i = 1 \dots n_s \quad (2.81)$$

$$\mathbf{C}(\mathbf{x}) \leq \mathbf{0} \quad (2.82)$$

We still allow general constraints on the initial conditions, sequence, segment decision variables and full decision vector that can be implemented for specific problems. The definition of an objective $J(\mathbf{x})$ is also left to a problem statement.

The impulsive tour model simplifies the search for optimal trajectories. Each segment has a single additional decision variable that uniquely determines the required maneuvers and trajectory of the segment. Finite burn segments more realistically model low-thrust spacecraft, but add to the complexity of the model since a two-point boundary value problem must be solved at each segment to satisfy intercept or rendezvous conditions. The addition of the finite burn feasibility constraints

to the impulsive tour model aims to ensure that the impulsive trajectory has a corresponding finite burn trajectory. This therefore allows for a two stage approach: search and optimization of an impulsive tour trajectory, followed by conversion of impulsive trajectories to realistic finite burn tours.

Chapter 3

Global Search Methodology

This chapter develops a search methodology for finding solutions to tour trajectory design and optimization problems. The approach is based on the Tabu search metaheuristic developed by Glover [27], but draws on elements from graph theory and path finding approaches including the A* search algorithm [32]. We develop the methodology in terms of building blocks common to local search approaches: the solution representation, neighborhood and objective function. First, we have a given or incumbent solution representing a tour trajectory denoted as \mathbf{x} . For a given problem, the solution \mathbf{x} may be represented or encoded in a variety of ways; the chosen solution representation can have a significant impact on the implementation and performance of the search. Next, we define a neighborhood of solutions nearby the incumbent. This neighborhood $\mathcal{N}(\mathbf{x})$ determines the candidate solutions that can be moved to from the incumbent \mathbf{x} . Finally, a scalar objective function $J(\mathbf{x})$ —provided in a problem statement—gives a metric for comparing solutions. We assume without loss of generality that the goal is to minimize this objective function. A simple local search algorithm illustrating these building blocks is given in Algorithm 1. The algorithm is considered greedy since at every iteration it moves to

Algorithm 1 Local search algorithm.

```
procedure LOCALSEARCH( $\mathbf{x}_0$ )  
  repeat  
     $\triangleright$  find the best solution in the neighborhood of the incumbent  
     $\mathbf{x}' \leftarrow \operatorname{argmin}_{\mathbf{x} \in \mathcal{N}(\mathbf{x}_0)} J(\mathbf{x})$   
     $\triangleright$  accept the solution as the new incumbent if it is an improvement  
     $\triangleright$  otherwise, we have converged to a locally optimal solution  
    if  $J(\mathbf{x}') < J(\mathbf{x}_0)$  then  
       $\mathbf{x}_0 \leftarrow \mathbf{x}'$   
    else  
      converged  
    end if  
  until converged  
   $\triangleright$  return the best solution found  
  return  $\mathbf{x}_0$   
end procedure
```

the best possible candidate solution in the neighborhood. Further, it can only find locally optimal solutions since it never moves beyond its neighborhood or accepts non-improving moves. We consider this approach, however, as a basis for developing more advanced approaches that address these weaknesses.

The following sections develop the solution representation, neighborhoods, and objective functions used in the search. These are then combined to form the search algorithm.

3.1 Solution Representation

A solution representation encodes the decision variables of a problem into a form that a search or optimization algorithm can evaluate and manipulate to move to new solutions. Since all solutions considered are in terms of this representation, its definition determines the search space. For example, consider the traveling salesman problem. For an n -city problem, one solution representation is a permutation of the

integers $1 \dots n$, where each number corresponds to a city and the order determines the sequence [43]. The search space consists of all of these permutations and has a size of $n!$ solutions. However, consider that this is a symmetric traveling salesman problem where the distances from cities i to j and j to i are equal. In this case, a tour and the same tour in reverse order can be considered equivalent, and the search space can be reduced by half. Further, since the problem statement requires the tour be a complete cycle, the starting city is unimportant and can be fixed. The search space can thus be reduced further to $\frac{(n-1)!}{2}$ solutions. The original solution representation yields a search space $2n$ times larger than what is required and therefore may be less efficient for solving the problem. Conversely, other solution representations may underrepresent the feasible solution space of the problem, leaving out good or even optimal solutions. A careful definition of the solution representation is critical to the performance of the search or optimization.

Section 2.1 gives a model for a general tour trajectory. The decision variables are t_0 and \mathbf{z}_0 representing the initial time and state, $s_1 \dots s_{n_s}$ representing the target object sequence, and $\mathbf{y}_1 \dots \mathbf{y}_{n_s}$ representing the continuous decision variables of each segment of the sequence. Recall a solution is denoted as \mathbf{x} . The most basic solution representation would be a concatenation of these decision variables, for example

$$\mathbf{x} = [t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}] \quad (3.1)$$

This solution representation gives the information needed to represent a full tour trajectory. However, other solution representations are possible.

3.1.1 Properties of Tour Trajectories

There are properties associated with tour trajectories that should be noted and considered in determining what solution representation to use. First, we note that the evaluation of a single tour trajectory can be computationally expensive. While

evaluating a solution to the traveling salesman problem is quick, only involving basic arithmetic, the evaluation of a tour trajectory solution is much more complex. The evaluation may involve numerically integrating equations of motion according to prescribed dynamics, computing maneuvers to target objects and other computationally expensive operations. The result is that in a fixed amount of time, we are able to compute far fewer tour trajectory evaluations than for other problems such as the traveling salesman. This translates to fewer iterations for the same search algorithm. The expense of tour evaluations should therefore be addressed in the design of the solution representation if possible.

Tour trajectories can naturally be decomposed sequentially by trajectory segments. A segment i can be completely computed given its initial state \mathbf{z}_{i-1} (the final state of the previous segment) and its segment decision variables s_i and \mathbf{y}_i . The final state for segment i is computed functionally as

$$\mathbf{z}_i = \mathbf{z}_i(\mathbf{z}_{i-1}, s_i, \mathbf{y}_i) \tag{3.2}$$

This is a recursive relationship, since the final state of every segment depends upon the final state of the previous segment. For example, the final states at various segments can be evaluated as

$$\mathbf{z}_1 = \mathbf{z}_1(\mathbf{z}_0, s_1, \mathbf{y}_1) \tag{3.3}$$

$$\mathbf{z}_2 = \mathbf{z}_2(\mathbf{z}_1(\mathbf{z}_0, s_1, \mathbf{y}_1), s_2, \mathbf{y}_2) \tag{3.4}$$

$$\mathbf{z}_3 = \mathbf{z}_3(\mathbf{z}_2(\mathbf{z}_1(\mathbf{z}_0, s_1, \mathbf{y}_1), s_2, \mathbf{y}_2), s_3, \mathbf{y}_3) \tag{3.5}$$

Clearly, as the number of segments n_s grows, the final state of the tour trajectory \mathbf{z}_{n_s} becomes more expensive to compute. Another consequence of this recursion, however, is that multiple tour trajectories can share past segments in common.

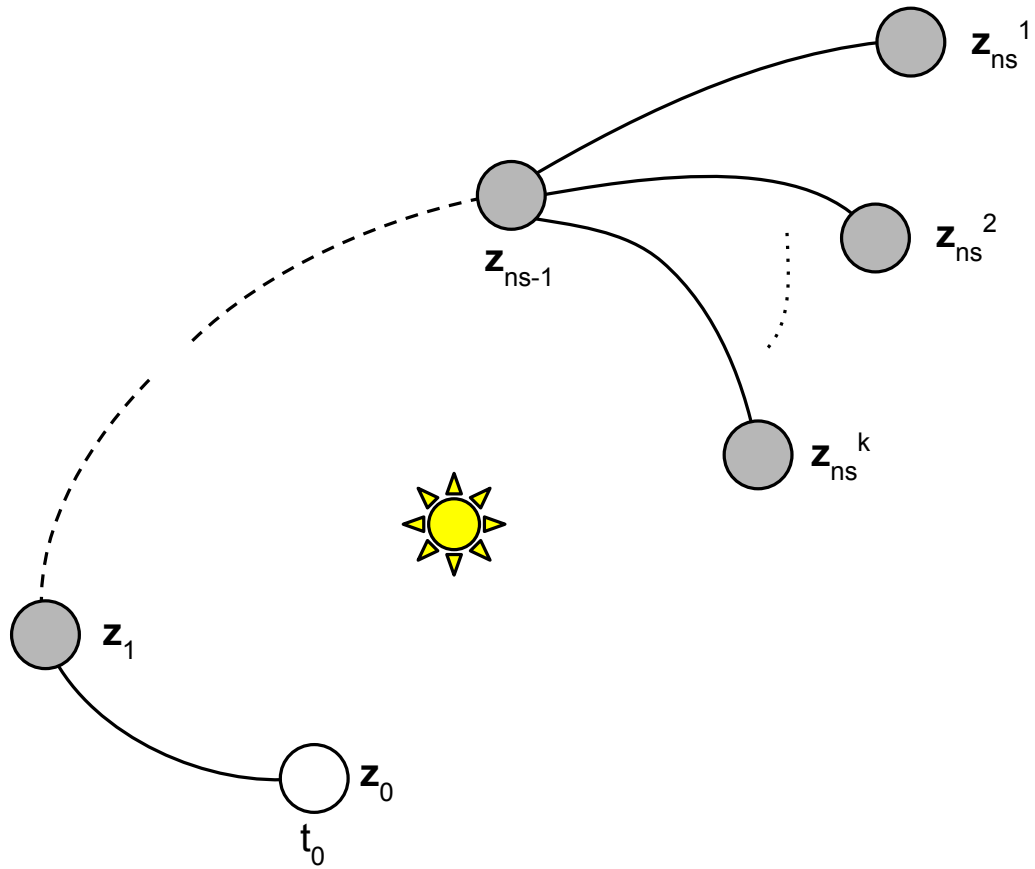

Figure 3.1: k tour trajectories are shown with final states $z_{n_s}^1 \dots z_{n_s}^k$. Each trajectory shares the previous $n_s - 1$ segments in common. The state z_{n_s-1} can be used in the computation of the k final segments.

Consider the scenario shown in Figure 3.1. There are k tour trajectories of length n_s ending with states $\mathbf{z}_{n_s}^1 \dots \mathbf{z}_{n_s}^k$. These k trajectories each share their first $n_s - 1$ segments in common. If the state \mathbf{z}_{n_s-1} is computed once and stored, it can be reused in computing the final segments for all k trajectories, reducing the total computation time significantly (by nearly a factor of k).

Objective and constraint evaluations may also be decomposed by segment. A general objective J is a function of the entire set of decision variables \mathbf{x} .

$$J(\mathbf{x}) = J(t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}) \quad (3.6)$$

However, consider the objective is based in part on the total change of state of the spacecraft $\Delta \mathbf{z}$, where

$$\Delta \mathbf{z} = \mathbf{z}_{n_s} - \mathbf{z}_0 \quad (3.7)$$

This could correspond to total fuel mass used during the tour, for example, and would be commonly minimized or constrained in a tour problem. Clearly $\Delta \mathbf{z}$ can be decomposed by segment as

$$\Delta \mathbf{z} = \sum_{i=1}^{n_s} (\mathbf{z}_i - \mathbf{z}_{i-1}) = \sum_{i=1}^{n_s} \Delta \mathbf{z}_i \quad (3.8)$$

Other objective contributions may be due directly to the decision variables of the segment s_i and \mathbf{y}_i , or results of the computations of the segment. Such contributions might include segment duration or maneuvers, which could correspond to minimizing or constraining total tour time or total maneuver magnitudes, for example. Many common objective functions can therefore be decomposed by segment with contributions J_i as

$$J(\mathbf{x}) = \sum_{i=1}^{n_s} J_i(\mathbf{z}_{i-1}, s_i, \mathbf{y}_i) \quad (3.9)$$

and constraints can be decomposed similarly. Thus, in addition to the final states of segments, objective and constraint contributions can be computed and stored per segment.

The ability to decompose and compute tour trajectories by segment allows for the use of constructive approaches. Rather than working only with full-length complete solutions, the search can work with partial solutions and construct them segment-by-segment over many iterations. Further, a constructive approach that also stores the results of segment computations for later re-use can reduce the number of evaluations required for evaluating large numbers of tour trajectories, allowing for exploration of a larger region of the search space.

3.1.2 Tree-Based Solution Representation

Consider a “tree” solution representation. Branches of the tree represent trajectory segments and their decision variables, and nodes of the tree correspond to states at the segment boundaries. A node of the tree may have multiple “children” corresponding to different segments. The tree can grow to arbitrary depth, representing tour trajectories of any length. Results of state, objective and constraint evaluations are stored in the tree, allowing for new solutions to be generated quickly by expanding the tree segment by segment. This allows existing solutions to be used as building blocks for new solutions, with no recomputation of existing segments required. Consider the group of trajectories shown in the left of Figure 3.2. There are eight complete trajectories corresponding to the eight terminal states. Although these trajectories all differ in their final segments, they each share at least one previous segment in common. These trajectories can be represented in a tree as shown at the right of Figure 3.2. New tour trajectories can be created simply by adding additional segments (branches) to nodes in the tree.

The new solution representation is now a single path through the tree. Recall

Figure 3.2: A group of trajectories. Colors identify different objects. The final bright green object is visited with three different segments corresponding to different segment decision variables \mathbf{y} .

the simple solution representation discussed in Equation (3.1),

$$\mathbf{x} = [t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}] \quad (3.10)$$

This same representation can be recovered from a path through the tree. Consider the more detailed view of the tree in Figure 3.2 shown in Figure 3.3. States and decision variables are annotated for two paths, where the superscripts 1 and 2 are used to differentiate them. The nodes are also numbered, where children of nodes are numbered in ascending order starting at 0. Consider the two paths through the tree, $(0, 0, 0, 0)$ and $(0, 0, 1, 1, 2)$. The values of the paths determine which node to move to at each step, beginning at the root of the tree. From these paths, different solutions can be recovered. In terms of the simple solution representation, we can

Figure 3.3: A detailed view of the tree representation of Figure 3.2 is shown. Children of nodes are numbered in ascending order starting at 0. Paths can be defined with ordered lists of node numbers starting at the root of the tree. States and decision variables are annotated for two paths, corresponding to the superscripts 1 and 2.

recover from the two example paths the solutions

$$(0, 0, 0, 0) \implies \mathbf{x}^1 = [t_0, \mathbf{z}_0, s_1, s_2^1, s_3^1, \mathbf{y}_1, \mathbf{y}_2^1, \mathbf{y}_3^1] \quad (3.11)$$

$$(0, 0, 1, 1, 2) \implies \mathbf{x}^2 = [t_0, \mathbf{z}_0, s_1, s_2^2, s_3^2, s_4^2, \mathbf{y}_1, \mathbf{y}_2^2, \mathbf{y}_3^2, \mathbf{y}_4^2] \quad (3.12)$$

For clarity we will continue to use \mathbf{x} to denote a solution and all of its associated decision variables, understanding that it corresponds to branches and nodes along a path through the tree.

We can analyze the performance of the tree solution representation by considering its use for enumerating all possible solutions for a tour problem. Although a total enumeration is not feasible for even moderately sized problems, this analysis can be used to show the relative performance of the tree solution representation compared to other approaches. Assume that there are N_o candidate objects that can be visited in a tour. Further, assume we compute tours that visit only n_s of these objects, where $n_s \leq N_o$. Each object may be visited only once, and each tour begins from the same initial state. The number of possible tour sequences is then

$$N_{seq} = \frac{N_o!}{(N_o - n_s)!} \quad (3.13)$$

Figure 3.4 shows the possible sequences in a tree solution representation for $N_o = n_s = 5$. The total number of tours possible is much larger than the number of sequences, however, when the continuous decision variables \mathbf{y}_i are allowed to vary for each segment $i \in 1 \dots n_s$ of each sequence $j \in 1 \dots N_{seq}$. If we assume that there are K discretizations of the continuous decision variables at each segment, then the number of possible tours is

$$N_{tours} = N_{seq} K^{n_s} = \frac{N_o!}{(N_o - n_s)!} K^{n_s} \quad (3.14)$$

Figure 3.4: All possible tour sequences shown in the tree solution representation for $N_o = 5$ candidate objects and sequence lengths of $n_s = 5$.

We consider the performance in terms of the number of trajectory segment evaluations required, since this is the most computationally expensive operation in the search. For the tree representation, the total number of segment evaluations is

$$\sum_{h=1}^{n_s} \frac{N_o!}{(N_o - h)!} K^h \quad (3.15)$$

If instead each solution is considered independently using another solution representation where segment computations are not stored and reused, then the number of segment evaluations required is larger at

$$n_s \frac{N_o!}{(N_o - n_s)!} K^{n_s} \quad (3.16)$$

We can compare the relative magnitude of these to determine the expected speedup of using the tree solution representation versus enumerating the tours independently, as

$$f = \frac{n_s K^{n_s}}{(N_o - n_s)! \sum_{h=1}^{n_s} \frac{K^h}{(N_o - h)!}} \quad (3.17)$$

We can simplify this expression to find bounds on the expected speedup. If we assume $N_o \rightarrow \infty$, $n_s = N_o$ and $K = 1$, we find a lower bound on f to be

$$\underline{f} = \frac{n_s}{e} \quad (3.18)$$

Conversely, if we assume $N_o \rightarrow \infty$ and $n_s \rightarrow 1$, we find an upperbound on f to be

$$\bar{f} = n_s \quad (3.19)$$

This upper bound corresponds to an ideal linear speedup in the length of the tour.

Figure 3.5 shows the number of tours and speedup for $N_o = 100$ candidate

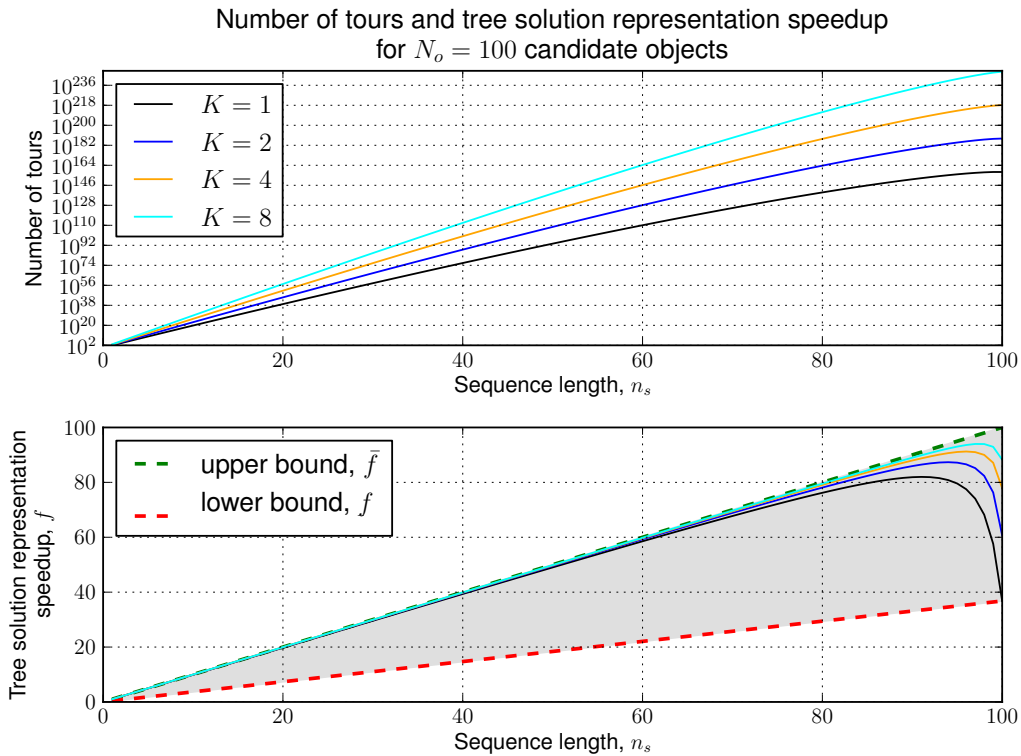

Figure 3.5: Number of tours and tree solution representation speedup for total enumeration of $N_o = 100$ candidate objects and segment discretizations of $K = 1, 2, 4, 8$.

objects and varying tour lengths and segment discretizations. We see a near ideal linear speedup over most of the domain of sequence lengths. This means that the tree solution representation will accelerate the evaluations—and therefore the search—compared to other representations that ignore the hierarchical structure of the search space. Recall, however, that total enumeration is impossible for these problems given the size of the search space; for this small example the number of possible tours quickly exceeds 10^{100} . Any search will only be able to explore a small region of the search space—however, a near linear speedup can be expected over the region of the search space that is explored.

The tree solution representation gives increased computational speed at the cost of storage: the results of all segment computations have to be held in memory. This is in contrast to more typical representations that only require storing one or a fixed number of solutions at a time. For problems with cheap evaluations, such as the traveling salesman, there is less benefit to using the tree representation—the cost of looking up a solution evaluation approaches the cost of simply recomputing it. However, for problems with expensive evaluations, the speedup is significant and is well represented by the current analysis. Finally, we note that the memory required for the tree representation grows as the search progresses. Eventually the memory required will exceed the memory available. In this case, regions of the tree would need to be pruned to make more memory available for the search to continue. This is not an issue for problems with sufficiently expensive evaluations, as the available memory exceeds that required for executing the search over a reasonable period of time.

In summary, we have defined a tree-based solution representation for use in a search. Each solution \mathbf{x} corresponds to a single path through the tree. This solution representation is especially efficient for problems with expensive evaluations: it gives a near linear speedup in the length of the tour. This results from the storage and re-use of segment computations. The representation also facilitates a constructive approach where trajectories are formed segment-by-segment. Additionally, an entire population of solutions is maintained during the search, in contrast to other approaches that maintain only a single (best) solution. The tree solution representation is a building block of a search or optimization algorithm and can be used with many approaches. Aspects of its software implementation are discussed in Appendix A.

3.2 Neighborhoods

Section 3.1 developed a tree-based solution representation for tour trajectories. This solution representation allows for a constructive search approach where partial solutions are expanded segment by segment by adding branches to the tree. However, at this point it has not yet been determined how this expansion of the tree should occur. In practice computing the full tree is infeasible, so it is important to expand it in a way that finds good solutions quickly. This section introduces the concept of neighborhoods, and describes various neighborhoods that can be used to guide the exploration of the tree.

Consider that we have a current solution \mathbf{x} , defined as the incumbent solution. We want to determine an improved solution \mathbf{x}' to move to from this incumbent. A neighborhood defines the set of nearby candidate solutions and is denoted as $\mathcal{N}(\mathbf{x})$. Then, as we iteratively move to a new solution \mathbf{x}' , we are choosing from available solutions in the neighborhood $\mathcal{N}(\mathbf{x})$. That is,

$$\mathbf{x}' \in \mathcal{N}(\mathbf{x}) \tag{3.20}$$

In a greedy search, we would simply move to the best solution in the neighborhood at every iteration, as

$$\mathbf{x}' = \underset{\mathbf{x} \in \mathcal{N}(\mathbf{x})}{\operatorname{argmin}} J(\mathbf{x}) \tag{3.21}$$

The properties of the neighborhood determine the behavior and performance of the search. For example, one might be tempted to define a very large neighborhood with many candidate solutions in an attempt to find an optimal solution in a small number of iterations. However, since each solution in the neighborhood has to be evaluated to determine which is best, these iterations will be slower. Further, a neighborhood consisting of the entire search space would constitute an exhaustive enumeration of the problem. If this were possible, there would be no need for a

search algorithm to begin with. Consequently, neighborhoods are typically defined to only contain a small number of solutions that can be evaluated quickly, and improved solutions are found over many iterations. Neighborhoods can also be defined to intensify or diversify a search about the incumbent solution. Intensification occurs when all candidate solutions in the neighborhood share attributes in common with the incumbent. The search will therefore tend to focus in a smaller region of the search space about the incumbent. Alternatively, a diversifying neighborhood might include solutions sharing little in common with the incumbent, or more explicitly might not have any solutions sharing attributes of the incumbent. The search in this case would tend to quickly move to different regions of the search space. Intensification and diversification can be strategically used to focus on promising regions of the search space or rapidly move away from unfavorable regions.

The remainder of this section develops specific neighborhoods for the tree-based solution representation. These are developed and discussed in terms of their sizes and tendency to diversify or intensify the search.

3.2.1 Neighborhoods for the Tree Solution Representation

Neighborhoods operating on the tree solution representation are constructive neighborhoods since they operate on partial solutions and provide neighboring solutions of longer lengths through expansion of the tree [27]. The tree of solutions grows as neighborhoods are evaluated over many iterations. This is in contrast to most neighborhoods used for combinatorial problems in the operations research literature that only work with complete solutions.

Graph and tree traversal algorithms can be applied and used as neighborhoods in the search given the tree-based solution representation. Before these are considered, let us first define terminology and notation. If we are at an incumbent solution \mathbf{x} , let the children of that solution (which are generated by adding segments

Figure 3.6: An annotated tree is shown for an incumbent solution \mathbf{x} . The root of the tree \mathbf{x}_{root} , children nodes $\mathcal{C}(\mathbf{x})$ and parent nodes $\mathcal{P}^k(\mathbf{x})$ are labeled.

to the tree) be denoted as $\mathcal{C}(\mathbf{x})$. Methods for generating the solutions $\mathcal{C}(\mathbf{x})$ will be discussed in later sections. A node of the tree is a leaf node if it has no current children. Its immediate children, if any are feasible, are generated and added to the tree when $\mathcal{C}(\mathbf{x})$ is evaluated. The leaf nodes that are descendants of a solution \mathbf{x} are denoted as $\mathcal{L}(\mathbf{x})$. The immediate parent of a solution is $\mathcal{P}^1(\mathbf{x})$. The grandparent is $\mathcal{P}^2(\mathbf{x})$, and further ancestors can be found as $\mathcal{P}^h(\mathbf{x})$. We define $\mathcal{P}^0(\mathbf{x})$ to be the solution \mathbf{x} itself. The root of the tree (corresponding to the initial state) is denoted

Figure 3.7: The neighborhood definition $\mathcal{N}(\mathbf{x}) = \mathcal{C}(\mathbf{x})$ leads to a depth-first search. At each iteration the incumbent solution moves deeper in the tree.

as \mathbf{x}_{root} . Figure 3.6 shows an annotated tree for these definitions.

Depth-First and Breadth-First Search

Consider a partial tour trajectory \mathbf{x} is the current incumbent solution and a leaf node of the tree. Since the incumbent is only a partial solution, there are a set of children solutions that can be constructed by adding segments to it. These children solutions are generated through the evaluation of $\mathcal{C}(\mathbf{x})$. Consider then a neighborhood defined as

$$\mathcal{N}(\mathbf{x}) = \mathcal{C}(\mathbf{x}) \tag{3.22}$$

This neighborhood corresponds to all of the children solutions of \mathbf{x} . If at every iteration of the search we move to a solution in this neighborhood, $\mathbf{x}' \in \mathcal{C}(\mathbf{x})$, the

result will be a depth-first search as shown in Figure 3.7 [17]. Although a depth-first search will quickly yield tours with long sequences, the resulting solutions are not likely to be near optimal. If we further assume that at each step we move to the best solution (corresponding to the objective definition) in the neighborhood such that

$$\mathbf{x}' = \underset{\mathbf{x} \in \mathcal{C}(\mathbf{x})}{\operatorname{argmin}} J(\mathbf{x}) \quad (3.23)$$

then we have a greedy depth-first search. This is analogous to the nearest-neighbor heuristic used in the traveling salesman problem, where at every step the salesman simply moves to the next nearest city until the tour is completed [58]. Such solutions are rarely optimal or near optimal and therefore are typically only used to provide a worst-case bound on the optimal solution. The same is true in this case—the greedy depth-first search will quickly find sub-optimal full length solutions. These solutions, however, can be used as upper bounds on the optimal solution and to establish baseline values for objectives and constraints.

Breadth-first search instead expands all of the children of the incumbent $\mathcal{C}(\mathbf{x})$ before progressing deeper into the tree [17]. The result is that all possible nodes at a given depth of the tree are generated before the search moves deeper in the tree, as shown in Figure 3.8. Thus, all tour trajectories of the shortest length are enumerated before longer tours are generated. Only in the late iterations of the search will full length solutions be found.

The depth-first search neighborhood leads to intensification about the incumbent solution. At every iteration, the neighboring solutions are descendants of the incumbent and therefore possess all attributes of the incumbent: the tour sequence and segment decision variables. Depth-first search neighborhoods can therefore be used to strategically focus on regions of the search space about promising solutions. The breadth-first neighborhood instead leads to diversification since it

Figure 3.8: The neighborhood corresponds to a breadth-first search. The search explores all nodes at the highest level of the tree before progressing deeper.

expands nodes highest in the tree first before expanding the incumbent. As the search iterates, it will move to solutions with differing attributes—different sequences and segment decision variable values. A breadth-first neighborhood can be used to strategically move away from the current region of the search space.

Best-First Search

Consider now that instead of expanding the tree with a predefined depth ordering, we explore the most promising nodes of the tree at each iteration. We can define a neighborhood of an incumbent \mathbf{x} as

$$\mathcal{N}(\mathbf{x}) = \mathcal{C}(\mathbf{x}) + \mathcal{L}(\mathbf{x}_{root}) \quad (3.24)$$

where $\mathcal{L}(\mathbf{x}_{root})$ is the set of all leaf nodes in the tree. If at every iteration we move to the new solution \mathbf{x}' ,

$$\mathbf{x}' = \underset{\mathbf{x} \in \mathcal{C}(\mathbf{x}) + \mathcal{L}(\mathbf{x}_{root})}{\operatorname{argmin}} J(\mathbf{x}) \quad (3.25)$$

then we have a best-first search algorithm [39]. At every iteration, the children of the incumbent solution $\mathcal{C}(\mathbf{x})$ are generated and added to the tree, and the best of

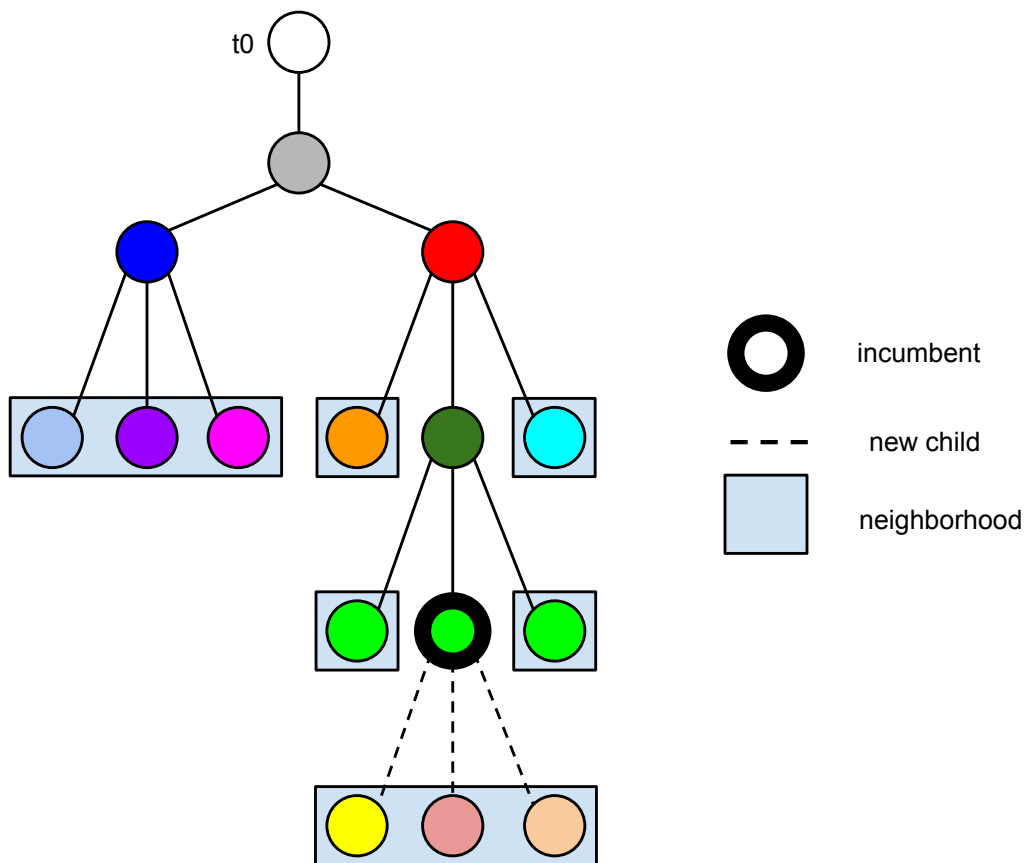

Figure 3.9: A group of four trajectories represented in the tree solution representation. The best-first neighborhood is highlighted.

all new and existing leaf nodes is moved to. The best-first neighborhood is shown in Figure 3.9.

While depth-first search can be viewed as an intensification strategy, and breadth-first search can be seen as a diversification strategy, best-first search is neither. It instead expands the tree only according to objective values with no preference for solution depth or length. Best-first search is the basis for many graph and tree search algorithms. The primary difference between these algorithms is their definition of the objective. For example, Dijkstra's algorithm is a best-first

search using only the objective evaluated on the current partial solution [21]. The A* algorithm instead uses the objective evaluated on the current partial solution in addition to a heuristic term predicting objective contributions of the best complete descendent solution [32]. Best-first search in many cases will find provably optimal solutions. However, a drawback is that as the algorithm iterates, the neighborhood continues to grow as the number of leaf nodes $\mathcal{L}(\mathbf{x}_{root})$ increases. The larger neighborhood is more expensive to evaluate and compare, resulting in slower iterations as the algorithm progresses.

3.2.2 Restricted Best-First Neighborhood

The neighborhood used in best-first search can be modified to allow for strategic intensification or diversification in the search. Recall the best-first search neighborhood is defined as

$$\mathcal{N}(\mathbf{x}) = \mathcal{C}(\mathbf{x}) + \mathcal{L}(\mathbf{x}_{root}) \quad (3.26)$$

An additional parameter h can be added that dictates how far upward in the tree to ascend before finding leaf nodes. While $\mathcal{L}(\mathbf{x}_{root})$ gives all leaf nodes of the tree starting from the root, $\mathcal{L}(\mathcal{P}^h(\mathbf{x}))$ gives all leaf nodes of the tree starting from the h^{th} ancestor of \mathbf{x} . The restricted best-first neighborhood is therefore

$$\mathcal{N}(\mathbf{x}, h) = \mathcal{C}(\mathbf{x}) + \mathcal{L}(\mathcal{P}^h(\mathbf{x})) \quad (3.27)$$

This neighborhood is shown in Figure 3.10. Small values of h lead to intensification, with $h = 0$ corresponding to depth-first search, while large values of h allow for diversification. When $h = n_s$, a breadth-first search is possible.

Further, h can be varied to affect the size of the neighborhood. For large trees, large h values can give neighborhoods with many solutions and lengthen the compute time per iteration. While existing leaf nodes do not have to be recomputed

Figure 3.10: A group of tour trajectories represented in the tree solution representation. The restricted best-first neighborhoods corresponding to different h values are shown.

since results are stored in the tree, simply sorting a large number of solutions by objective can be expensive for large neighborhoods—finding the single best solution is $\mathcal{O}(n)$ in the number of solutions [17]. Therefore, in these cases h can be decreased to reduce the size of the neighborhood.

The restricted best-first neighborhood is the most flexible of the tree-based neighborhoods presented so far. It allows for strategic intensification and diversification of the search as well as implicit limiting of the neighborhood size through its parameter h . It will therefore be used as the neighborhood in the overall search algorithm.

3.3 Objectives

The objective $J(\mathbf{x})$ is provided as part of the problem statement. It gives a scalar value that is used to compare solutions to each other and judge which is superior. This objective function is appropriate to use when comparing complete (full-length) solutions. However, in the context of the tree-based solution representation, it instead may be used to compare partial solutions composed of only a few segments with complete solutions composed of many. In these cases, the provided objective function may not be appropriate. For example, objectives based on minimizing resource consumption such as fuel usage will tend to favor partial solutions with few segments. The search would then tend to be a breadth-first search of the tree. Conversely, objectives based on mission goals such as maximizing the number of visited objects will tend to favor complete longer-length solutions. In this case, the search would tend toward a depth-first search. Although the provided $J(\mathbf{x})$ is the metric for judging complete solutions at the end of the search, it should not be used to guide the exploration and construction of partial solutions during the search.

3.3.1 Guiding Objective

A guiding objective can be defined and used during the search in place of the provided objective $J(\mathbf{x})$. The goal of this objective would be to better compare partial solutions of only a few segments with solutions containing many segments. The idea is that a partial solution with a currently poor objective value may produce a better solution if expanded to full length than a near-complete solution with a better objective value. The guiding objective therefore attempts to quantify the potential value of partial solutions. Specifically, it attempts to estimate the best possible solution that can result from expanding a partial solution to full length. In this way, it can more effectively guide the search into promising regions of the search space. This approach is inspired by the objective definition in the A* search algorithm, which has a heuristic term predicting the best achievable objective originating from the current path [55]. While problem-specific heuristics can be developed to determine the value of the guiding objective, this section focuses on developing a general strategy that can be applied to any tour problem and objective definition.

We can define the guiding objective $J^*(\mathbf{x})$ in terms of a constrained value of the problem, such as a limited mass of fuel or limited mission time. For example, assume the total mission time is limited to t_{max} , according to the tour model of Section 2.2.6. A partial tour begins at time t_0 , and each segment ends at time t_i . The final segment of the tour ends at t_{n_s} . The remaining allowed mission time is then $t_{max} - t_{n_s}$. The guiding objective should include an estimate of the best possible complete tour originating from the current partial tour. Assume that the future objective contribution is linear in the time of flight. The contribution can then be defined by a parameter $\frac{dJ^*}{dt}$. This parameter can be used in the heuristic term in the guiding objective. The guiding objective is then defined as

$$J^*(\mathbf{x}) = J(\mathbf{x}) + \frac{dJ^*}{dt} (t_{max} - t_{n_s}) \quad (3.28)$$

Figure 3.11: The guiding objective contains the objective defined in the problem statement evaluated on the partial trajectory $J(\mathbf{x})$, and a heuristic term based on the parameter $\frac{dJ^*}{dt}$ estimating contributions over the remaining mission time.

The guiding objective contains the objective defined in the problem statement evaluated on the partial trajectory and a heuristic term estimating contributions over the remaining mission time. Figure 3.11 shows the guiding objective schematically.

The choice of $\frac{dJ^*}{dt}$ governs the expansion of the tree from iteration to iteration. Ideally the chosen value would perfectly represent the best solution originating from the current solution and therefore guide the search directly to the globally optimal solution. However, since this is not possible, we must consider the effects of under or overestimating the value. For simplicity, assume that the objective we attempt to

minimize monotonically decreases as trajectory segments are added to a tour. Such an objective definition would correspond to mission goals: gaining value for every object visited in the tour.

A pessimistic value for $\frac{dJ^*}{dt}$ will cause the guiding objective to underestimate the best solution possible from a partial solution. Consider the limiting case of $\frac{dJ^*}{dt} = 0$. This simplifies the guiding objective to the problem-provided objective so that $J^*(\mathbf{x}) = J(\mathbf{x})$. The guiding objective now predicts no improvement in the objective from adding segments to the partial tour \mathbf{x} . Since the objective $J(\mathbf{x})$ monotonically decreases with the tour length, any solution that is expanded will then do better than the guiding objective predicted. The guiding objective will thus tend to favor longer solutions with many segments over shorter solutions with few, and the iterations will tend toward a depth-first search of the tree. The search will quickly yield solutions for long tours.

An optimistic value for $\frac{dJ^*}{dt}$ will instead cause the guiding objective to overestimate the best solution possible from the current solution. Consider now $\frac{dJ^*}{dt} = -M$. The guiding objective is then

$$J^*(\mathbf{x}) = J(\mathbf{x}) - M (t_{max} - t_{n_s}) \quad (3.29)$$

If M is sufficiently large, then the guiding objective will predict more improvement than is possible from adding segments to a tour. Any solution that is expanded will do worse than the guiding objective predicted. The guiding objective will thus tend to favor shorter solutions with fewer segments, and the iterations will tend toward a breadth-first search of the tree. We can compare an optimistic guiding objective definition to an “admissible heuristic” in the A* search algorithm [20]. The heuristic is termed admissible since it guarantees that the search will never overlook the possibility of a lower cost path. When a complete solution is found, it must therefore be optimal. The concept extends to this case as well.

In practice we neither want to favor depth-first search nor breadth-first search, but an adaptive exploration of the tree based on the search history. Consider now varying the heuristic term of the guiding objective with

$$0 \geq \frac{dJ^*}{dt} \geq -M \quad (3.30)$$

If we start the search with $\frac{dJ^*}{dt} = 0$, then we will quickly find solutions for long tours in a depth-first search manner. We decrease (make more optimistic) $\frac{dJ^*}{dt}$ as better solutions are found, causing the search to focus on increasingly more promising solutions. Eventually when the magnitude of $\frac{dJ^*}{dt}$ is large enough, the heuristic term will become admissible and thus guarantee that any complete solutions found will be optimal. The search then has the desirable properties of finding solutions for long tours quickly, continually improved solutions over many iterations and provably optimal solutions as the run time approaches infinity.

$\frac{dJ^*}{dt}$ can be chosen from a desired goal objective for the problem, J_{goal} . In turn, the goal objective can be adjusted adaptively as the search progresses. Given a value for J_{goal} , we define

$$\frac{dJ^*}{dt} = \frac{J_{goal}}{(t_{max} - t_0)} \quad (3.31)$$

The value of J_{goal} gives the predicted best solution from the initial conditions of the search. That is,

$$J_{goal} = J^*(\mathbf{x}_{root}) \quad (3.32)$$

We adjust J_{goal} rather than $\frac{dJ^*}{dt}$ directly so that the units of the parameter match the units of the problem-provided objective $J(\mathbf{x})$. This allows for easier use of a priori information, such as known achievable objectives, into the search. In the absence of such information, we initialize J_{goal} to zero (thus initializing $\frac{dJ^*}{dt}$ to zero) and then adaptively decrease it as solutions with objectives better than the goal objective are found. The change in J_{goal} is according to a user-defined parameter,

ΔJ_{goal} . A procedure for the adaptive update is shown in Algorithm 2. We note that the update makes use of only the objective $J(\mathbf{x})$ and not the guiding objective.

Algorithm 2 Adaptively update guiding objective heuristic

procedure UPDATEGUIDINGOBJECTIVEHEURISTIC
 \triangleright find the best objective of all solutions in the tree
 $J_{best} \leftarrow \min_{\mathbf{x} \in \mathcal{L}(\mathbf{x}_{root})} J(\mathbf{x})$
 \triangleright if the best objective found is better than the goal, then decrease the goal and update $\frac{dJ^*}{dt}$
if $J_{best} \leq J_{goal}$ **then**
 $J_{goal} \leftarrow J_{best} - \Delta J_{goal}$
 $\frac{dJ^*}{dt} \leftarrow \frac{J_{goal}}{(t_{max} - t_0)}$
 \triangleright the guiding objective definition has changed; clear stored $J^*(\mathbf{x})$ results
clear stored $J^*(\mathbf{x})$ results
end if
end procedure

The defined guiding objective $J^*(\mathbf{x})$ quantifies the potential of a partial solution by estimating the best achievable solution originating from it. This allows for better comparison of solutions of varying lengths. Further, the guiding objective definition is adaptively updated as the search progresses, causing it to favor increasingly promising solutions over time. In the limit as the run time approaches infinity, the guiding objective will lead the search to find provably optimal solutions.

3.3.2 Budget Penalty Terms

Spacecraft tour trajectory problems will all in practice have resource constraints that solutions must satisfy in order to be feasible. Such constraints include a limited mass of available fuel or equivalently a maximum allowed ΔV , for example. These constraints are provided in the problem statement as constraints on the final state of the spacecraft. In the context of our tree-based search, these constraints are

evaluated on partial solutions as they are constructed, and solutions violating them are rejected. Assume again that the objective is based on mission goals such as maximizing the number of visited objects. Longer-length solutions will be favored, and we can expect that these longer-length solutions will also be of longer duration. Thus, solutions where all the resources are used very early in the mission are not likely be near optimal. We therefore wish to discourage the search from exploring solutions that use limited resources too quickly. We accomplish this by penalizing the objective when the resource usage exceeds a provided budget.

Consider the impulsive spacecraft tour model defined in Section 2.2.6. If the spacecraft thrusts continuously at a constant magnitude T , then it will deplete its fuel at a constant rate of

$$\dot{m} = -\frac{T}{I_{sp} g_0} \quad (3.33)$$

Then, noting that the mass can never fall below the spacecraft's dry mass, its mass at time t can be computed as

$$m(t) = \max [m_0 + \dot{m}(t - t_0), m_{dry}] \quad (3.34)$$

Given the mass history, the corresponding cumulative ΔV can be calculated as

$$\Delta V(t) = I_{sp} g_0 \ln \frac{m_0}{m(t)} \quad (3.35)$$

Given a maximum thrust magnitude T_{max} , the maximum allowed mass depletion rate is

$$\dot{m}_{max} = -\frac{T_{max}}{I_{sp} g_0} \quad (3.36)$$

The corresponding mass and ΔV profiles define the feasible region for a finite burn trajectory. However, we can also budget the available fuel mass over the maximum allowed duration of the tour so long as we do not exceed this maximum mass rate.

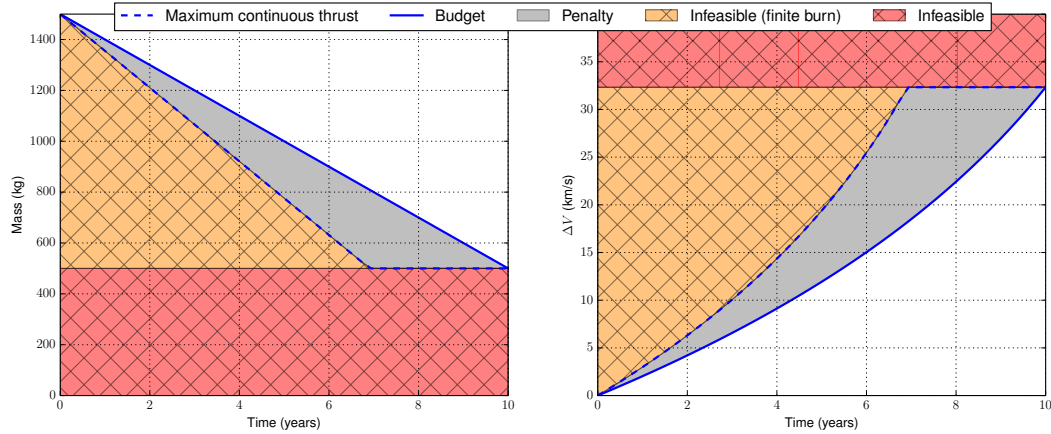

Figure 3.12: The mass and ΔV time histories are shown for maximum continuous thrust until fuel exhaustion and the budgeted amount. The regions where penalties are added to the objective are highlighted. The infeasible regions for a finite burn model and for the final state constraints are shown. The spacecraft parameters correspond to the GTOC4 problem [12].

Then, we have

$$\dot{m}_{budget} = \max \left[-\frac{m_0 - m_{dry}}{t_{max} - t_0}, \dot{m}_{max} \right] \quad (3.37)$$

The corresponding mass and ΔV profiles define a budget over the time of the trajectory. We wish to penalize trajectories that exceed this budget. Figure 3.12 shows the mass and ΔV histories corresponding to maximum continuous thrust and the budgeted mass usage, and also highlights the regions of infeasibility for both the finite burn and general cases. We penalize solutions falling within the penalty region shown.

Penalty terms can be defined by a non-negative weight and the magnitude exceeding the budget. We can define penalties for both the mass and the ΔV as

$$P_m(\mathbf{x}) = w_m \max [m_{budget}(t_{n_s}) - m(t_{n_s}), 0] \quad (3.38)$$

$$P_{\Delta V}(\mathbf{x}) = w_{\Delta V} \max [\Delta V(t_{n_s}) - \Delta V_{budget}(t_{n_s}), 0] \quad (3.39)$$

Only one such term should have a positive weight, however, as they have similar effects on the objective. These non-negative penalty terms are then added to the guiding objective, giving

$$J^*(\mathbf{x}) = J(\mathbf{x}) + \frac{dJ^*}{dt} (t_{max} - t_{n_s}) + P_m(\mathbf{x}) + P_{\Delta V}(\mathbf{x}) \quad (3.40)$$

3.4 Solution Construction (Node Expansion)

This section describes the construction of new solutions during the search. When the search begins, the tree is created with only a root node representing initial conditions. This solution, \mathbf{x}_{root} , is the basis for all future solutions generated during the search. These new solutions are generated from iteration to iteration as neighborhoods of incumbents are evaluated. The neighborhood evaluation triggers expansion of nodes in the tree when terms $\mathcal{C}(\mathbf{x})$ representing the children of a solution are evaluated. It is only when these children are explored that new solutions are generated and added to the tree. The remainder of this section details the generation of children solutions $\mathcal{C}(\mathbf{x})$.

When $\mathcal{C}(\mathbf{x})$ is evaluated, trajectory segments are added to the solution \mathbf{x} to generate a set of children solutions. The parent solution's final state is the children's initial state. The new children solutions therefore only require the definition of s and \mathbf{y} , the next target object and the continuous decision variables of the trajectory segment. The children generated determine the part of the search space that can be explored. Children solutions should therefore be created for all feasible possibilities.

The simplest approach for generating $\mathcal{C}(\mathbf{x})$ would be to enumerate all possible values for s and \mathbf{y} , construct the corresponding solutions, and keep the solutions that are feasible to the problem constraints. The enumeration of s is straightforward: consider all values of $s \in O$ feasible to the problem statement. Let us define a function $\mathcal{F}(\mathbf{x})$ that determines the set of feasible objects that may be visited next

in a given tour \mathbf{x} . If there are no restrictions on the tour itinerary (i.e. each object can be visited any number of times and in any order), then

$$\mathcal{F}(\mathbf{x}) = O \quad (3.41)$$

If, however, there are restrictions on the itinerary, then the feasible objects would instead be a subset of O . If each object may only be visited once in a tour, then

$$\mathcal{F}(\mathbf{x}) = O \setminus \{s_1 \dots s_{n_s}\} \quad (3.42)$$

We then generate solutions for all $s \in \mathcal{F}(\mathbf{x})$. Then, for each enumeration of s , values for \mathbf{y} must also be enumerated. Since \mathbf{y} represents continuous decision variables, there are an infinite number of possible values. So, a discretization of \mathbf{y} must occur. We define for each element $y_i \in \mathbf{y}$ a range, $y_{i_{min}}$ and $y_{i_{max}}$, and a number of discretizations K_i . If there are n_y elements of \mathbf{y} , then there are K total discretizations of the continuous decision variables \mathbf{y} , where

$$K = \prod_{i=1}^{n_y} K_i \quad (3.43)$$

The total number of solutions evaluated in the generation of $\mathcal{C}(\mathbf{x})$ is then

$$\|\mathcal{F}(\mathbf{x})\| K = \|\mathcal{F}(\mathbf{x})\| \prod_{i=1}^{n_y} K_i \quad (3.44)$$

Only a subset of these solutions will be feasible and define $\mathcal{C}(\mathbf{x})$.

Consider the impulsive tour model of Section 2.2.6 as an example for generating children solutions. In this case, we have

$$\mathbf{y} = \begin{pmatrix} \tau \\ \Delta t \end{pmatrix} \quad (3.45)$$

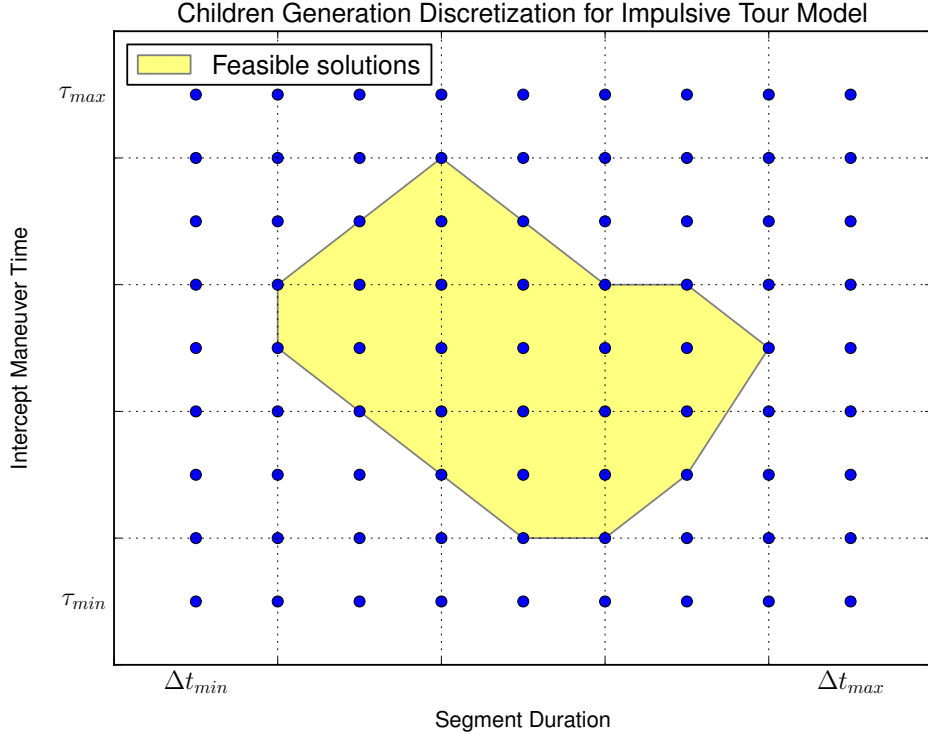

Figure 3.13: For the next target object s , a discretized grid of possible new children solutions over the range of allowed τ and Δt values. The set of solutions found to be feasible after evaluation is highlighted.

We define a corresponding range for the elements as

$$\mathbf{y}_{min} = \begin{pmatrix} \tau_{min} \\ \Delta t_{min} \end{pmatrix} \quad \mathbf{y}_{max} = \begin{pmatrix} \tau_{max} \\ \Delta t_{max} \end{pmatrix} \quad (3.46)$$

and a number of discretizations K_1 for τ and K_2 for Δt . For a single object $s \in \|\mathcal{F}(\mathbf{x})\|$, we can form a grid of $K = K_1 K_2$ possible new children. Figure 3.13 shows the enumeration. Each solution in this grid is evaluated. If the solution is feasible according to the constraints of the problem, then it is added to the set of children solutions $\mathcal{C}(\mathbf{x})$. In this example we see that many more solutions are evaluated

than are found feasible. Since these evaluations are computationally expensive, the excess evaluations can slow down the search dramatically. When possible, specific knowledge of the problem should be used to inform this grid search so as to minimize exploration of the infeasible search space.

We have presented a simple method for generating the feasible children solutions $\mathcal{C}(\mathbf{x})$. This method enumerates all possibilities subject to a discretization of the continuous decision variables and discards those solutions that are found to be infeasible. While this approach does generate all the feasible child solutions as desired, it does so inefficiently: many infeasible solutions may be evaluated, and these evaluations are computationally expensive. Chapter 4 presents a space pruning approach that accelerates this approach.

3.5 Tabu Search

Tabu search is a metaheuristic search algorithm first proposed by Glover in 1986 and later formalized in 1989 [24, 25]. Like most metaheuristic approaches, it does not find provably global optimal solutions; it instead is an approximate method that attempts to find good, near-optimal solutions quickly. It is thus widely used on problems where exact methods are not practical. The algorithm is an extension of local search: at every iteration a new solution is moved to from a neighborhood of solutions nearby the incumbent. While local search procedures tend to get stuck at local optima, tabu search explores the search space beyond local optimality and thus is able to find globally good solutions. The fundamental characteristic of tabu search is its use of memory: during the search it records attributes of solutions visited and uses this information to inform future moves and strategy. Unlike other metaheuristic approaches, tabu search does not rely on randomization and is thus deterministic.

Tabu search escapes local optima in two ways. Similar to the “steepest as-

cent mildest descent” method (for maximization) developed by Hansen, tabu search allows for non-improving moves when the neighborhood has no improving solutions [31]. It moves to the best solution in the neighborhood, which is either the most improving or least disimproving. This allows the algorithm to move away from a local optimum. However, this alone does not prevent the search from returning to the same local optimum on subsequent iterations. This behavior, known as cycling, is prevented in tabu search through the use of memory. During the search, the solutions visited are recorded. These recently visited solutions are then marked as “tabu” such that they cannot be visited again for a given number of iterations. More generally, the search can record attributes of solutions (rather than the solutions themselves) to prevent the search from returning to solutions similar to those already visited. The tabu restrictions act to filter the full neighborhood $\mathcal{N}(\mathbf{x})$ into a candidate neighborhood of admissible (non-tabu) solutions, $\tilde{\mathcal{N}}(\mathbf{x}) \subseteq \mathcal{N}(\mathbf{x})$. This approach is termed recency-based tabu search. The number of iterations a solution attribute is considered tabu is the tabu tenure. Recency-based memory is one of the most commonly used approaches in tabu search implementations [27].

Advanced tabu search algorithms also employ strategic intensification and diversification [27]. When promising solutions are found, the search can be intensified about them, causing solutions with similar attributes to the promising incumbent to be favored. This results in a more thorough exploration of the promising region of the search space in the hopes that the best solutions in that region will be found. Conversely, diversification may be strategically used when the search is focusing too heavily in a restricted region of the search space. Although good solutions may be found there, more interesting or promising regions of the search space may be left unexplored, and the best solutions to the problem may not be found. Since tabu search is fundamentally a local search procedure, diversification is viewed as a critical component to finding globally good solutions [23]. An extreme form of

diversification can be implemented as an escape procedure, causing the search to rapidly move away from the region of the incumbent. Escape procedures are used when simpler forms of diversification have failed. These strategic intensification, diversification and escape methods may be implemented in a variety of ways. Simple approaches involve manipulating the tabu tenure: a short tabu tenure allows for intensification, while a long tabu tenure forces diversification. Other approaches involve changing the definition of the neighborhood through a dynamic neighborhood selection process.

A basic tabu search algorithm demonstrating these approaches is shown in Algorithm 3. The remainder of this section develops components of this tabu search algorithm in terms of the previously developed solution representation, neighborhoods and objectives.

3.5.1 Recency-based Tabu Memory

The fundamental component of the tabu search algorithm described in Algorithm 3 is the recency-based tabu memory used in the `ISTABU(\mathbf{x})` and `UPDATETABUATTRIBUTES(\mathbf{x})` procedures. This memory maintains a history of recently visited solutions and prevents the search from returning to those solutions for a period of time, which in turn prevents cycling. The memory can more generally maintain attributes of recently visited solutions, and thus prevent the search from visiting a range of solutions similar to those already visited. The definition of the tabu attributes determines how narrow or broad the resulting tabu restrictions are. We continue by describing the tabu memory structure and defining tabu attributes.

The recency-based tabu memory is stored in an array called the tabu list, which we denote as \mathcal{T} . At each iteration, attributes of the new incumbent solution are added to the tabu list. We denote these attributes as $A(\mathbf{x}_i)$ for the incumbent solution of iteration i . Solutions sharing any of the attributes in the tabu list are

Algorithm 3 Basic tabu search algorithm [63].

▷ execute tabu search beginning at initial solution \mathbf{x}_0

procedure TABUSEARCH(\mathbf{x}_0)

else if Diversification conditions satisfied **then**

 DIVERSIFY(\mathbf{x}_{i+1})

end if

 ▷ increment iteration counter

$i \leftarrow i + 1$

until Stopping criteria satisfied

return best solution found

end procedure

not admissible in the search and are thus not allowed in the candidate neighborhood $\tilde{\mathcal{N}}(\mathbf{x})$. The tabu list has a finite length: this is the tabu tenure $N_{\mathcal{T}}$ and a parameter of the search algorithm. A small value of $N_{\mathcal{T}}$ gives a short tabu tenure; solution attributes are then only considered tabu for a short period of time. The result is that the search is allowed to intensify about the incumbent solution. If the tabu tenure is too short, then the search may also cycle about a local optimum. A large value of $N_{\mathcal{T}}$ gives a long tabu tenure and instead has a diversifying effect: the search will tend to move to different regions of the search space. While dynamic adjustment of the tabu tenure is possible, we instead use a static tabu tenure throughout the search. As Glover notes, many problem instances have a robust range of good tabu tenure values that produce good results and can be determined empirically [26]. When the tabu list is full and new attributes are added, the oldest attributes are dropped from the list in a first-in first-out manner and once again allowed in the search. Figure 3.14 shows this behavior.

We now consider tabu attributes for tour trajectory solutions. Recall the solution definition from Equation 3.1,

$$\mathbf{x} = [t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}] \quad (3.47)$$

At one extreme we can mark an exact solution as tabu, defining the the tabu attributes of a solution as

$$A(\mathbf{x}) = [t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}] \quad (3.48)$$

This is the narrowest tabu attribute we can apply; it would prevent the particular solution from being visited again for the duration of the tabu tenure. We note however that this type of tabu behavior is implicit in the tree-based solution representation and neighborhood definitions: only leaf nodes are considered in the neighborhood,

Figure 3.14: The tabu list \mathcal{T} is an array of solution attributes that are prohibited in the search. Its length is the tabu tenure $N_{\mathcal{T}}$ and determines how many iterations attributes are considered tabu. As attributes of new incumbent solutions $A(\mathbf{x}_i)$ are added to the list, the oldest tabu attributes are forgotten.

and the new incumbent is always expanded at the next iteration. Therefore, an incumbent solution can only ever be visited once, and cycling among exact solutions is impossible. Instead we consider more general attributes of the incumbent. Consider defining a family of trajectories by the ordered sequence of objects they visit. The attribute definition is then

$$A(\mathbf{x}) = [s_1 \dots s_{n_s}] \quad (3.49)$$

This contains only the discrete decision variables of the solution and is a broader tabu restriction on the neighborhood since it matches more solutions. Recall the construction of new solutions during the search described in Section 3.4. From an incumbent solution, new solutions are constructed for each feasible target object for K discretizations of the continuous decision variables \mathbf{y} . This results in up to K new feasible tours for the same sequence. More generally, total enumeration from the root of the tree allows up to K^{n_s} solutions for the same sequence. The trajectory family tabu attribute prevents the search from cycling among these similar solutions, promoting the exploration of varying sequences even if one particular sequence is promising.

We can formalize the procedure for testing if a solution is tabu and therefore admissible or not in the candidate neighborhood. This procedure `isTABU(x)` is referenced in the basic tabu search algorithm (Algorithm 3) and is defined below in Algorithm 4. If any of the attributes of the solution are present in the tabu list, then the solution is tabu. After a non-tabu solution is chosen as the new incumbent, the tabu list is updated with attributes of the new solution. This procedure, `updateTabuAttributes(x)` adds tabu attributes of \mathbf{x} to the tabu list and removes the oldest tabu attributes. Algorithm 5 shows the procedure. The definition of tabu attributes $A(\mathbf{x})$, the tabu list \mathcal{T} and the tabu tenure $N_{\mathcal{T}}$ define all that is necessary for the implementation of recency-based tabu memory.

Algorithm 4 Test if a solution \mathbf{x} is tabu.

end for

 ▷ add attributes of solution \mathbf{x} to the front of the tabu list

$\mathcal{T}_1 \leftarrow A(\mathbf{x})$

end procedure

3.5.2 Strategic Intensification and Diversification

We have defined the recency-based tabu memory with the primary goal of preventing cycling. This short-term memory can be viewed as a basic form of diversification: it prevents the search from visiting similar solutions in sequence within the limits of the tabu tenure. We now consider methods to more strategically guide the search beyond the basic recency-based approach. Specifically, we consider an approach that adaptively intensifies and diversifies the search based on its performance. When we intensify the search, we choose to move toward solutions similar to the incumbent. Conversely, diversification guides the search away from such solutions. The remainder of this section develops the conditions that trigger intensification and diversification as well as the modifications to the search that implement them.

The conditions that trigger intensification and diversification can be based on any component of the search. For example, we can choose to intensify the search when a new best solution is found. The resulting intensification would favor solutions sharing attributes of that best solution in the hopes of finding more improved solutions. We can also diversify the search when solutions are visited too often in order to explore a more representative sample of the search space; this approach is typically implemented with a longer term frequency-based tabu memory [27]. In determining these triggering conditions, however, we must consider the unique characteristics of our search and our solution representation in particular. The tree-based solution representation represents partial solutions, and the neighborhoods we have defined expand or contract these partial solutions in constructive and destructive processes. From iteration to iteration, the incumbent solution thus varies in length, ranging from partial solutions with few trajectory segments to complete solutions with many. We wish to maintain a balanced exploration during the search, both visiting long-length complete solutions that solve the original problem statement and expanding short-length partial solutions to reveal new promising paths. This is

another form of diversity in the search, not based on specific attributes of solutions but instead on their length. The length of a solution is defined by its sequence length n_s or equivalently its depth in the tree. In the context of our search then, we define intensification to cause solutions to be expanded to longer lengths. These longer-length solutions share trajectory segments in common with the incumbent, or may even be completely based on the incumbent. Diversification instead moves upward in the tree to shorter solutions that share little in common with the incumbent.

We define a stall condition for identifying when the search should be intensified or diversified. A stall occurs when the search is stuck in a limited range of solution lengths over a specified number of iterations. The stall condition is thus identified with two parameters: a minimum solution length range \underline{R} and a period of iterations over which the range is measured N_{stall} . The range of solution lengths over the previous N_{stall} iterations is given by

$$R(N_{stall}) = \max_{\mathbf{x} \in \{\mathbf{x}_i \dots \mathbf{x}_{i-N_{stall}}\}} \mathbf{x}[n_s] - \min_{\mathbf{x} \in \{\mathbf{x}_i \dots \mathbf{x}_{i-N_{stall}}\}} \mathbf{x}[n_s] \quad (3.50)$$

A stall thus occurs when

$$R(N_{stall}) \leq \underline{R} \quad (3.51)$$

Figure 3.15 shows an example search history where the search proceeds depth-first and then stalls. After a period of iterations the stall ends and the search proceeds deeper in the tree. The resulting solution length range calculations are shown. The stall condition is not evaluated until at least N_{stall} iterations have occurred. We see the stall is detected N_{stall} iterations after it begins.

Once a stall is detected, we wish for the search to dynamically adjust in order to break the stall. Based on our development so far, we have two options: we can either intensify the search about the incumbent or instead diversify. Either approach can break the stall. An intensification can force the search deeper in the tree to

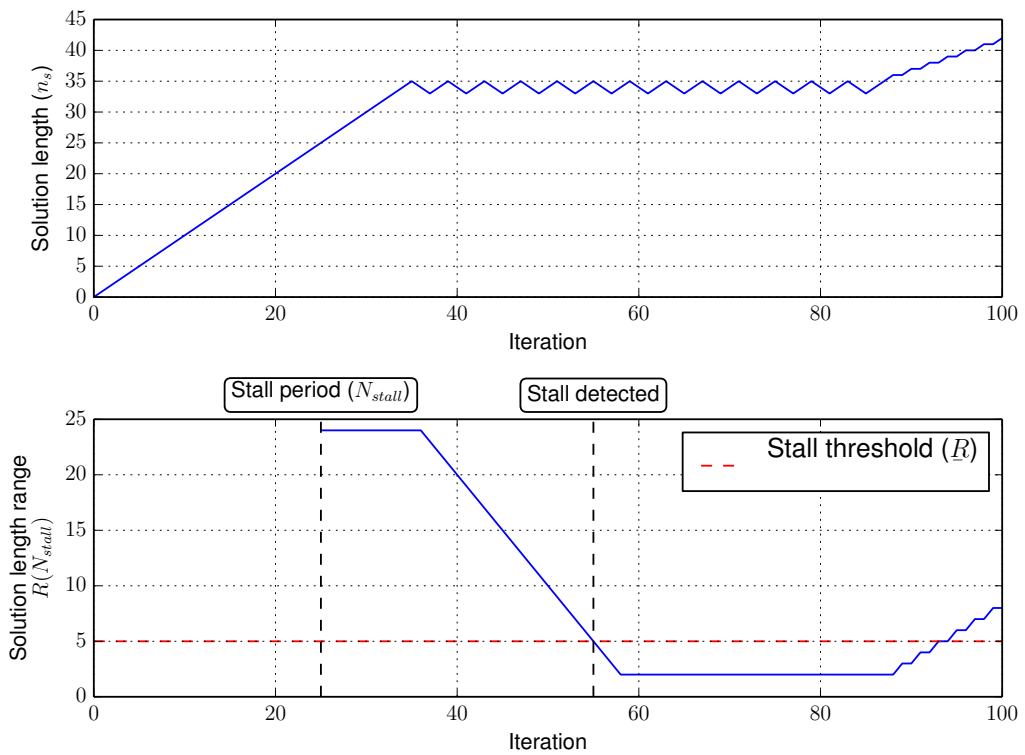

Figure 3.15: An example search history. The incumbent solution lengths are shown along with the stall condition evaluated for $N_{stall} = 25$ and $R = 5$.

longer solution lengths, while a diversification will allow the search to move upward in the tree to shorter solutions. We thus choose to react to stalls using both of these approaches, using the properties of the incumbent to determine which approach is used. In order to optimize the problem-provided objective $J(\mathbf{x})$, we generally want to find long-length solutions. We therefore choose by default to react to stalls with intensification to encourage these long-length solutions. However, intensification in the form we have described works only when the incumbent solution can be feasibly expanded. When a tour is near the limits of the problem constraints, any expansion of the tour will lead to infeasible children solutions. At this point, intensification can no longer break a stall and will instead prolong it. When this occurs, we instead choose to break the stall with diversification, which allows the search to move to shorter-length solutions and find new promising paths in different regions of the search space. The condition at which we choose diversification rather than intensification may be defined in terms of any of the problem constraints, such as limited fuel mass or mission duration. We have already developed budget constraints to limit fuel usage in Section 3.3.2, so we choose the maximum mission duration as the limiting condition. Specifically, when the incumbent solution’s mission duration is sufficiently close to the limit, we choose to react with diversification. When a stall is detected we react with intensification or diversification according to the conditions below.

$$\text{stall reaction} = \begin{cases} \text{intensification} & t_{n_s} - t_0 \leq 0.9 (t_{max} - t_0) \\ \text{diversification} & t_{n_s} - t_0 > 0.9 (t_{max} - t_0) \end{cases} \quad (3.52)$$

We can now detect stalls and decide whether to intensify or the diversify the search in order to escape them. We now need to determine how the desired intensification and diversification should be implemented. For this we can dynamically change the neighborhood. Dynamic neighborhood selection is an advanced approach

used on its own in metaheuristic local search procedures as well as in tabu search implementations [44, 27]. Recall the restricted best-first neighborhood developed in Section 3.2.2, defined as

$$\mathcal{N}(\mathbf{x}, h) = \mathcal{C}(\mathbf{x}) + \mathcal{L}(\mathcal{P}^h(\mathbf{x})) \quad (3.53)$$

The only parameter of the neighborhood is h which dictates how far upward to move in the tree before finding leaf nodes. We found that small values of h led to intensification, with $h = 0$ forcing a depth-first search. Large values of h allow for diversification up to the limit of breadth-first search. We now choose to adaptively update h to achieve intensification or diversification—decreasing it to intensify and increasing it to diversify. We define additional parameters to bound the values of h , such that

$$h_{min} \leq h \leq h_{max} \quad (3.54)$$

Algorithms 6 and 7 define procedures for intensifying and diversifying the search. These procedures are called when the stall condition is satisfied according to the conditions in Equation (3.52).

Algorithm 6 Intensify the search about the solution \mathbf{x} .

```

procedure INTENSIFY( $\mathbf{x}$ )
  ▷ intensify by updating the restricted best-first neighborhood  $\mathcal{N}(\mathbf{x}, h)$ 
  ▷ subject to  $h_{min} \leq h \leq h_{max}$ 
  if  $h > h_{min}$  then
     $h \leftarrow h - 1$ 
  end if
end procedure

```

While the intensification and diversification approaches developed are sufficient for addressing most stalls, there may still be scenarios where a stall persists. For these cases we develop an escape procedure to more drastically react. Escape

Algorithm 7 Diversify the search about the solution \mathbf{x} .

procedure DIVERSIFY(\mathbf{x})
▷ diversify by updating the restricted best-first neighborhood $\mathcal{N}(\mathbf{x}, h)$
▷ subject to $h_{min} \leq h \leq h_{max}$
if $h < h_{max}$ **then**
 $h \leftarrow h + 1$
end if
end procedure

procedures are another component of tabu search that are used in reactive tabu search methods and ejection chain approaches [27]. We implement the escape procedure as a stronger form of the diversification in Algorithm 7. That approach adjusted the h parameter of the neighborhood by an increment of 1 on each call, up to a maximum for h_{max} . In the escape procedure we instead increment h by $\Delta h_{escape} \geq 1$ with no maximum limit. The escape procedure is shown in Algorithm 8. The conditions for triggering the escape procedure are expectedly more

Algorithm 8 Escape from the region of the search space near the solution \mathbf{x} .

procedure ESCAPE(\mathbf{x})
▷ diversify by updating the restricted best-first neighborhood $\mathcal{N}(\mathbf{x}, h)$
▷ no constraints on h
 $h \leftarrow h + \Delta h_{escape}$
end procedure

strict. First, we only consider using the escape procedure when diversification has failed to break a stall. Since the diversification procedure may be called multiple times and increase the neighborhood parameter h up to a value of h_{max} , we only consider triggering the escape procedure when $h = h_{max}$. Further, we only consider escaping if the stall has been active for $N_{escape} \geq N_{stall}$ iterations. The triggering conditions for the escape procedure are thus

$$h \geq h_{max} \wedge R(N_{escape}) \leq \underline{R} \tag{3.55}$$

At this point we have developed methods for reacting to stalls, including intensification, diversification and in extreme cases an escape procedure. Each of these approaches changes the neighborhood in order to break the stall. When the search is operating nominally—that is, exploring a sufficiently diverse range of solution lengths—we should revert the neighborhood to a nominal state. We thus define a value of the solution length range $\bar{R} > \underline{R}$ indicative of a sufficiently diverse exploration. When the range of solution lengths meets or exceeds this range, we react by relaxing or diversifying the neighborhood up to the limit of h_{max} using the diversify procedure already defined. The search is already exploring sufficiently diverse solution lengths in this case; the diversification increases the size of the neighborhood to allow for more promising paths to be found. The triggering conditions for the relaxation are then

$$R(N_{stall}) \geq \bar{R} \tag{3.56}$$

The strategic intensification, diversification and escape procedures—as well as the neighborhood relaxation—can now all be integrated into a single dynamic neighborhood selection strategy. However, we introduce one final parameter: a cool down period, $N_{cooldown}$. The cool down period gives a minimum number of iterations between changes to the neighborhood, restricting how often neighborhood changes may occur. This in turn allows the effects of a neighborhood change to be measured before more changes are made. Algorithm 9 shows the combined neighborhood modification procedure.

3.6 Algorithm Summary

The previous sections developed the components of the overall global search methodology. These include the tree-based solution representation for efficiently handling tour trajectory solutions and neighborhoods that operate on that solution repre-

Algorithm 9 Dynamically update the neighborhood based on the search performance.

```

procedure UPDATENEIGHBORHOOD( $\mathbf{x}_i \dots \mathbf{x}_0$ )
  ▷ do nothing if we are in the cool down period
  if  $i - neighborhoodUpdated \leq N_{cooldown}$  then

      INTENSIFY( $\mathbf{x}_i$ )
    else if  $\mathbf{x}_i[t_{n_s}] - \mathbf{x}_i[t_0] > 0.9 (t_{max} - \mathbf{x}_i[t_0])$  then
      DIVERSIFY( $\mathbf{x}_i$ )
    end if
     $neighborhoodUpdated \leftarrow i$ 
    return
  end if
  ▷ increase the size of the neighborhood if the search is proceeding nominally
  if  $R(N_{stall}) \geq \bar{R}$  then
    DIVERSIFY( $\mathbf{x}_i$ )
     $neighborhoodUpdated \leftarrow i$ 
    return
  end if
end procedure

```

sentation to enable a local search approach. A guiding objective was defined for use during the search to better compare solutions of varying lengths. The process of constructing new solutions based on existing partial solutions was outlined. Finally, a tabu search algorithm was developed in terms of these building blocks. The tabu search algorithm includes a recency-based tabu memory to avoid cycling as well as a dynamic neighborhood selection procedure to strategically intensify and diversify the search for better performance. Table 3.1 summarizes the components and parameters of the search. Algorithm 10 gives the complete algorithm.

The use of the tree-based solution representation is novel in the context of tabu search. It allows a constructive approach that is especially beneficial for problems with expensive solution evaluations. Further, the tree solution representation implicitly maintains a population of solutions, thereby providing a collection of solution alternatives at the termination of the search rather than just a single best solution.

Name	Description
\mathbf{x}_i	Incumbent solution of iteration i ; \mathbf{x}_0 is the initial solution
$[y_{i_{min}}, y_{i_{max}}]$	Range of allowed values for the i^{th} element of the continuous segment decision variables \mathbf{y}
K_i	Number of discretizations for the i^{th} element of the continuous segment decision variables \mathbf{y}
\mathcal{T}	Tabu list
$N_{\mathcal{T}}$	Tabu tenure
$A(\mathbf{x})$	attributes of solution \mathbf{x} to consider for tabu status
$\mathcal{N}(\mathbf{x}, h)$	Restricted best-first neighborhood of solution \mathbf{x}
h	Restricted best-first neighborhood: maximum ascendance in tree
$[h_{min}, h_{max}]$	Range of allowed values for h for intensification or diversification
Δh_{escape}	Change in h for escape procedure
$\tilde{\mathcal{N}}(\mathbf{x})$	Candidate neighborhood of non-tabu solutions
$J^*(\mathbf{x})$	the guiding objective for use during the search (different than the problem-provided objective)
$\frac{dJ^*}{dt}$	parameter of the guiding objective that predicts objective contributions over the remaining allowed time
ΔJ_{goal}	parameter for updating $\frac{dJ^*}{dt}$ when a new best solution is found
$w_m, w_{\Delta V}$	budget penalty weights for mass and ΔV terms used in the guiding objective
$N_{cooldown}$	Cool down period: number of iterations between allowed changes to the neighborhood
N_{stall}	Stall period: number of iterations over which the stall condition is evaluated
N_{escape}	Escape period: number of iterations over which the escape condition is evaluated
\underline{R}	Stall threshold: a stall occurs when the range of solution lengths is below \underline{R} for N_{stall} iterations
\bar{R}	Relaxation threshold: when the range of solution lengths is above \bar{R} , the neighborhood is relaxed

Chapter 4

Search Space Pruning

In this chapter we develop a search space pruning approach to accelerate the construction of new feasible trajectories. The goal of pruning procedures in general is to prune out regions of the search space known to be infeasible or non-optimal. This reduces the size of the search space and accelerates the underlying optimization algorithm. In the context of our work, we apply search space pruning to the solution construction (node expansion) phase of the tree-based tabu search algorithm developed in Chapter 3. We continue by describing the brute-force approach already developed and its performance characteristics. We then develop the search space pruning procedure and compare its performance to the brute-force approach.

4.1 Brute-force Approach

Section 3.4 developed a basic procedure for solution construction. Recall that at each iteration, new trajectories are constructed by adding new trajectory segments to an incumbent solution \mathbf{x} . Although many trajectory segments may be computed, only those that are found to be feasible to the problem constraints are kept. These feasible trajectory segments are then added to the tree-based solution representation, and

$[\tau_{min}, \tau_{max}]$	Range of allowed segment intercept maneuver times (fraction of segment duration)
K_τ	Discretizations of τ
$[\Delta t_{min}, \Delta t_{max}]$	Range of allowed segment durations
$K_{\Delta t}$	Discretizations of Δt

Table 4.1: Sampling parameters for trajectory segments in the augmented impulsive tour model.

those found to be infeasible are discarded after computation. The basic approach developed was a total enumeration of all possible segment decision variable values subject to bounds and discretization. Recall that $\mathcal{F}(\mathbf{x})$ gives us the set of target objects that may be feasibly visited next in a solution \mathbf{x} , and that we make K_i discretizations of each of the n_y continuous decision variable for $i \in 1 \dots n_y$. A brute force approach enumerates all of these possibilities. The number of trajectory segments created during expansion of a single node is thus

$$\|\mathcal{F}(\mathbf{x})\| \prod_{i=1}^{n_y} K_i \quad (4.1)$$

However, the total number of these trajectory segments that are feasible can be much less depending on the problem constraints.

We now consider the specific case of the augmented impulsive tour model developed in Section 2.2.6 for the rest of the development. We again have $\mathcal{F}(\mathbf{x})$ representing the feasible next target objects. However now we have two continuous decision variables,

$$\mathbf{y}_i = \begin{pmatrix} \tau_i \\ \Delta t_i \end{pmatrix} \quad (4.2)$$

representing the time of the intercept maneuver and the duration of the trajectory segment i . These are subject to minimum and maximum bounds and a discretization that are summarized in Table 4.1. The number of trajectory segments computed in

the brute force approach for this model is now

$$\|\mathcal{F}(\mathbf{x})\| K_\tau K_{\Delta t} \tag{4.3}$$

The definition of $\mathcal{F}(\mathbf{x})$ is problem-specific, but an upper bound is the full set of N_O target objects. Therefore, an upper bound on the number of trajectory segment computations for expansion of a single node in the tree for any problem is

$$N_O K_\tau K_{\Delta t} \tag{4.4}$$

We can further quantify the computations based on the number of Kepler propagations and Lambert targeting calls required, which we denote as k and l , respectively. The Lambert targeting procedure is in general more computationally expensive than a Kepler propagation; the specific performance difference depends on the underlying algorithms used for each and their implementation. The evaluation of a trajectory segment in this case requires two Kepler propagations. The first finds the position of the spacecraft at the time of the intercept maneuver,

$$t_{i-1} + \tau_i \Delta t_i \tag{4.5}$$

The second computes the position of the target object at the end time of the segment,

$$t_{i-1} + \Delta t_i \tag{4.6}$$

When $\tau_i = 0$ then the first Kepler call is not required as the final state of the previous segment is known; however in the general case we must account for it. A single Lambert targeting call then computes the maneuver between these two positions over the elapsed time. Thus, for the brute force approach expanding the

solution \mathbf{x} and reusing the results of computations when allowed we have

$$k_{BF} = K_\tau K_{\Delta t} + \|\mathcal{F}(\mathbf{x})\| K_{\Delta t} \quad (4.7)$$

$$l_{BF} = \|\mathcal{F}(\mathbf{x})\| K_\tau K_{\Delta t} \quad (4.8)$$

We wish to minimize both of these quantities in a more efficient solution construction procedure. Since the Lambert targeting procedure is more expensive, we wish to especially minimize its use. We will measure the performance of the space pruning procedure we develop in terms of the number of required computations k and l .

4.2 Trajectory Envelopes

This section describes the use of trajectory envelopes to prune infeasible trajectory segments from the search space. The trajectory envelope forms the reachable domain of the spacecraft; any target objects not intersecting this envelope cannot be feasibly visited, and therefore should not be considered in solution construction. This reduces the number of trajectory segment computations required which in turns accelerates the search. However, computing the trajectory envelope has its own associated cost as well.

Vinh et al. introduced the concept of the reachable domain, which is a set of points attainable by an interceptor with a limited ΔV capability [68]. Their work analyzed the reachable domain for interception of targets at hyperbolic speeds for short times of flight. They proved that the largest reachable domain is achieved when the maximum allowed impulse is applied as early as possible (under the assumption of short time of flight). Independent works by Wen and Xue develop analytical approaches for computing the reachable domain of a spacecraft in elliptic motion subject to a single upper-bounded impulsive maneuver [70, 73]. However, the approaches compute the reachable domain without consideration to time: either

the limited trajectory duration or the time accessibility of the reachable space (e.g. a target object’s orbit may intersect the reachable domain but may not be reachable at the time of intersection). We develop an alternative simulation-based approach that defines the reachable domain both based on position in space and time.

We begin by generating a collection of spacecraft trajectories for a set of possible impulsive maneuvers. Each trajectory begins at the final state of the previous segment $\mathbf{z}_{i-1}(t - 1)$ where

$$\mathbf{z}_{i-1}(t_{i-1}) = \begin{pmatrix} \mathbf{r}(t_{i-1}) \\ \mathbf{v}(t_{i-1}) \\ m(t_{i-1}) \end{pmatrix} \quad (4.9)$$

For the purpose of computing the trajectory envelope, we assume that maneuvers occur at the beginning of the trajectory segment with the largest allowed magnitude. We can compute the maximum feasible magnitude of an impulsive maneuver based on the mass of the spacecraft and the maximum allowed trajectory segment duration. We further assume that the impulsive maneuver is an idealization for a low-thrust spacecraft, and constrain the impulse appropriately. The maximum thrust magnitude T_{max} and specific impulse I_{sp} are provided as part of the spacecraft parameters given in Chapter 2 (Table 2.2). Assuming the spacecraft thrusts over the maximum duration of a trajectory segment, then the maximum corresponding impulsive maneuver magnitude is

$$\Delta V_{max} = I_{sp} g_0 \ln \left(\frac{m(t_{i-1})}{m(t_{i-1}) - \frac{T_{max}}{I_{sp} g_0} \Delta t_{max}} \right) \quad (4.10)$$

Figure 4.1 shows values for ΔV_{max} for different allowed trajectory segment durations and the spacecraft parameters of the fourth annual global trajectory optimization competition (GTOC4) shown in Table 5.2. The resulting values depend also on the

Figure 4.1: The values for ΔV_{max} are shown over varying spacecraft initial mass and values of Δt_{max} . The spacecraft parameters correspond to the fourth annual global trajectory optimization competition (GTOC4) summarized in Table 5.2.

initial mass of the spacecraft at the trajectory segment—the spacecraft becomes more efficient as its mass decreases. Using this approach we can compute an appropriate ΔV_{max} when new trajectory segments are to be generated during solution expansion. We note that a range of trajectory segment durations are allowed; we compute ΔV_{max} corresponding to Δt_{max} which is an upper bound for values associated with lesser values of Δt .

The impulsive maneuver may occur in any unit direction, which we can parameterize with spherical angles α and β as

$$\hat{\mathbf{u}} = \begin{pmatrix} \cos \alpha \cos \beta \\ \sin \alpha \cos \beta \\ \sin \beta \end{pmatrix} \quad (4.11)$$

Then, the set of maximum allowed impulsive maneuvers is given by

$$\Delta \mathbf{V}_{max} = \Delta V_{max} \hat{\mathbf{u}}(\alpha, \beta) \quad (4.12)$$

for any values of α and β . We can discretize the angles to form a finite set of these maneuvers; we allow α to vary between $[0, 2\pi]$ and β to vary between $[-\pi/2, \pi/2]$. Within these ranges we choose K_α and K_β evenly spaced values for α and β respectively. Then, the total number of maneuver discretizations is

$$K_{\Delta V} = K_\alpha K_\beta \quad (4.13)$$

Figure 4.2 shows the discretizations of $\Delta \mathbf{V}_{max}$. The set of possible maneuvers form a sphere of radius ΔV_{max} .

We can now enumerate the $K_{\Delta V}$ possible maneuvers to form the set of initial conditions for the trajectories forming the trajectory envelope. These initial

Figure 4.2: Discretization of all possible impulsive maneuvers for a magnitude of ΔV_{max} . The maneuver direction is discretized over the spherical angles α and β for a total of $K_{\Delta V} = K_{\alpha}K_{\beta}$ discretizations.

conditions are given by

$$\mathbf{X}_j(t_{i-1}) = \begin{pmatrix} \mathbf{r}(t_{i-1}) \\ \mathbf{v}(t_{i-1}) + \Delta V_{max} \hat{\mathbf{u}}(\alpha_j, \beta_j) \end{pmatrix} \text{ for } j = 1 \dots K_{\Delta V} \quad (4.14)$$

We can propagate each of these $K_{\Delta V}$ states forward in time by Δt_{max} . The resulting trajectories form the trajectory envelope that bounds the reachable domain of the spacecraft given a single maneuver originating at the state $\mathbf{z}_{i-1}(t_{i-1})$ with an upper-bounded maneuver magnitude of ΔV_{max} . Figure 4.3 shows an example of the trajectories forming the envelope.

A target object whose orbit intersects this envelope may be reachable by the spacecraft; otherwise it can be pruned from the search space. Intersecting the envelope is a necessary but not sufficient condition for reachability. First, ΔV_{max} is an upper bound computed for the maximum segment duration Δt_{max} . Secondly, intersecting the spatial region of the envelope does not mean the target object is

Figure 4.3: The trajectories forming a trajectory envelope are shown for $\Delta V_{max} = 1$ km/s and $\Delta t_{max} = 0.55$ years. The spherical angles α and β are each discretized over a 15 degree spacing.

reachable at the time of intersection; the trajectory envelope is again an upper bound in this regard. Finally, although we can visualize this envelope, we do not yet have a method for determining when such target object orbit intersections occur.

4.2.1 Bounding Boxes

This section develops a procedure for determining when a target object's orbit intersects the trajectory envelope. At a high level we need to determine if a path-volume intersection occurs, where the path is the target object orbit and the volume is the trajectory envelope. However, although we have the trajectories bounding the envelope, we do not have an analytical representation of its volume. Computing these intersections is thus challenging. It is analogous to a collision detection problem, where it must be determined if two objects of arbitrary shape intersect or not. Such problems commonly occur in physical simulations, for example. A common approach to accelerate this collision detection is to generate simpler shapes that bound

the more complicated shape of the object. If the simpler shapes intersect, then the objects themselves may collide—otherwise no collision is possible. The most common approach is the use of bounding boxes; for each object a bounding box is computed that contains the shape. The bounding box is an upper bound on the actual volume. The problem we face here is most similar to the ray tracing algorithm of computer graphics, where individual rays of light are traced through a scene, and ray-object intersections must be computed to determine visibility and lighting [56]. We apply and extend the bounding box procedure commonly used in such algorithms to our case here.

The trajectory envelope bounds a three-dimensional region of space. However, the trajectories making up the envelope also include time information. For example, the later parts of the envelope are only reachable by the spacecraft for longer times of flight (approaching Δt_{max}). Even if a target object intersects the spatial volume of the trajectory envelope then, it may still not be reachable due to the timing of the intersection. We therefore add another dimension to our bounding boxes—time—and create multiple bounding boxes over discrete time intervals. A path now intersects a bounding box if it intersects its spatial volume at a time within its time bounds. The bounding box is still only a necessary condition for reachability, but it represents a tighter upper bound with the additional timing restriction. A bounding box may be oriented arbitrarily; however for simplicity we use axis-aligned bounding boxes such that the spatial bounds are along the Cartesian dimensions of the underlying coordinate system. Therefore, each bounding box is represented by the spatial and time bounds shown in Figure 4.4.

We create N_{BB} bounding boxes over the feasible trajectory segment durations $[\Delta t_{min}, \Delta t_{max}]$ provided in the trajectory segment sampling parameters. The

Figure 4.4: An axis-aligned bounding box bounds a volume in the spatial region of $([x_{min}, x_{max}], [y_{min}, y_{max}], [z_{min}, z_{max}])$. We additionally constrain the bounding box with a time range $[t_{min}, t_{max}]$.

minimum and maximum time bounds for each bounding box b are then given by

$$\begin{aligned} (t_{min})_b &= t_{i-1} + \Delta t_{min} + \frac{b-1}{N_{BB}} (\Delta t_{max} - \Delta t_{min}) \\ (t_{max})_b &= t_{i-1} + \Delta t_{min} + \frac{b}{N_{BB}} (\Delta t_{max} - \Delta t_{min}) \end{aligned} \quad \text{for } b = 1 \dots N_{BB} \quad (4.15)$$

These time bounds are constant once the bounding box is created. The spatial extents of a bounding box are formed by propagating the trajectories that form the envelope (Equation (4.14)) and expanding the bounding boxes over discrete points of each trajectory. A bounding box is expanded according to Algorithm 11. Similarly,

Algorithm 11 Expand the bounding box b given the position (x, y, z) at time t .

```

procedure EXPANDBOUNDINGBOX( $b, (x, y, z), t$ )
  ▷ the current spatial extents are  $([x_{min}, x_{max}], [y_{min}, y_{max}], [z_{min}, z_{max}])_b$ 
  ▷ expand the bounding box only if within its time bounds
  if  $(t_{min})_b \leq t \leq (t_{max})_b$  then
     $(x_{min})_b \leftarrow \min[x, (x_{min})_b]$ 
     $(y_{min})_b \leftarrow \min[y, (y_{min})_b]$ 
     $(z_{min})_b \leftarrow \min[z, (z_{min})_b]$ 

     $(x_{max})_b \leftarrow \max[x, (x_{max})_b]$ 
     $(y_{max})_b \leftarrow \max[y, (y_{max})_b]$ 
     $(z_{max})_b \leftarrow \max[z, (z_{max})_b]$ 
  end if
end procedure

```

we can test if a trajectory intersects a bounding box by testing if any point along its trajectory is within its spatial and time bounds; Algorithm 12 shows the procedure. These two procedures form the basis for the overall search space pruning procedure.

We form the spatial extents of all the bounding boxes by propagating each of the $K_{\Delta V}$ initial states of Equation (4.14) forward in time and expanding each bounding box as required. We consider K_{BB} discrete time intervals for each of the N_{BB} bounding boxes. Therefore, we have $N_{BB}K_{BB} + 1$ samples of each trajectory

Algorithm 12 Test if the bounding box b contains the position (x, y, z) at time t .

```

procedure INTERSECTSBOUNDINGBOX( $b, (x, y, z), t$ )
  ▷ the current spatial extents are  $([x_{min}, x_{max}], [y_{min}, y_{max}], [z_{min}, z_{max}])$ 
  ▷ test the position only if within bounding box time bounds
  if  $(t_{min})_b \leq t \leq (t_{max})_b$  then
    if  $(x_{min})_b \leq x \leq (x_{max})_b$  and  $(y_{min})_b \leq y \leq (y_{max})_b$  and  $(z_{min})_b \leq z \leq$ 
 $(z_{max})_b$  then
      return True
    end if
  end if
  return False
end procedure

```

and $K_{\Delta V}(N_{BB}K_{BB} + 1)$ total samples for the trajectory envelope. Each of these samples requires a single Kepler propagation. Figure 4.5 shows $N_{BB} = 10$ bounding boxes computed for the trajectory envelope of Figure 4.3. We see that the bounding boxes overlap in space, and that the overlap increases toward the end of the envelope. This is expected as the trajectories forming the envelope diverge from each other over time.

Finally, given the bounding boxes associated with the trajectory envelope, we can compute when target objects intersections with the envelope may occur (in space and time). As in the brute force approach, we sample each target object in the feasible set $\|\mathcal{F}(\mathbf{x})\|$ over $K_{\Delta t}$ times. In each case we propagate the target object to the time $t_{i-1} + \Delta t_i$ and test for a bounding box intersection. Figure 4.6 shows an example of the target object bounding box intersections for the GTOC4 problem. If the target object intersects a bounding box at a given time, then we construct trajectory segments to the target object at that time and compute the required maneuvers using the Lambert procedure. If we assume the number of target object bounding box intersections is a factor of f less than the total number enumerated, then the complexity of this approach in terms of Kepler propagations k and Lambert

Figure 4.5: $N_{BB} = 10$ bounding boxes are shown for the trajectory envelope of Figure 4.3 ($\Delta V_{max} = 1$ km/s).

Figure 4.6: The target object bounding box intersections are shown for the case in Figure 4.5.

targeting calls l is

$$k_{SP} = K_{\Delta V} (N_{BB}K_{BB} + 1) + \|\mathcal{F}(\mathbf{x})\| K_{\Delta t} + K_{\tau}K_{\Delta t} \quad (4.16)$$

$$l_{SP} = \frac{\|\mathcal{F}(\mathbf{x})\| K_{\tau}K_{\Delta t}}{f} \quad (4.17)$$

The first term of Equation (4.16) represents the computations that expand the bounding boxes of the trajectory envelope; the second gives the required propagations to compute target object bounding box intersections; and the third is an upper bound on computing the position of the spacecraft at the time of maneuver for the required Lambert targeting calls of Equation (4.17). We see an increase in the required Kepler propagations of $K_{\Delta V} (N_{BB}K_{BB} + 1)$ due to the bounding box generation, but a decrease by a factor of f in required Lambert targeting calls. Since the Lambert procedure is more computationally expensive, we expect to see a performance increase. Further, the increase in k is of constant complexity, while the decrease in l scales with the number of target objects, and is thus of greater benefit for larger problems with many target objects.

4.2.2 Summary

The search space pruning approach we have developed forms a trajectory envelope bounding the reachable domain of the spacecraft. The trajectory envelope is based on an upper-bounded single impulsive maneuver occurring at the beginning of a trajectory segment. In order to more simply compute intersections of target object orbits with this envelope and to consider the time feasibility of resulting trajectory segments, we developed an approach based on bounding boxes. The approach results in fewer trajectory segments being created, and therefore reduces the number of Lambert procedure calls and accelerates solution construction. The trade-off is an increase in Kepler propagations required to generate the envelope. The parameters

ΔV_{max}	Maximum allowed impulsive maneuver
K_α, K_β	Number of discretizations of the spherical angles α and β for possible impulsive maneuver directions
$K_{\Delta V}$	Total number of discretizations for impulsive maneuvers (equal to $K_\alpha K_\beta$)
N_{BB}	Number of bounding boxes
K_{BB}	Number of time intervals for each bounding box

Table 4.2: Parameters for the trajectory envelope search space pruning procedure.

of the search space pruning approach are shown in Table 4.2. We further note that since the procedure is simulation-based, it can easily be applied to dynamics other than two-body motion.

4.3 Performance

This section considers the relative performance of the search space pruning approach compared to the brute force method. Here we only consider the number of required computations: Kepler propagations k and Lambert targeting calls l . We consider the full performance impact of the space pruning approach later for the GTOC4 problem in Section 5.3.3.

We fix the sampling parameters for the search space pruning procedure at $N_{BB} = 10$ bounding boxes and $K_{BB} = 10$ time intervals per bounding box. We discretize the spherical angles of the unit impulse direction at intervals of 15 degrees, resulting in $K_\alpha = 24$ and $K_\beta = 13$ for a total of $K_{\Delta V} = 312$ impulsive maneuvers to enumerate for the trajectory envelope. We then consider the performance over varying values of ΔV_{max} for the initial maneuvers. We use the trajectory segment sampling parameters from the GTOC4 application in Chapter 5. All of these parameters are summarized in Table 4.3. Finally, we assume the set of feasible target objects for new trajectory segments is the set of all asteroids in the GTOC4 problem.

Search space pruning parameters		
K_α, K_β	Number of discretizations of the spherical angles α and β for possible impulsive maneuver directions	24, 13
$K_{\Delta V}$	Total number of discretizations for impulsive maneuvers (equal to $K_\alpha K_\beta$)	312
N_{BB}	Number of bounding boxes	10
K_{BB}	Number of time intervals for each bounding box	10
Sampling parameters		
$[\tau_{min}, \tau_{max}]$	Range of allowed segment intercept maneuver times (fraction of segment duration)	[0.0, 0.0]
K_τ	Discretizations of τ	1
$[\Delta t_{min}, \Delta t_{max}]$	Range of allowed segment durations	[0.05, 0.55] years
$K_{\Delta t}$	Discretizations of Δt	50

Table 4.3: Search space pruning parameters and trajectory segment sampling parameters for performance analysis of the space pruning procedure.

For the GTOC4 problem there are $N_O = 1436$ asteroids, such that

$$\|\mathcal{F}(\mathbf{x})\| = N_O = 1436 \quad (4.18)$$

The required number of computations for the brute force approach are given in Equations (4.7) and (4.8) and are of constant complexity in the trajectory segment sampling parameters. We can compute their values directly as

$$k_{BF} = K_\tau K_{\Delta t} + \|\mathcal{F}(\mathbf{x})\| K_{\Delta t} = 71850 \quad (4.19)$$

$$l_{BF} = \|\mathcal{F}(\mathbf{x})\| K_\tau K_{\Delta t} = 71800 \quad (4.20)$$

These are the computations required for expanding a single solution which occurs once per iteration. The required computations for the space pruning approach are given in Equations (4.16) and (4.17). Once again we have constant complexity in the number of required Kepler propagations; however the required Lambert targeting calls is determined by the number of target object intersections which we quantify with the factor f . Therefore for the space pruning approach we have

$$k_{SP} = K_{\Delta V} (N_{BB} K_{BB} + 1) + \|\mathcal{F}(\mathbf{x})\| K_{\Delta t} + K_\tau K_{\Delta t} = 103362 \quad (4.21)$$

$$l_{SP} = \frac{\|\mathcal{F}(\mathbf{x})\| K_\tau K_{\Delta t}}{f} = \frac{71800}{f} \quad (4.22)$$

We see that additional Kepler propagations are required for computing the bounding boxes of the trajectory envelope, such that $k_{SP} > k_{BF}$. However, the number of Lambert computations required in the space pruning approach is bounded from above by the brute force approach such that $l_{SP} \leq l_{BF}$. We continue by computing the trajectory envelopes for various values of ΔV_{max} so that we can measure the improvement directly. We assume the spacecraft has initial conditions matching the Earth at $t_{i-1} = 54000$ MJD for the tests. Table 4.4 summarizes the results, and

ΔV_{max}	Intersecting asteroids	Intersecting points	Reduction factor, f
0.25 km/s	11	32	2243.75
0.5 km/s	23	80	897.50
1.0 km/s	46	209	343.54
1.5 km/s	69	421	170.55
2.0 km/s	92	700	102.57
2.5 km/s	125	1048	68.51
3.0 km/s	149	1455	49.35
3.5 km/s	183	1930	37.20
4.0 km/s	224	2479	28.96

Table 4.4: Results of the search space pruning approach applied to the GTOC4 problem over varying values of ΔV_{max} .

Figure 4.7 shows the trajectory envelope bounding boxes for several of the tests. We see the reduction factor f is largest for small values of ΔV_{max} ; this corresponds to the smaller trajectory envelope of the more limited impulse magnitude. As ΔV_{max} increases, we see a lesser but still significant improvement, however. The factor f gives the reduction in overall required Lambert computations, or equivalently the reduction in number of trajectory segments to compute. In this example we see greater than $100\times$ improvements when using the search space pruning approach. We note however that this does not consider the additional Kepler propagations to form the envelope. However, those computations are of fixed complexity while the space pruning improvement scales with problem size. Later analysis considers the improvement in the overall search due to the space pruning procedure.

The critical assumption in the trajectory envelope approach is that the reachable domain of the spacecraft is given by the maximum allowed impulsive maneuver occurring at the beginning of the segment. In our tests here with $\Delta t_{max} = 0.55$ years we have validated this assumption. However, clearly there are cases where this is not true—for example if Δt_{max} corresponds to a full period of the spacecraft, then a

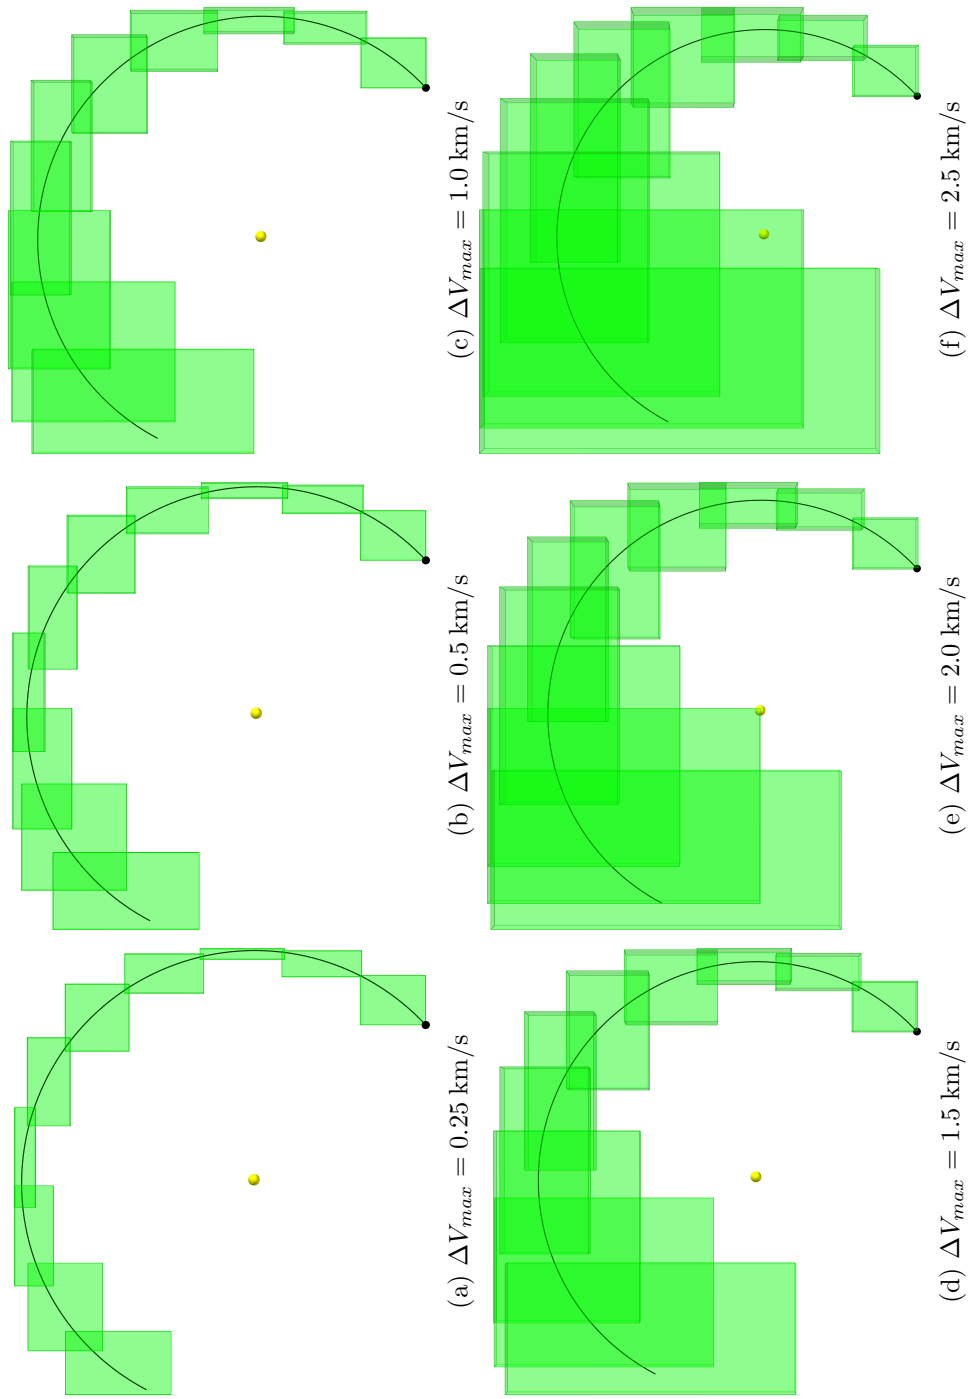

Figure 4.7: The bounding boxes associated with trajectory envelopes from the results in Table 4.4.

maneuver at the half-period time will allow the spacecraft to reach regions that a maneuver at the beginning of the segment will not. In such cases the approach can be extended and additional envelopes can be computed for varying maneuver times over the duration of the trajectory segment.

We further note that no effort has been made to tune the search space pruning parameters of Table 4.3 for optimal performance. For example, a larger number of bounding boxes may provide a tighter upper bound on the trajectory envelope. This is an optimization problem unto itself and we leave this analysis to future work. Other bounding shapes (besides boxes) and coordinate systems (such as spherical coordinates) are also possible in the bounding procedure that are worth exploration. Finally, we note that the search space pruning procedure developed here can be combined with other space pruning approaches, such as analytical constraints for specific problem dynamics, for even greater performance improvements.

Chapter 5

Application to Fourth Global Trajectory Optimization Competition

This chapter applies the search methodology developed in Chapter 3 to the fourth annual Global Trajectory Optimization Competition (GTOC) problem. The chapter begins with a description of the GTOC4 problem and its known solutions. The methodology is then applied under varying parameter sets and the results are discussed. Finally, low-thrust finite burn solutions are generated from specific impulsive solutions found in the search.

The GTOC was created in 2005 by the Advanced Concepts Team of the European Space Agency [34]. The competition presents challenging global optimization problems in interplanetary trajectory design, and has enjoyed wide international participation. Each of the seven past competition problems have involved optimizing a mission sequence of some kind [1]. For example, the first GTOC problem required the determination of flyby sequences for gravity assists. The second through fifth and seventh GTOC competitions were each asteroid intercept and/or rendezvous

Problem	Mission sequence
GTOC1: “Save the Earth”	multiple gravity assists
GTOC2: “Multiple asteroid rendezvous”	multiple asteroid rendezvous
GTOC3: “Multiple sample return”	multiple asteroid rendezvous, Earth gravity assists allowed
GTOC4: “Asteroids billiard”	multiple asteroid intercept and final asteroid rendezvous
GTOC5: “Penetrators”	multiple asteroid rendezvous and intercept
GTOC6: “Global mapping of Galilean moons”	repeated flybys of four Galilean moons of Jupiter
GTOC7: “Multiple ship mission to main belt asteroids”	multiple spacecraft each with multiple asteroid rendezvous

Table 5.1: Summary of past Global Trajectory Optimization Competition (GTOC) problems and their mission sequences to be optimized [1].

missions where the asteroid sequence was free to be chosen. The sixth GTOC required the design of multiple flybys and gravity assists. The past GTOC problems are summarized in Table 5.1. Each of these mission sequences can be represented by discrete decision variables in the problem formulation. The persistence of these problem types in the competition emphasizes the importance of combinatorial optimization methods for spacecraft trajectory optimization.

The fourth GTOC (GTOC4) occurred in 2009 and was organized by the Interplanetary Mission Analysis team of the Centre National d’Etudes Spatiales de Toulouse, the winners of the third GTOC competition [12]. The mission proposed was entitled “how to maximize the relevance of a rendezvous mission to a given NEA by visiting the largest set of intermediate asteroids”. The mission begins when a spacecraft is launched from the Earth. The spacecraft must then flyby a maximum number of asteroids before rendezvousing with a final asteroid. The GTOC4 problem is specifically considered as a benchmark problem for the global search methodology developed in this work.

Maximum launch hyperbolic excess velocity, $v_{\infty_{max}}$	4.0 km/s
Minimum launch date, $t_{0_{min}}$	00:00 January 1, 2015 (57023 MJD)
Maximum launch date, $t_{0_{max}}$	24:00 December 31, 2025 (61041 MJD)
Maximum mission duration, $\Delta t_{mission}$	10 years
m_0	1500 kg
m_{dry}	500 kg
T_{max}	0.135 N
I_{sp}	3000 s

Table 5.2: GTOC4 mission and spacecraft parameters [12].

5.1 Problem Definition

This section summarizes the GTOC4 problem statement from [12]. The spacecraft is launched from Earth with a hyperbolic excess velocity \mathbf{v}_{∞} of up to 4.0 km/s in magnitude and in unconstrained direction. The launch must occur within the years of 2015 and 2025, and the total mission duration must not exceed ten years. The spacecraft is equipped with an electric propulsion system, and gravity assists are not allowed during the mission. The mission and spacecraft parameters are summarized in Table 5.2. The Earth and asteroids follow Keplerian orbits about the Sun. The sun’s gravitational parameter and Earth’s orbital elements are given in Table 5.3. A collection of 1436 near Earth asteroids (NEAs) are given; their orbital elements are provided in Appendix B. Figure 5.1 shows the asteroids’ semimajor axis and eccentricity values. The highlighted regions indicate the asteroid types: Atiras, Atens, Apollos and Amors [45].

After being launched from Earth, the spacecraft must flyby a maximum number of intermediate asteroids and then rendezvous with a final asteroid. Each asteroid may be visited at most once (intercept or rendezvous). An intercept requires

Sun gravitational parameter, μ (km^3/s^2)	1.32712440018E11
Semimajor axis, a (AU)	0.999988049532578
Eccentricity e	1.671681163160E-2
Inclination i (deg)	0.8854353079654E-3
Longitude of ascending node Ω (deg)	175.40647696473
Argument of periapsis ω (deg)	287.61577546182
Mean anomaly at epoch M (deg)	257.60683707535
Epoch t (MJD)	54000

Table 5.3: The sun’s gravitational parameter and Earth orbital elements for GTOC4 problem in J2000 heliocentric ecliptic reference frame [12].

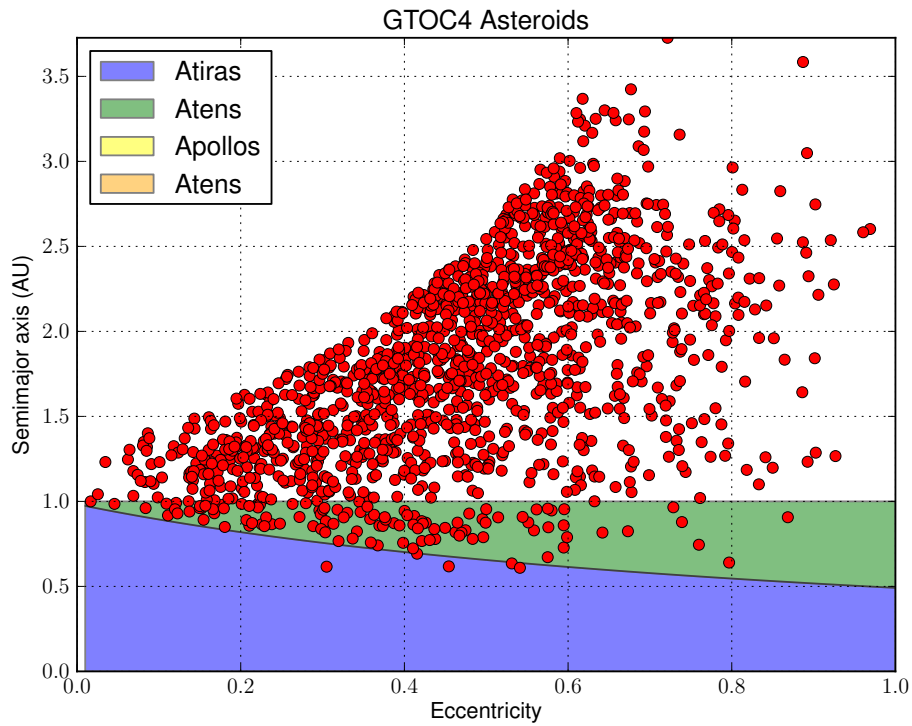

Figure 5.1: The set of 1436 asteroids for the GTOC4 problem. The highlighted regions show combinations of semimajor axis and eccentricity for Atiras, Atens, Apollos and Amors near-Earth asteroids [45].

a match of position between the spacecraft and asteroid, while a rendezvous requires a match of both position and velocity. The objective to be maximized is the number of intermediate asteroids. The provided objective function is given by

$$J = \sum_{j=1}^n \alpha_j \quad (5.1)$$

where n is the total number of asteroids provided, and $\alpha_j \in \{0, 1\}$ denotes the number of times asteroid j is visited during the mission, excepting the final rendezvous. That is, the final asteroid j_f corresponds to $\alpha_{j_f} = 0$. Therefore the objective function J cannot exceed $n - 1$. If multiple solutions have the same objective value J , the best solution is that which maximizes the final mass, given by the secondary objective function

$$K = m_f \quad (5.2)$$

5.1.1 GTOC4 Augmented Impulsive Tour Model

We use the augmented impulsive tour model developed in Section 2.2.6 for the GTOC4 problem. Following the notation defined there and defining the objective for minimization rather than maximization, we define the objective as

$$J(\mathbf{x}) = -(n_s - 1) \quad (5.3)$$

which corresponds to the number of intermediate asteroids. The mission launch timing and duration constraints are given by

$$t_{0_{min}} \leq t_0 \leq t_{0_{max}} \quad (5.4)$$

$$t_{n_s} \leq t_0 + \Delta t_{mission} \quad (5.5)$$

The spacecraft begins the mission at Earth with a constrained hyperbolic excess velocity. Its initial conditions are constrained as

$$\mathbf{r}(t_0) = \mathbf{r}_{earth}(t_0) \quad (5.6)$$

$$\|\mathbf{v}(t_0) - \mathbf{v}_{earth}(t_0)\| \leq v_{\infty_{max}} \quad (5.7)$$

Each asteroid may only be visited once in the tour. Rather than write explicit constraints on the sequence decision variables $s_1 \dots s_{n_s}$, we instead specify the set of feasible target objects for solution construction according to Section 3.4 as

$$\mathcal{F}(\mathbf{x}) = O \setminus \{s_1 \dots s_{n_s}\} \quad (5.8)$$

where O is the set of all GTOC4 asteroids. The feasible target objects $\mathcal{F}(\mathbf{x})$ are evaluated every time new segments are added to an existing tour. For a given trajectory segment i of the tour then, this constrains the feasible target objects that may be chosen as

$$s_i \in O \setminus \{s_1 \dots s_{i-1}\} \quad (5.9)$$

The GTOC4 problem requires intercepting a number of intermediate asteroids before rendezvousing with a final asteroid. When we add new trajectory segments onto an existing tour then, we can attempt to either intercept or rendezvous with the next target. If we intercept the next target, then we say the result is a partial solution, since it may still be expanded to produce a longer tour. If however we rendezvous with the next target, the solution is complete since it satisfies the original problem statement and can no longer be expanded. During solution construction, we create both intercept and rendezvous segments to the next target object s_i , and the feasible segments are kept.

We restate the augmented impulsive tour model developed in Section 2.2.6 here with the additional constraints developed for GTOC4. The GTOC4 augmented

impulsive tour model is thus

$$\text{Determine } \mathbf{x} = [t_0, \mathbf{z}_0, s_1 \dots s_{n_s}, \mathbf{y}_1 \dots \mathbf{y}_{n_s}] \quad (5.10)$$

$$\text{minimizing } J(\mathbf{x}) = -(n_s - 1) \quad (5.11)$$

$$\text{subject to } \mathbf{z}(t) = \mathbf{f}(t, \mathbf{x}) \implies \Delta \mathbf{V}_1 \dots \Delta \mathbf{V}_{N_{\Delta V}} \quad (5.12)$$

$$m(t_{n_s}) \geq m_{dry} \quad (5.13)$$

$$(t_{fb_0})_0 \geq t_0 \quad (5.14)$$

$$(t_{fb_f})_{N_{\Delta V}} \leq t_{n_s} \quad (5.15)$$

$$(t_{fb_f})_i \leq (t_{fb_0})_{i+1} \quad \text{for } i \in 1 \dots N_{\Delta V} - 1 \quad (5.16)$$

$$t_{0_{min}} \leq t_0 \leq t_{0_{max}} \quad (5.17)$$

$$t_{n_s} \leq t_0 + \Delta t_{mission} \quad (5.18)$$

$$\mathbf{r}(t_0) = \mathbf{r}_{earth}(t_0) \quad (5.19)$$

$$\|\mathbf{v}(t_0) - \mathbf{v}_{earth}(t_0)\| \leq v_{\infty_{max}} \quad (5.20)$$

$$\mathbf{r}(t_i) = \mathbf{r}_{s_i}(t_i) \quad \text{for } i = 1 \dots n_s \quad (5.21)$$

$$\mathbf{v}(t_{n_s}) = \mathbf{v}_{s_{n_s}}(t_{n_s}) \quad (5.22)$$

The dynamics $\mathbf{f}(t, \mathbf{x})$ are computed according to the augmented impulsive tour model, where ballistic arcs are propagated according to Kepler's problem and impulsive maneuvers are found as the solution to Lambert's problem. Equations (5.21) define the intermediate intercepts of the tour, and for $i = n_s$ Equations (5.21) and (5.22) define the final rendezvous for complete solutions. These constraints determine the required maneuvers (whether a rendezvous maneuver is necessary) and are implicitly satisfied in the computation of the dynamics. Finally, Equations (5.14) through (5.16) constrain estimates of representative finite burn maneuvers from overlapping in time or exceeding the mission time bounds. These estimates are based on the development in Section 2.2.5 and include the effects of gravity losses.

5.2 Best Known Solutions

We choose to apply the methodology to the GTOC4 problem in part because there exist a collection of known solutions to the problem generated using a variety of methods. We use these existing solutions as a benchmark to judge the performance of our own search algorithm. The final results of the GTOC4 competition are shown in Table 5.4. The winning solution was found by Moscow State University and visited 44 intermediate intercepts before finally rendezvousing with asteroid 2000SZ162.

We emphasize that these solutions are low-thrust finite burn trajectories, whereas the solutions we generate during the search use impulsive maneuvers. Although we constrain the impulsive solutions based on estimates of representative finite burns in an effort to ensure a finite burn conversion is feasible, a direct comparison is still not appropriate. We however reference the objectives achieved by these solutions in the discussion of our results. In later sections we find optimal low-thrust finite burn trajectories based on these impulsive solutions that are feasible to the original GTOC4 problem statement.

5.3 Results

In this section we apply the tabu search algorithm developed in Chapter 3 to the GTOC4 problem. We first examine results of a base case for a given set of search parameters. We then conduct a sensitivity analysis to determine the effects of varying these parameters and components of the search algorithm. For each case we generate a collection of results corresponding to a range of launch times t_0 . Unless indicated otherwise, we generate results for 1,024 launch epochs evenly spaced over the allowed 10 year launch window and run each search for 2 hours. Each case therefore requires 2,048 hours of compute time. This is summarized in Table 5.5.

Table 5.5: For each case, a collection of 1024 runs are generated over a range of launch epochs. Each run executes for 2 hours, requiring 2048 compute hours in total.

All results were computed on the Stampede supercomputer at the Texas Advanced Computing Center (TACC) at the University of Texas at Austin [2]. The author thanks TACC for supporting this work.

5.3.1 Base Case

We define a set of parameters for the tabu search algorithm in Table 5.6. We generate new trajectory segments in the search according to the sampling parameters provided. For this case, intercept maneuvers always occur at the beginning of the trajectory segment, and we consider segment durations from 0.05 to 0.55 years with 50 discretizations. When a new best solution is found, we decrease the goal objective (which in part defines the guiding objective) by $\Delta J_{goal} = 1$. The guiding objective penalizes excess ΔV over the defined budget with a weight of 1. A tabu tenure of 10 iterations is used to prevent cycling among similar solutions. The parameters for the dynamic neighborhood selection procedure are also shown.

We first examine the runs in terms of their best solutions found. Recall that a partial solution consists only of intermediate intercepts, while a complete solution also includes a rendezvous with a final target asteroid. Figure 5.2 and Table 5.7 shows the results for the 1024 runs of the base case. We see that we achieve better objectives for partial solutions than for complete solutions. This is expected as the rendezvous conditions are more difficult to satisfy; the target asteroid must be in a similar orbit to the spacecraft in order for a final rendezvous maneuver to be feasible. We further see approximately normal distributions of the best objectives achieved, with no particular range of launch epochs more or less favorable. For complete solutions, the median best objective found is $J = -42$, with the best solutions found to be $J = -45$. The $J = -45$ solutions exceed the best known GTOC4 solutions—we note again however that these are impulsive solutions rather

Sampling parameters		
$[\tau_{min}, \tau_{max}]$	Range of allowed segment intercept maneuver times (fraction of segment duration)	[0.0, 0.0]
K_τ	Discretizations of τ	1
$[\Delta t_{min}, \Delta t_{max}]$	Range of allowed segment durations	[0.05, 0.55] years
$K_{\Delta t}$	Discretizations of Δt	50
Guiding objective parameters		
ΔJ_{goal}	Parameter for updating $\frac{dJ^*}{dt}$ when a new best solution is found	1
w_m	Budget penalty weight for mass in guiding objective	0.0
$w_{\Delta V}$	Budget penalty weight for ΔV in guiding objective	1.0
Tabu search parameters		
N_τ	Tabu tenure	10
$[h_{min}, h_{max}]$	Allowed range of neighborhood parameter h for intensification or diversification	[3, 7]
Δh_{escape}	Change in neighborhood parameter h for escape procedure	10
$N_{cooldown}$	Cool down period: number of iterations between allowed changes to the neighborhood	25
N_{stall}	Stall period: number of iterations over which the stall condition is evaluated	25
N_{escape}	Escape period: number of iterations over which the escape condition is evaluated	50
\underline{R}	Stall threshold: a stall occurs when the range of solution lengths is below \underline{R} for N_{stall} iterations	5
\bar{R}	Relaxation threshold: when the range of solution lengths is above \bar{R} , the neighborhood is relaxed	15

than low-thrust finite burn solutions.

We examine the entire population of complete solutions generated in the base case and find solutions corresponding to each of the final rendezvous asteroids from the GTOC4 competition results. These are shown in Table 5.8. We see that in all cases we find results that meet or exceed the GTOC4 competition results. In fact, for only two of the rendezvous asteroids do the results not meet the GTOC4 winning objective of $J = -44$. This demonstrates the broad set of good solutions the search is able to find.

We now investigate an individual run of the 1024 runs executed for the base case. We choose run #409/1024 which corresponds to a launch epoch of $t_0 = 58629.41$ MJD. This is one of the several runs that found complete solutions for $J = -45$. We find that this run alone finds solutions rendezvousing with 10 of the 13 final asteroids from the GTOC4 results, also shown in Table 5.8. Fig-

Figure 5.3: Base case: run #409/1024. The objective history for the incumbent solution and best found partial and complete solutions are shown.

Figure 5.3 shows the objectives achieved over the iteration history. The search executes more than 15,000 iterations over the two hour run time. The search quickly finds complete solutions better than $J = -40$ and finds $J = -45$ complete solutions approximately half way through. We see an oscillatory behavior in the incumbent solution objective. Recall that the objective corresponds to the solution length n_s , or equivalently the depth in the search tree. These oscillations therefore represent a diverse exploration of the search tree, as solutions of varying lengths are visited and stalls are quickly broken. We attribute this diversity of the search in part to the dynamic neighborhood selection procedure that modifies the neighborhood when stalls are detected. The impact of dynamic neighborhood selection is investigated further in Section 5.3.4.

We now examine one of the $J = -45$ solutions generated by this run. Figure 5.4 shows the trajectory of a solution rendezvousing with the asteroid 2006BZ147. The full tour itinerary is shown in Table 5.9. The mass history over the trajectory closely follows the linear mass budget. We see portions of the trajectory where the spacecraft uses more mass than budgeted; the partial solutions ending at these segments would be penalized during the search. However, they are still feasible and

ultimately the search expands the trajectory to the complete solution shown.

Overall we find that the search produces a diverse population of good solutions to the GTOC4 problem using the base case parameters. We find trajectories exceeding the best known solutions of the GTOC4 problem. We now continue by varying aspects of the search and studying the effects in comparison to this base case.

Figure 5.4: Base case: run #409/1024. The trajectory is shown for a $J = -45$ solution rendezvousing with asteroid 2006BZ147.

5.3.2 Finite Burn Constraints

The finite burn constraints in the augmented impulsive tour model (Equations (5.14) through (5.16)) ensure that estimates for finite burn maneuvers representing each impulsive maneuver do not overlap in time or occur outside the mission time of flight. These finite burn estimates are developed in Section 2.2.5 and include the effects of gravity losses. The goal of these constraints is to restrict the search to find only impulsive solutions that can likely be feasibly converted to low-thrust finite burn trajectories.

The additional constraints further limit the feasible solution space of the problem. We run an additional case without these constraints in order to study their effects. We use the base case search parameters of Table 5.6, but ignore the finite burn constraints in the augmented impulsive tour model. Figure 5.5 shows the best solutions found over 1024 runs in comparison to the base case. The differences are significant: the median best complete solution ignoring finite burn constraints is $J = -46$, better than the best overall complete solution found in the base case. Further, we find complete solutions visiting up to 50 intermediate asteroids ($J = -50$). These solutions, although not practical, are impressive compared to the known GTOC4 solutions. We can also examine the quantity and diversity of solutions found. Recall a family of trajectories is identified by its asteroid sequence $s_i \dots s_{n_s}$. Figure 5.6 compares the number of trajectory families found for complete solutions to the base case. We see at least an order of magnitude more solutions over each range of objectives, with some ranges seeing a nearly 5 order of magnitude difference. The disparity is greatest for objectives near zero—these solutions correspond to short sequences. The spacecraft is less efficient when its mass is maximum early in a trajectory; for the early maneuvers then the finite burn estimates will be of longer duration, and the finite burn constraints will eliminate more solutions. This explains

Figure 5.5: The best solutions found for the base case and the case ignoring finite burn constraints.

Figure 5.6: The number of trajectory families found for complete solutions in the base case and the case ignoring finite burn constraints.

in part these larger differences.

The finite burn constraints prune at least an order of magnitude of the solutions away over every range of objectives. These pruned solutions represent better objective values; however they are not likely to have feasible low-thrust finite burn counterparts and are thus not of interest in the search. Further, the search tree is smaller in size when such solutions are pruned, which increases the efficiency of the search.

5.3.3 Search Space Pruning

The search space pruning procedure developed in Chapter 4 is designed to accelerate the generation of new solutions by discarding infeasible trajectory segments before they are computed. This in turn accelerates the computation of each iteration and allows the search to explore a larger region of the search space in a fixed time. We now disable the space pruning procedure and re-run results to measure the performance improvement in comparison to the base case. We otherwise use the same base case search parameters of Table 5.6.

We first run results for the same fixed run time of 2 hours and consider the performance in terms of the number of iterations computed during that time. Figure 5.7 shows a comparison against the base case with space pruning enabled. We see that in all runs more iterations are computed with space pruning enabled than not. A median of $10.5\times$ more iterations are computed when space pruning is enabled. This order of magnitude improvement allows the search to explore and find more improved solutions for the same fixed compute time. Over 95% of the runs see at least a $5\times$ improvement. The improvement directly impacts the quality of solutions found. Figure 5.8 shows a comparison of the best solutions found in comparison to the base case. The differences are significant; without space pruning, the median objective found for complete solutions is only $J = -38$, much worse

Figure 5.7: Performance of base case (search space pruning) versus case with space pruning disabled for 1024 runs. The run time is constrained to 2 hours. A median of $10.5\times$ more iterations are computed with space pruning enabled, with 95% of runs seeing at least a $5\times$ improvement.

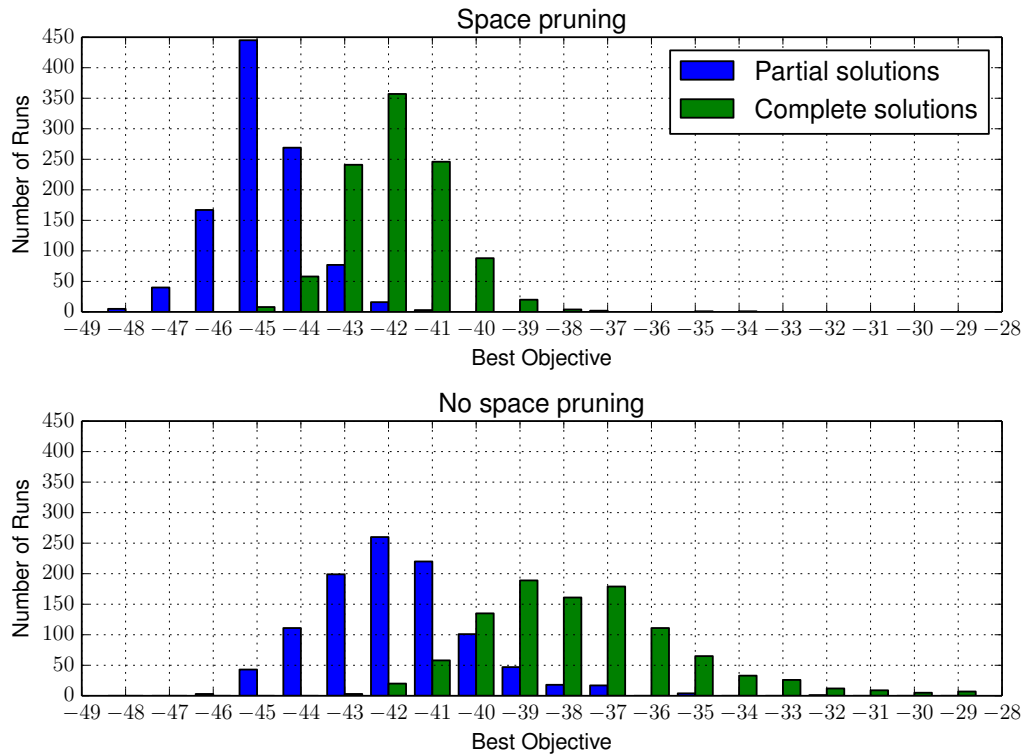

Figure 5.8: Results of base case (search space pruning) versus case with space pruning disabled for 1024 runs. The run time is constrained to 2 hours. The best partial and complete solutions are shown.

than the base case value of $J = -42$.

We run another comparison against the base case, but this time fix the runs at 1,000 iterations total with an unrestricted run time. We then compare the performance in terms of the required run time. Figure 5.9 shows the results. All of the runs with space pruning enabled complete in a shorter run time than those without space pruning. The median runtime speedup of the space pruning approach is $11.0\times$. Again, we see more than an order of magnitude improvement. Over 99% of the runs see a greater than $5\times$ runtime speedup.

Figure 5.9: Performance of base case (search space pruning) versus case with space pruning disabled for 1024 runs. 1000 iterations are computed and the run time is unconstrained. The median runtime speedup is $11.0\times$ with 99% of the runs seeing at least a $5\times$ speedup.

The search space pruning procedure provides a median order of magnitude performance improvement to the search, with practically all runs seeing at least a $5\times$ improvement. We can either compute an order of magnitude more iterations in the same allowed run time, or compute the same number of iterations an order of magnitude faster. This provides a significant boost to the search performance, especially important in the context of limited compute resources or a limited time during which to solve a problem. We see a distribution of performance gains rather than a fixed improvement due to the variability in the number of infeasible trajectory segments that are pruned during solution construction. We expect to see a larger improvement when fewer feasible solutions exist, since more solutions can be discarded prior to computation. When most of the candidate solutions are feasible, the space pruning approach is of less benefit.

5.3.4 Dynamic Neighborhood Selection

The dynamic neighborhood selection procedure developed in Section 3.5.2 dynamically intensifies and diversifies the search in an effort to provide improved overall solutions compared to statically defined neighborhoods. It achieves this by maintaining a diverse exploration of the search tree, breaking any stalls about particular regions of the search space that may occur. In this section we compare the dynamic neighborhood selection approach to various static neighborhoods.

Recall that we use the restricted best-first neighborhood defined in Section 3.2.2 in the tabu search algorithm. This neighborhood has one parameter h that dictates the neighborhood's size, in terms of how far upward in the tree to move before finding neighboring leaf nodes to expand. The dynamic neighborhood selection procedure adjusts h throughout the search. A static neighborhood instead maintains a fixed value of h .

We now run cases for various fixed values of h . These cases use the same

search parameters as the base case (Table 5.6) but do not dynamically update the neighborhood. The results for several trial values of h are shown in Figure 5.10. We see that the $h = 3$ case significantly underperforms the base case, with a median best complete solution of only $J = -31$. The performance improves as h is increased. The $h = 5$ is a small improvement with a median best complete solution of $J = -32$. The improvement continues with the $h = 20$ case giving a median best complete solution of $J = -41$, nearly as good as the base case with dynamic neighborhood selection enabled ($J = -42$). From these metrics then, it appears that the results steadily improve as h is increased.

We now compare the extreme case of $h = \infty$ with the base case directly. Figure 5.11 shows the results. The distributions of best solutions found for each run appear nearly identical, with the $h = \infty$ case having several runs achieving best complete solutions of only $J = -28$ while all runs of the base case (dynamic neighborhood selection) achieve at least $J = -34$. However, the results are further distinguished when we consider the quantity and variety of solutions found rather than just the best single solution of each run. Recall that we define a family of trajectories by their target object sequence $s_1 \dots s_{n_s}$. Figure 5.12 compares the $h = \infty$ case against the dynamic neighborhood selection case based on the number of trajectory families found for complete solutions. We see many more families of solutions are found for the dynamic neighborhood selection case. This is an important result, as it indicates the search is providing a more varied set of trajectory options in the population of final solutions. We attribute this to the strategic intensification and diversification of the search provided by the dynamic neighborhood selection procedure. We can quantify this diversity in part by the variation in the incumbent solution lengths over the iterations. Figure 5.13 shows that the standard deviation of incumbent solution lengths is much higher for the dynamic neighborhood selection

Figure 5.10: The results of the base case are re-run with dynamic neighborhood selection disabled for various static values of the restricted best-first neighborhood parameter h . The best solutions found are shown for each case.

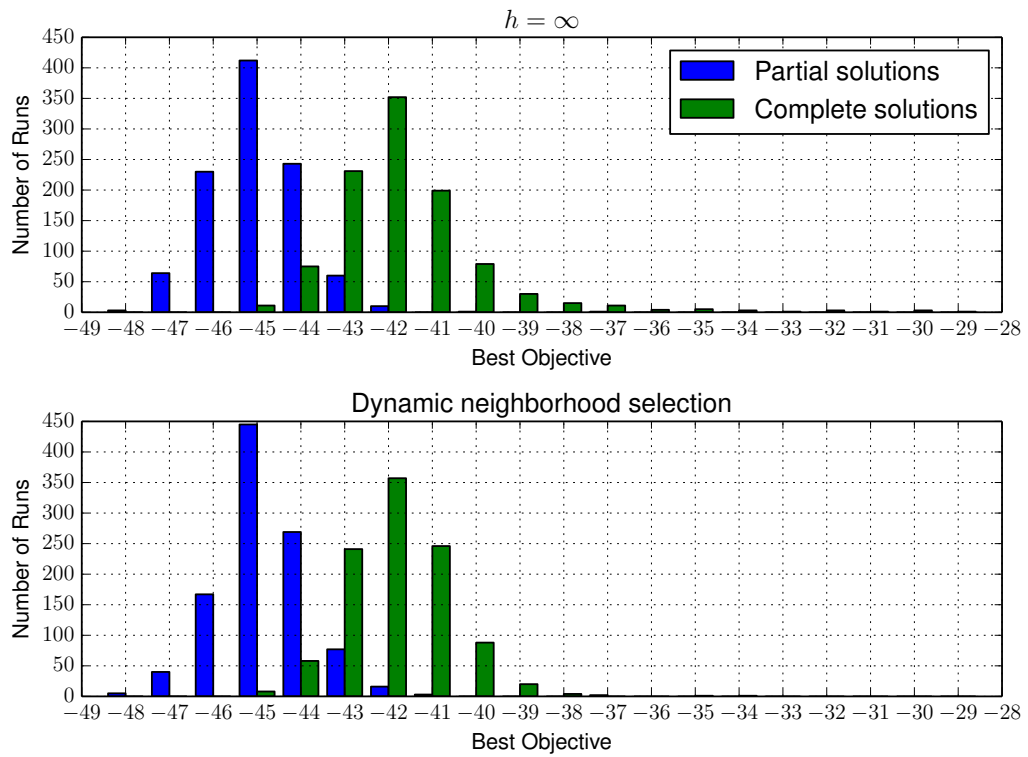

Figure 5.11: The best solutions found for the static neighborhood $h = \infty$ case and the dynamic neighborhood selection case.

Figure 5.12: The number of trajectory families found for complete solutions in the dynamic neighborhood selection case and the static neighborhood $h = \infty$ case.

Figure 5.13: The standard deviation of the incumbent solution length for all runs in the dynamic neighborhood selection case and the static neighborhood $h = \infty$ case.

case as expected.

Although a static neighborhood can give good results, it does not give the breadth of solutions that dynamic neighborhood selection provides. Further, with $h = \infty$ the neighborhood size will monotonically increase as the search tree grows over the iterations. We would then expect to see a performance decrease over time compared to the dynamic neighborhood selection approach which restricts the neighborhood size. This scalability is important if we consider running the search over longer periods of time.

	Base Case	Reduced Performance A (5% change)	Reduced Performance B (10% change)
T_{max}	0.135 N	0.12825 N	0.1215 N
m_{dry}	500 kg	525 kg	550 kg

Table 5.10: Spacecraft parameters for base case and reduced spacecraft performance cases.

5.3.5 Reduced Spacecraft Performance

We now modify the spacecraft parameters for reduced performance. We consider a reduction to the spacecraft’s maximum thrust magnitude T_{max} as well as to its available fuel mass. The reduction in thrust capability extends the duration of finite burn estimates for the impulsive maneuvers. The longer finite burn maneuvers consequently also experience greater gravity losses. The reduced fuel mass further limits the maneuverability of the spacecraft. The resulting solutions are more tightly constrained than those of the base case. We study this case both to examine the impact of reduced spacecraft performance on the quality of solutions found and to find more conservative solutions that are more likely to converge to low-thrust finite burn trajectories, noting that the finite burn feasibility constraints placed on impulsive solutions are based only on estimates of the corresponding finite burn maneuvers.

Table 5.10 gives the spacecraft parameters for the base case and two reduced performance cases. For the Reduced Performance A case, we decrease the spacecraft’s maximum thrust magnitude by 5% and increase its dry mass by 5% (keeping the initial mass constant and therefore reducing the available fuel mass). For the Reduced Performance B case we instead change the values by 10% for even more conservative results. We generate results for the reduced performance cases using the base case parameters shown in Table 5.6 with the new reduced spacecraft performance parameters. Figure 5.14 shows the best solutions for these cases (over 1024

	Minimum	Median	Maximum
Partial solutions			
Base case	-48	-45	-37
Reduced performance A	-47	-44	-40
Reduced performance B	-46	-43	-37
Complete solutions			
Base case	-45	-42	-34
Reduced performance A	-45	-42	-34
Reduced performance B	-43	-40	-32

Table 5.11: Summary of best solutions found for base case and reduced spacecraft performance cases.

runs) in comparison to the base case.

We see the reduced performance cases have similar results to the base case. However, the objective distributions have shifted. For partial solutions, the median objective value increases by one for each 5% reduction in the spacecraft’s performance. For complete solutions, the Reduced Performance A case achieves the same minimum, median and maximum objective, while the values for the Reduced Performance B case are increased by two. Table 5.11 summarizes the differences in the solution statistics. We continue by investigating individual runs from both reduced performance cases.

Reduced Performance Case A

We examine a single run from the collection of 1024 runs of Reduced Performance Case A. We consider run 622 corresponding to a launch date of 59466.01 MJD and a best complete solution objective of $J = -45$. The run’s iteration history is shown in Figure 5.15. The best complete solution objective of $J = -45$ is achieved

early within the two hour run time at iteration 6100 of 22401. We extend this run to compute for 36 hours—however we see no further improvement for partial or complete solutions.

We examine a single complete solution from this run for $J = -45$. We choose a trajectory rendezvousing with asteroid 2006QQ56. Figure 5.16 shows the trajectory, and Table 5.12 shows the tour itinerary. The spacecraft mass history closely follows the linear budget as in the other cases. Since this trajectory uses more conservative values for the spacecraft performance, we expect that this solution

could more easily be converted into a feasible low-thrust finite burn trajectory.

Reduced Performance Case B

We similarly examine a single run from the collection of 1024 runs of Reduced Performance Case B. We consider run 402 corresponding to a launch date of 58601.92 MJD and a best complete solution objective of $J = -43$. The run's iteration history is shown in Figure 5.17. The best complete solution objective of $J = -43$ is achieved

at iteration 8196 of the total 13892 iterations for the two hour run time. Again, we extend the search to 36 hours to see if better solutions can be found. We see that the search does not provide any improved complete solutions with the additional runtime. The best partial solution objective improves to $J = -46$ before 4 hours has elapsed, but improves no further afterward.

We examine a single complete solution from this run for $J = -43$. We choose a trajectory rendezvousing with asteroid 2006UB17. Figure 5.18 shows the trajectory, and Table 5.13 shows the tour itinerary. The spacecraft mass history closely follows the linear budget as in the other cases. Again, since this trajectory uses more conservative values for the spacecraft performance, we expect that this solution could more easily be converted into a feasible low-thrust finite burn trajectory.

For both runs of the reduced performance cases, we see that the search finds its best complete solutions within two hours of run time, even when the searches are continued for up to 36 hours. Thus, the search algorithm appears to find good solutions rapidly, with little improvement for extended run times.

5.3.6 Comparison to GTOC4 Winning Solution

In the previous sections we generated solutions across the full 10-year range of allowed launch epochs (Table 5.5) and found solutions that compared favorably to the overall GTOC4 competition results. In this section we instead wish to more directly compare against the winning GTOC4 solution found by Moscow State University [11]. In their solution, the spacecraft departs the Earth at 58676.40 MJD and visits 44 intermediate asteroids before completing a final rendezvous with asteroid 2000SZ162, achieving an objective value of $J = -44$. We now examine solutions for the same launch epoch, and place emphasis on solutions that similarly rendezvous with asteroid 2000SZ162.

We first generate solutions for the base case parameters given in Table 5.6 for the launch epoch of 58676.40 MJD and allow the search to run for 12 hours. Figure 5.19 shows the number of trajectory families found and their objective values for complete solutions. The best overall solution is found after 12 hours and rendezvouses with asteroid 2008JP24 for an objective value of $J = -43$. The best solution rendezvousing with asteroid 2000SZ162 is found after 4 hours and visits 41 intermediate asteroids, fewer than the 44 achieved by the winning GTOC4 solution. The $J = -41$ objective achieved is close to the median of $J = -42$ for all runs of the base case (Table 5.7). Although a $J = -44$ solution rendezvousing with asteroid 2000SZ162 was not found for the base case parameters at this launch epoch, we note that the base case executed across the full range of launch epochs did find such solutions (Table 5.8). These were found at the nearby launch epochs of 58032.41 MJD, 58323.06 MJD, 58448.74 MJD and 58955.41 MJD.

The base case solutions found are constrained so that finite burn estimates for the impulsive maneuvers do not overlap in time in an effort to ensure that the resulting impulsive trajectories also have valid finite burn representations. These constraints are only estimates, however, and are specific to the impulsive tour model

Figure 5.19: Number of trajectory families found versus objective for the base case parameters and a launch epoch of 58676.40 MJD. The search is allowed to run for 12 hours. Only complete solutions are shown.

used in this work. Further, these constraints do not guarantee that a feasible conversion is possible and may instead over- or under-constrain the search. Section 5.3.2 showed that the constraints significantly reduce the feasible solution space, in turn limiting the objectives achievable. We note that the Moscow State University search methodology also operates on impulsive trajectories, but allows finite burn estimates for impulsive maneuvers to overlap in time [29]. When the finite burn conversion occurs, many of these overlaps are resolved in the optimization, while some asteroids are dropped from the itinerary as necessary. It therefore makes sense to consider relaxing (but not eliminating) the finite burn constraints used in our model.

Increased Spacecraft Performance

We now consider relaxing the finite burn constraints through an increase to the maximum allowed thrust T_{max} of the spacecraft. The increased T_{max} reduces the duration of finite burn estimates for the impulsive maneuvers, and therefore makes the finite burn constraints less restrictive. One can equivalently view this as allowing an overlap in finite burn estimates for the original T_{max} value. We generate solutions for the base case parameters again for a launch epoch of 58676.40 MJD, but increase the value of T_{max} by 5% from 0.135 N to 0.14175 N. Figure 5.20 shows the distribution of trajectory families found for complete solutions up to a 12 hour runtime. The best solutions are found after 4 hours and achieve an objective of $J = -46$, exceeding the best results of the base case previously executed across the full 10-year launch window. These best three trajectory families rendezvous with two different final asteroids, 2006DN and 2003YG136. Ten trajectory families rendezvousing with seven final asteroids are found with objective values of $J = -45$. One of these rendezvouses with asteroid 2000SZ162. We have found a solution rendezvousing with the same final asteroid for the same launch epoch that improves upon the winning GTOC4 solution. Figure 5.21 shows the trajectory, and Table 5.14

Figure 5.20: Number of trajectory families found versus objective for the increased spacecraft performance case and a launch epoch of 58676.40 MJD. The spacecraft's maximum allowed thrust T_{max} is increased by 5% from 0.135 N to 0.14175 N. The search is allowed to run for 12 hours. Only complete solutions are shown.

shows the tour itinerary. We do note that the sequence of intermediate asteroids in this solution is different than that of the winning GTOC4 solution. In our results we were unable to reproduce that solution’s exact sequence. We have however found a comparable trajectory for the same launch epoch and rendezvous asteroid, as well as many other solutions with the same or superior objective values. Due to the large asteroid population and the vast number of feasible sequences, we find it unlikely that any two methodologies will reproduce the same asteroid sequence in reasonable compute times. This is in part due to the differing constraints, objec-

Figure 5.21: Increased spacecraft performance case: The trajectory is shown for a $J = -45$ solution rendezvousing with asteroid 2000SZ162.

tives and penalties placed on solutions during the search, and is supported by the original GTOC4 results where no two asteroid sequences were replicated. Further, we note that the top two solutions had similar launch epochs (within two weeks of each other) and rendezvoused with the same final asteroid, but differed significantly in the intermediate asteroid sequence, sharing only three asteroids in common.

Relaxing the finite burn constraints through an increase to the spacecraft's maximum allowed thrust magnitude T_{max} increases the variety and quality of solutions found and allows us to find solutions comparable to the winning GTOC4 solution. We note again that these are impulsive solutions, however, and that there is a trade-off: with less restrictive finite burn constraints, we expect the subsequent finite burn conversion to be more difficult. The next section considers the low-thrust finite burn conversion of selected impulsive solutions.

5.3.7 Low-thrust Finite-burn Conversion

The GTOC4 problem statement requires low-thrust finite burn trajectories that adhere to the specified maximum thrust T_{max} . The solutions we have presented up to this point have all been impulsive, ignoring this limit on the thrust magnitude. We have however constrained the impulsive solutions based on estimates of representative finite burn maneuvers; these constraints further limit the feasible solution space in an effort to only find trajectories that can be converted to low-thrust finite burn solutions. These finite burn estimates are only approximations, however, and we are not guaranteed that our solutions will converge to valid finite burn trajectories. This section evaluates the finite burn conversion and optimization of selected impulsive solutions. The resulting low-thrust finite burn trajectories can be compared directly to the best known solutions of GTOC4 (Section 5.2).

An impulsive solution generated by the search algorithm can act as an initial guess for a low-thrust finite burn trajectory. In this conversion, the sequence of target asteroids of the impulsive solution becomes fixed. The impulsive maneuvers are then replaced with finite burn maneuvers that must satisfy the original problem constraints. The resulting problem is a continuous optimization problem with no discrete decision variables. We can solve the problem in a variety of ways, either formulating it as a parameter optimization problem or instead taking an optimal control approach, for example. Existing tools such as Copernicus are well suited to this task [71]. Olympio has developed an optimal control formulation that can optimize GTOC4 trajectories directly [52]. The method takes an initial guess in the form of the asteroid sequence, asteroid visit times, and spacecraft velocity and mass values along the trajectory and generates mass-optimal low-thrust finite burn trajectories. We use Olympio’s approach and software to find finite burn solutions based on our impulsive solutions. The optimization varies the thrust history of the spacecraft, but in our usage treats the asteroid encounter dates as fixed. The

Figure 5.22: Workflow for GTOC4 solution process. The impulsive search algorithm generates a population of impulsive trajectories. The user then selects specific impulsive trajectories, optimizes them impulsively, and passes them to the black-box finite burn conversion and optimization tool.

resulting solutions are optimal for the fixed encounter dates, but we expect they would be further improved if the encounter dates were also free to vary.

Reduced Performance Case A

We first consider the $J = -45$ impulsive trajectory from Reduced Performance Case A (Figure 5.16 and Table 5.12). This solution was generated for a 5% reduction in the spacecraft’s maximum thrust magnitude and a 5% increase in its dry mass.

We generate the initial guess using the search-generated impulsive solution and run the optimization using Olympio’s approach. In this case, we are not initially able to find a feasible finite burn solution satisfying the problem constraints. A limitation of our usage of Olympio’s approach is that the asteroid encounter dates are fixed—in general these encounter dates could also be optimized, or in this case modified to find a feasible solution. We now consider the additional step of optimizing the search-generated impulsive trajectory to maximize the final mass, noting that the search-generated solutions are not optimal in part because the encounter dates are chosen from a discretization of possible dates. We use the same constraints as in the search; however we now consider the asteroid sequence to be fixed, and only optimize the launch date and encounter dates. The workflow for the full solution process is shown in Figure 5.22.

We find that optimizing the launch and encounter dates for the impulsive trajectory increases the final mass from 525.32 kg to 643.86 kg. The optimized

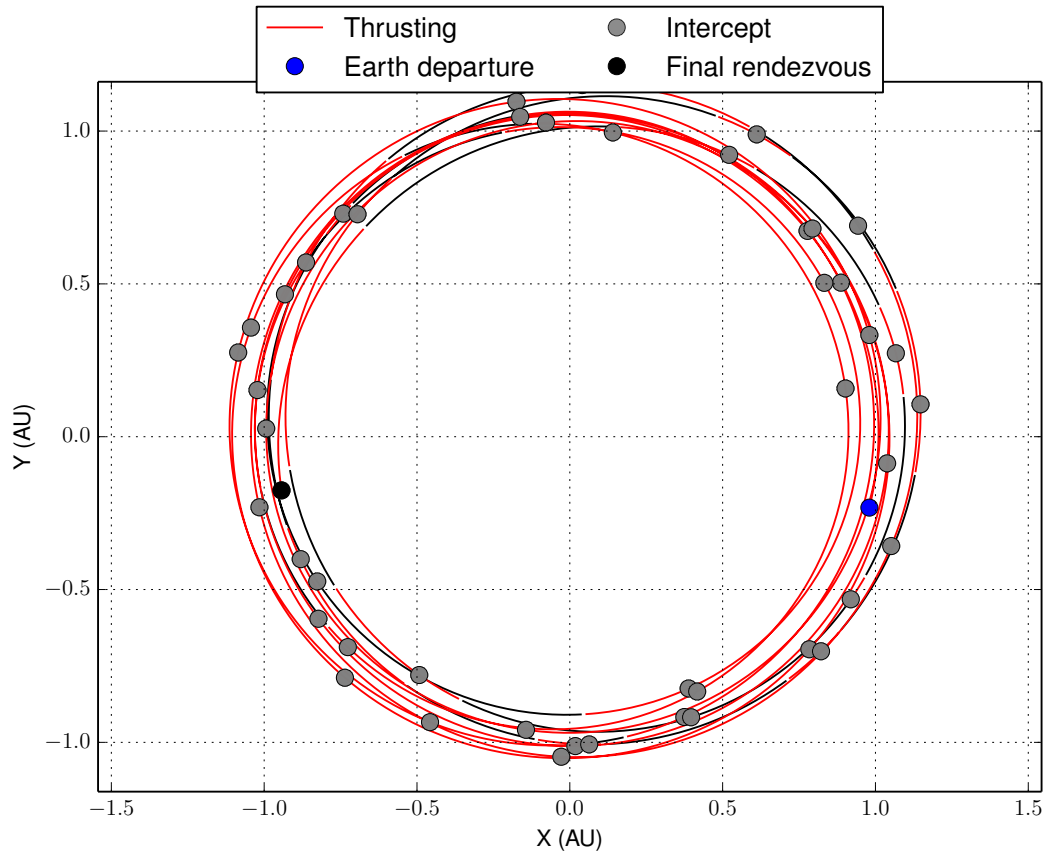

Figure 5.23: Low-thrust finite burn trajectory corresponding to the $J = -45$ impulsive trajectory of the reduced spacecraft performance case shown in Figure 5.16 and Table 5.12.

impulsive trajectory still adheres to the original model constraints. We now optimize this solution using Olympio’s approach, and find that it does converge to an optimal low-thrust finite burn trajectory. Figures 5.23 and 5.24 show the solution, and Table 5.15 shows the tour itinerary. The final mass of the trajectory is 505.12 kg, just above the limit of 500 kg. This solution exceeds the best known GTOC4 solution of $J = -44$.

Figure 5.24: Low-thrust finite burn trajectory corresponding to the $J = -45$ impulsive trajectory of the reduced spacecraft performance case shown in Figure 5.16 and Table 5.12. The original impulsive trajectory is also shown.

Table 5.15: Low-thrust finite burn trajectory corresponding to the $J = -45$ impulsive trajectory of the reduced spacecraft performance case shown in Figure 5.16 and Table 5.12. The tour itinerary is shown.

Reduced Performance Case B

We now consider the $J = -43$ impulsive trajectory from Reduced Performance Case B (Figure 5.18 and Table 5.13). This solution was generated for a 10% reduction in the spacecraft’s maximum thrust magnitude and a 10% increase in its dry mass.

We again follow the workflow shown in Figure 5.22. Optimizing the launch and encounter dates for the impulsive trajectory increases the final mass from 579.46 kg to 679.11 kg. We now optimize this solution using Olympio’s approach, and find that it does converge to an optimal low-thrust finite burn trajectory. Figure 5.25 and 5.26 show the solution, and Table 5.16 shows the tour itinerary. The final mass of the trajectory is 583.91 kg, well above the limit of 500 kg. This solution would have placed third in the original GTOC4 competition.

We found that both of the impulsive trajectories from both reduced performance cases could be converted to optimal low-thrust finite burn solutions. In these cases we added an intermediate impulsive optimization to maximize the final mass. The low-thrust finite burn trajectory corresponding to the first case represents the best known solution to the GTOC4 problem. This validates the overall global search methodology. More specifically, the feasible finite burn conversion validates that our estimates for representative finite burn maneuvers sufficiently constrain the impulsive solution space.

5.4 Summary

This chapter applied the search methodology developed in Chapter 3 to the GTOC4 problem, and found impulsive solutions exceeding the best known. The method uses no a priori information of these best known solutions, but rather adaptively updates parameters of the search to find increasingly better solutions over time. We var-

Table 5.16: Low-thrust finite burn trajectory corresponding to the $J = -43$ impulsive trajectory of the reduced spacecraft performance case shown in Figure 5.18 and Table 5.13. The tour itinerary is shown.

ied several components of the search to study their impact on the results. We found that the finite burn feasibility constraints reduce the feasible solution space by orders of magnitude. Additionally, we found the search space pruning approach developed in Chapter 4 accelerates the search by an order of magnitude. The dynamic neighborhood selection procedure provides more diverse solutions through its dynamic intensification and diversification of the search. Finally, we generated optimal low-thrust finite burn trajectories for selected impulsive trajectories, and found a solution exceeding the best known for GTOC4.

The search procedure developed in this work is meant as the first stage of a multi-stage workflow. It finds impulsive solutions that are constrained in a way that helps ensure they can be converted to low-thrust finite burn trajectories. However, this conversion is not guaranteed to be feasible. In the future a second stage of this workflow should be developed that automatically converts and optimizes selected impulsive solutions into low-thrust finite burn trajectories.

Chapter 6

Conclusions

6.1 Dissertation Summary

This dissertation describes the spacecraft tour trajectory optimization problem, and develops an overall methodology for finding promising solutions. The method is based on many of the tenets of tabu search, and represents an automated, adaptive and efficient approach to finding globally good solutions to a broad class of spacecraft tour trajectory problems.

Chapter 2 begins by developing a general model and parameterization for tour trajectories. This model is a complication to the traveling salesman problem, where now both the agent and targets objects are allowed to move with time according to a set of prescribed dynamics. A model for spacecraft tour trajectories subject to two body dynamics and impulsive maneuvers is then presented. Constraints are developed on impulsive maneuvers to prune away solutions that are unlikely to have equivalent finite burn trajectories. These additional constraints are only approximations, but allow the model to be used for preliminary design for low-thrust trajectory optimization problems as well. This augmented model is used in later applications to the fourth annual Global Trajectory Optimization Competition

problem (GTOC4).

Chapter 3 develops the overall global search methodology, and is the core chapter of the dissertation. It begins by implementing the building blocks common to local search algorithms: the solution representation, neighborhoods, and objectives. A tree-based solution representation is defined that is shown to be especially efficient for problems with expensive solution evaluations. Neighborhoods are then defined to operate on this representation, leading to a neighborhood definition that allows for strategic intensification and diversification during the search. A guiding objective is then developed which allows the algorithm to adaptively target increasingly better solutions as the search progresses. Finally, these components are combined within the context of the tabu search algorithm. Tabu attributes and recency-based tabu memory are presented, as well as a strategic intensification and diversification approach that dynamically adjusts the neighborhood to ensure a sufficiently diverse exploration of the search space. The final result of the chapter is a tabu search algorithm applicable to general tour trajectory optimization problems. The algorithm is deterministic and generates a diverse population of feasible solutions.

Chapter 4 develops a numerical search space pruning procedure which can be used to improve the performance of the tabu search algorithm. The chapter first describes the brute force approach, and then develops the concept of a trajectory envelope that bounds the reachable domain of the spacecraft. A simple numerical procedure is then developed to compute an upper bound on the trajectory envelope. The procedure is based on the generation of bounding boxes in space and time. Target objects intersecting these bounding boxes may be feasibly reached by the spacecraft; those not intersecting can be safely pruned from the search space. The pruning condition is thus a necessary, but not sufficient, condition for reachability. The performance of the space pruning method is analyzed for a simple example

according to an assumed discretization, and a significant reduction in the number of required Lambert targeting computations is shown, which should yield speedups in real applications.

Chapter 5 then applies all of these components together to the fourth annual Global Trajectory Optimization Competition (GTOC4). The impulsive tour model is extended with constraints specific to GTOC4, and the tabu search algorithm is executed for a broad set of cases. Each case is executed in parallel on the Stampede supercomputer to generate a distribution of results across a range of launch epochs. The algorithm finds impulsive solutions meeting or exceeding every solution from the original GTOC4 results. Impulsive solutions are also found exceeding the currently best known GTOC4 solution. A sensitivity analysis is then conducted, examining the impact of components of the search algorithm including the finite burn feasibility constraints, search space pruning procedure and dynamic neighborhood selection procedure. In particular, the search space pruning approach is found to yield an order of magnitude speedup in performance. We then examine cases where the spacecraft is assumed to have reduced performance through lower thrust capability and available fuel to see the impact of solution quality. Finally, we convert solutions from the reduced performance cases into fully optimized low-thrust finite burn solutions, making use of an indirect optimal control approach provided by Olympio. The results are new solutions to the GTOC4 problem, including one exceeding the best known solution in the literature.

6.2 General Conclusions

The primary contribution of this work is the development of a tabu search methodology for the spacecraft tour trajectory optimization problem. This work represents the first application of tabu search to spacecraft trajectory optimization, and it is the hope of the author that such methods will find more practical applications in

the future. The resulting algorithm represents an automated and adaptive approach for finding promising solutions to tour problems, and yields a broad population of feasible solutions in short run times. Another contribution is the extension of tabu search to tree-based solution representations and neighborhoods. The tree-based representation leads to increased speed and efficiency on problems with expensive solution evaluations. We believe this is the first time a tree-based solution representation has been used with a tabu search algorithm. The search space pruning procedure based on trajectory envelopes is also novel, and could be applicable other problems with different trajectory dynamics. Finally, the work resulted in a collection of new solutions to the GTOC4 problem, including a new solution exceeding the previously best known.

6.3 Future Work

This work does not represent an exhaustive exploration of search approaches for spacecraft tour trajectory optimization, nor does it fully explore the ways in which tabu search can be used to attack such problems. It is the hope of the author that future work is able to build upon and improve the methods developed here. Although the tabu search approach has been demonstrated successfully on the GTOC4 problem, it should also be applied to other problems to further test its applicability and performance. The ability to adapt the definitions of the solution representation and neighborhoods should make the algorithm easily applicable to diverse problem types, in particular other GTOC problems. Further, applying it to the design of active debris removal trajectories addressing the Earth orbital debris problem could be fruitful.

A particular area for future work is the parallelization of the algorithm. Although we ran the software on large-scale supercomputing clusters, we did so by running independent instances for varying launch epochs. Another approach is to

parallelize the solution representation and neighborhood computations directly. The tree-based solution representation is especially amenable to distributed parallelization, as subtrees of the overall search tree can be distributed across a supercomputing cluster and computed on in an embarrassingly parallel manner. Such a parallelization would further improve the speed of search and possibly aid in the discovery of improved solutions to challenging problems in spacecraft tour trajectory optimization.

Appendix A

Software Implementation

A software package was developed that implements all components of the tabu search methodology presented in this work. This cross-platform application has a graphical user interface and visualization capabilities that allow users to interactively run, adjust parameters and analyze results of the tabu search algorithm (Figure A.1). Additionally, the application can run in batch mode for large-scale studies, such as those executed in Chapter 5 on the Stampede supercomputer at the Texas Advanced Computing Center [2]. The application, written in C++, relies heavily on an object-oriented programming model. This section briefly describes the implementation of the tree-based solution representation used throughout the work as well as the neighborhoods built on that representation. The implementation is described using C++ terminology; however the strategy described here can be implemented in other object-oriented programming languages.

A.1 Tree-Based Solution Representation

The tree-based solution representation developed in Section 3.1 is implemented using an object-oriented approach. Recall that branches of the tree represent trajectory

Figure A.1: The software package that implements the tabu search methodology allows users to interactively run, adjust and analyze results of the search through its user interface and visualization capabilities.

Method	Description
GETPARENT()	returns parent node of the current node
GETCHILDREN()	returns children node(s) of the current node
GETANCESTOR(h)	returns h^{th} ancestor of the current node
GETLEAVES()	returns all descendant leaf node(s) of the current node

Table A.1: Tree traversal methods implemented in the *TreeNode* class.

segments and their decision variables, and nodes of the tree correspond to states at the segment boundaries. Each node of the tree may have multiple children nodes, and except for the root node, each has a single parent node. Results of state, objective and constraint evaluations are stored in the tree, allowing for efficient generation of new solutions through iterative expansion of the tree.

The tree and all of its basic traversal operations are implemented using a single class in C++ named *TreeNode*. This class contains member variables representing the trajectory segment decision variables and evaluations as well as member methods (or functions) that operate on this data. The class also contains pointers that reference children nodes as well as the parent node. When this class is instantiated it forms an object. Any number of these objects can be instantiated, and through assigning the children and parent pointers, the tree structure is formed. Figure A.2 shows a *TreeNode* object and both the parent and children nodes it references.

The methods defined in the *TreeNode* class allow for traversing the search tree through use of the parent and child node pointers. Table A.1 lists several of these methods. The GETPARENT() and GETCHILDREN() methods are simple: they simply return the member pointers to the corresponding *TreeNode* objects. The remaining methods, GETANCESTOR(h) and GETLEAVES(), rely on recursion to compute their results. Algorithm 13 gives pseudocode for a GETLEAVES() imple-

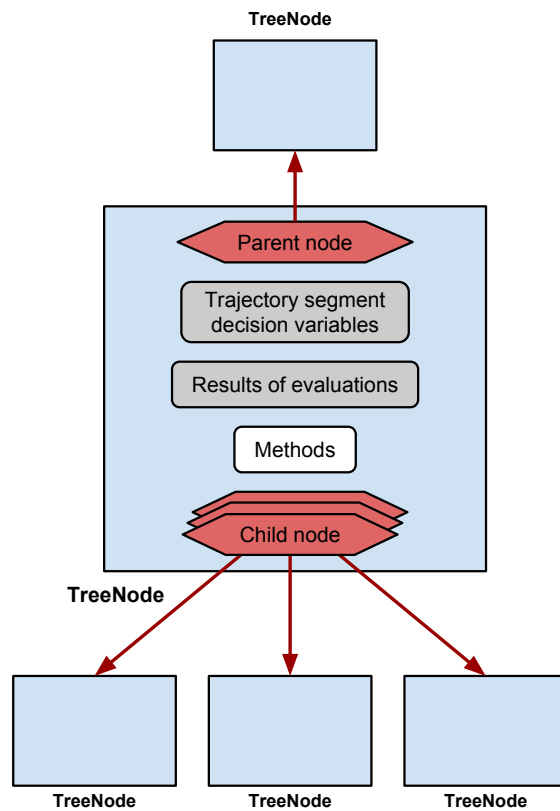

Figure A.2: The *TreeNode* class represents nodes in the tree-based solution representation. A *TreeNode* object is shown with the parent and children nodes it references. The collection of *TreeNode* objects combine to form the search tree.

mentation. For a large tree, the `GETLEAVES()` method will be called recursively

Algorithm 13 Example `GETLEAVES()` implementation.

```

▷ return all descendant leaf node(s) of the current node
▷ on initial call, leafNodes is an empty list
▷ upon termination, leafNodes contains the full set of leaf node(s)

procedure GETLEAVES(leafNodes)
  ▷ get list of children of current node
  children = this → GETCHILDREN()
  ▷ if there are no children, add this node to the list of leaf nodes and return
  ▷ otherwise, continue recursively to find the remaining leaf nodes
  if LENGTH(children) == 0 then
    leafNodes = leafNodes + this
    return
  else
    for child in children do
      child → GETLEAVES(leafNodes)
    end for
  end if
  return
end procedure

```

many times to populate the full list of leaves. Other operations on the tree-based solution representation are implemented in a similar manner. For example, when a *TreeNode* object is deleted from memory, upon destruction it will recursively delete all of its children nodes and their descendants. In this manner, entire subtrees of the overall search tree can be easily pruned.

Neighborhoods can also be computed using these basic tree traversal methods. Recall the restricted best-first neighborhood presented in Section 3.2.2, defined as

$$\mathcal{N}(\mathbf{x}, h) = \mathcal{C}(\mathbf{x}) + \mathcal{L}(\mathcal{P}^h(\mathbf{x})) \quad (\text{A.1})$$

In this case the solution \mathbf{x} is a node of the tree. This neighborhood is composed of the children of the current node \mathbf{x} (which are generated on-demand) and the

leaf nodes of the h^{th} ancestor of \mathbf{x} . The two terms of the neighborhood can then concisely be computed as

$$\mathbf{neighborhood} = \mathbf{x} \rightarrow \text{GENERATECHILDREN}() \quad (\text{A.2})$$

$$\mathbf{x} \rightarrow \text{GETANCESTOR}(h) \rightarrow \text{GETLEAVES}(\mathbf{neighborhood}) \quad (\text{A.3})$$

We limit the discussion here to the implementation of the basic tree data structure and operations required by the search. The object-oriented approach gave a great deal of flexibility in the search algorithm design, and simplified the overall implementation of the tabu search methodology.

Vita

Gregory Phillip Johnson was born to Don and Sharon Johnson on January 17, 1983 in Dallas, Texas. He completed his Bachelor of Science in Aerospace Engineering (with high honors) at The University of Texas at Austin in 2005, continuing on to the graduate aerospace program at UT to obtain his Master of Science in Engineering in 2007, and now his Ph.D. in 2014. During his time as a graduate student, Gregory also worked full time at the Texas Advanced Computing Center.

This dissertation was typeset with L^AT_EX 2_ε¹ by the author.

¹L^AT_EX 2_ε is an extension of L^AT_EX. L^AT_EX is a collection of macros for T_EX. T_EX is a trademark of the American Mathematical Society. The macros used in formatting this dissertation were written by Dinesh Das, Department of Computer Sciences, The University of Texas at Austin, and extended by Bert Kay, James A. Bednar, and Ayman El-Khashab.
