**Key words:** colony, microenvironment, N<sub>2</sub> fixation, oxygen, *Trichodesmium*.

- To understand the role of micrometer-scale oxygen (O<sub>2</sub>) gradients in facilitating dinitrogen (N<sub>2</sub>) fixation, we characterized O<sub>2</sub> dynamics in the microenvironment around free-floating trichomes and colonies of *Trichodesmium erythraeum* IMS101.
- Diurnal and spatial variability in O<sub>2</sub> concentrations in the bulk medium, within colonies, along trichomes and within single cells were determined using O<sub>2</sub> optodes, microsensors and model calculations. Carbon (C) and N<sub>2</sub> fixation as well as O<sub>2</sub> evolution and uptake under different O<sub>2</sub> concentrations were analyzed by stable isotope incubations and membrane inlet mass spectrometry.
- We observed a pronounced diel rhythm in O<sub>2</sub> fluxes, with net O<sub>2</sub> evolution restricted to short periods in the morning and evening, and net O<sub>2</sub> uptake driven by dark respiration and light-dependent O<sub>2</sub> uptake during the major part of the light period. Remarkably, colonies showed lower N<sub>2</sub> fixation and C fixation rates than free-floating trichomes despite the long period of O<sub>2</sub> undersaturation in the colony microenvironment.
- Model calculations demonstrate that low permeability of the cell wall in combination with metabolic heterogeneity between single cells allows for anoxic intracellular conditions in colonies but also free-floating trichomes of *Trichodesmium*. Therefore, whereas colony formation must have benefits for *Trichodesmium*, it does not favor N<sub>2</sub> fixation.

## Introduction

Fixation of dinitrogen (N<sub>2</sub>) by marine diazotrophic bacteria and cyanobacteria provides a significant source of nitrogen to phytoplankton in oligotrophic systems. The N<sub>2</sub>-fixing enzyme nitrogenase is inhibited by oxygen (O<sub>2</sub>) via oxidative damage to the iron sulfur clusters (Burgess & Lowe, 1996), proteolysis (Durner *et al.*, 1996) as well as suppression of nitrogenase synthesis and posttranslational modification (Gallon, 1992). To protect nitrogenase from O<sub>2</sub>, many single-celled cyanobacteria separate photosynthesis from N<sub>2</sub> fixation in time, conducting N<sub>2</sub> fixation during the night, whereas many filamentous cyanobacteria restrict N<sub>2</sub> fixation to specialized cells termed heterocysts. The genus *Trichodesmium* spp., a globally important, colony-forming diazotroph, is an exception in that it fixes N<sub>2</sub> during the day although it lacks heterocysts. A range of O<sub>2</sub>-protective mechanisms has been suggested for *Trichodesmium*: the formation of anoxic microzones within colonies (Paerl & Bebout, 1988); a downregulation of photosynthesis during the peak of N<sub>2</sub> fixation at midday (Berman-Frank *et al.*, 2001); a restriction of N<sub>2</sub> fixation to specialized cells termed diazocytes (Bergman & Carpenter, 1991; Berman-Frank *et al.*, 2001); and dynamic switches between different photosynthetic activity states by

reversible uncoupling of phycobilisomes from the photosystems on the time scale of minutes (Küpper *et al.*, 2004, 2009). The prevalence and coordination of these different mechanisms is still debated, partly due to conflicting results in previous studies.

Regarding cell specialization, several studies have reported nitrogenase to be present only in 10–15% of cells within a trichome (diazocytes), which are not terminally differentiated cells, do not have thicker cell walls than vegetative cells, and contain photosystem II, by contrast to heterocysts (Carpenter *et al.*, 1990; Siddiqui *et al.*, 1992a; Fredriksson & Bergman, 1995; Berman-Frank *et al.*, 2001). Other studies observed no differences in nitrogenase expression and/or N<sub>2</sub> fixation between single cells and therefore questioned the prevalence of diazocytes (Paerl & Bebout, 1988; Finzi-Hart *et al.*, 2009; Ohki & Taniuchi, 2009). Also the formation of anoxic microzones in colonies has been challenged by field measurements showing strong O<sub>2</sub> supersaturation in *Trichodesmium* colonies (Eichner *et al.*, 2017), questioning the assumed benefit of colony formation for N<sub>2</sub> fixation. Direct comparisons of colonies and single trichomes are scarce. Field studies have traditionally shown a bias towards studying colonies rather than single trichomes (Letelier & Karl, 1998), whereas most laboratory studies on *Trichodesmium* physiology, including those demonstrating the inhibitory effects of O<sub>2</sub> on N<sub>2</sub>

fixation *in vivo* (Küpfer *et al.*, 2004; Berman-Frank *et al.*, 2005, 2008; Staal *et al.*, 2007), have been conducted on cultures of *Trichodesmium erythraeum* IMS101 grown as single trichomes.

To re-evaluate the hypothesis that anoxic microenvironments allow for higher N<sub>2</sub> fixation in colonies compared with single trichomes, we conducted an in-depth analysis of O<sub>2</sub> dynamics and feedbacks on N<sub>2</sub> fixation in colonies and free-floating trichomes of *Trichodesmium erythraeum* IMS101. We directly compared carbon (C) and N<sub>2</sub> fixation rates in colonies vs single trichomes and characterized cellular gross and net O<sub>2</sub> fluxes, diurnal variations in O<sub>2</sub> concentrations in the bulk medium, and O<sub>2</sub> concentrations within colonies, on the surface of single trichomes and within single cells.

## Materials and Methods

### Culture conditions

Cultures of *Trichodesmium erythraeum* IMS101 were grown on YBCII culture medium (Chen *et al.*, 1996) with decreased phosphate concentrations ( $4.61 \pm 0.79 \mu\text{mol l}^{-1}$ , determined with QuAAtro39, Seal Analytics), at 27–29°C and 240–280  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$  under a 12 h: 12 h, light : dark cycle. Stock cultures were grown on a shaking table (80 rounds  $\text{min}^{-1}$ , IKA KS 130 basic), and transferred to roller tanks once colonies had started to form in order to maintain colonies physically intact for longer. Additional colonies formed in roller tanks, including mostly puffs, but also tuft- and needle-shaped colonies. Depending on the culture volume required for the specific measurements, different roller tank set-ups were used, including bottles with a volume between 60 ml and 2.5 l. pH levels (National Bureau of Standards (NBS) scale) were determined with a two-point calibrated glass electrode (Aquatrode plus Pt1000; Metrohm, Herisau, Switzerland).

### Elemental composition

For determination of elemental ratios, samples for particulate organic carbon, nitrogen and phosphorus (POC, PON and POP) and chlorophyll *a* (Chl*a*) were taken *c.* 7 h after beginning of the light phase. Technical duplicate samples of culture including both free trichomes and colonies were filtered onto precombusted GF/F filters and stored at –20°C. Samples for analysis of POC and PON were acidified with 200  $\mu\text{l}$  HCl ( $0.2 \text{ mol l}^{-1}$ ) and subsequently measured on an elemental analyzer (EuroEA, Eurovector). POP was determined spectrophotometrically (UV-1202; Shimadzu, Kyoto, Japan) according to Hansen & Koroleff (1999). Chl*a* was extracted in 90% acetone at 4°C for > 12 h with ultrasonication (10 s) and measured fluorometrically (10-AU, Turner Designs; Holm-Hansen & Riemann, 1978).

### Optode measurements

The diurnal cycle of O<sub>2</sub> concentrations in cultures was monitored with contactless optical O<sub>2</sub> sensors glued into culture vessels (silicon glue, sensor spots of 5 mm diameter and a FireStingO2/

FireStingGO2 oxygen meter, Pyroscience). Measurements were performed in 120 ml serum bottles closed without headspace and incubated in roller tanks. Additionally, O<sub>2</sub> concentrations were monitored in the set-up used for stock cultures, that is, culture vials closed with a gas permeable frit (VWR) that were incubated on a shaking table. O<sub>2</sub> concentrations were recorded at 2 Hz for up to 7 d. Optodes were two-point calibrated using medium that was bubbled with either N<sub>2</sub> gas or air to achieve 0% and 100% air saturation, respectively.

### Microsensor measurements

Microsensor measurements on colonies were performed in a custom-made flow system (Ploug & Jørgensen, 1999) in YBCII medium at 26°C. Single colonies were suspended in the flow chamber (flow <  $0.1 \text{ mm s}^{-1}$ ), fixed with a thin glass needle and observed through a stereomicroscope (Stemi SV6; Zeiss). For recording depth profiles through the colony center, microsensors were moved towards and into the colony with a motor-driven micromanipulator (VT-80, Micos/Faulhaber Minimotor SA).

In a total of 13 colonies, O<sub>2</sub> concentrations in and around colonies were measured with Clark-type microelectrodes (tip diameter *c.* 10–15  $\mu\text{m}$ , response time *c.* 1 s). Rates of respiration and net photosynthesis were calculated from the steady-state O<sub>2</sub> gradient at the colony surface according to Fick's first law of diffusion:

$$J = -D(\Delta C/\Delta r),$$

where *J* represents the interfacial O<sub>2</sub> flux, *D* the diffusion coefficient for O<sub>2</sub> ( $2.26 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$  at 25°C and salinity 34; Broecker & Peng, 1974), and  $\Delta C$  the concentration difference measured over the respective distance,  $\Delta r$ , at the colony surface. Surface area and volume were determined for each colony assuming ellipsoid geometry and used to convert interfacial flux to volume-normalized rates. The theoretical maximum O<sub>2</sub> uptake supported by diffusive O<sub>2</sub> supply (that is, the O<sub>2</sub> uptake rate yielding anoxia at the center of the colony) was calculated as a function of colony volume as described by Ploug *et al.* (1997). An apparent diffusivity of O<sub>2</sub> within the colony of  $0.95 \times$  that of seawater, a Sherwood number of 1 (that is, no difference between the motion of the colony and that of the surrounding water, resulting in mass transfer merely by molecular diffusion but not advection), a bulk O<sub>2</sub> concentration of  $212 \mu\text{mol l}^{-1}$  (that is, air saturation), and a uniform respiration rate throughout the colony were assumed.

Additionally, measurements of chlorophyll fluorescence were performed on nine of the colonies using a MicrofiberPAM (Walz) with a microfiber tapered to 10–20  $\mu\text{m}$  width at the tip. A red LED (650 nm) was used for excitation. Measurements were performed in the dark, between 1 and 9 h after beginning of the light phase. Photochemical quantum yield ( $F_v/F_m$ ) is reported only for those positions in and around colonies for which signal strength was high enough for a clear fluorescence induction curve to be observed.

For microsensor measurements on single trichomes with higher spatial resolution, the trichomes were embedded in 0.5%

agar, in which the effective diffusion coefficient of O<sub>2</sub> is similar as in seawater (Ploug & Passow, 2007). Ultra-pure low melting point agar (Invitrogen) was dissolved, allowed to cool down to < 30°C, and then mixed in a ratio of *c.* 1 : 1 with culture in a Petri dish. Measurements were performed on a total of 29 trichomes with Clark-type microelectrodes (tip diameter 5–10 µm, response time *c.* 1 s) under an inverted microscope (Axiovert 25; Zeiss) at ×20 magnification, room temperature and *c.* 150 µmol photons m<sup>-2</sup> s<sup>-1</sup> (unless specified otherwise), at various time points between the start and 1 h after the end of the light period. Differences in O<sub>2</sub> concentrations along trichomes were probed by moving the sensor along the trichome within *c.* 3 µm distance from the cell surface as observed in the microscope, and recording O<sub>2</sub> concentrations in consecutive steps of three to four cells. Additionally, O<sub>2</sub> concentrations were recorded continuously at the surface of individual cells while switching the light on and off.

### Membrane inlet mass spectrometry

Gross and net O<sub>2</sub> fluxes were measured with a custom-built membrane inlet mass spectrometer (MIMS; mass spectrometer Isoprime, custom-built 8 ml cuvette) using the <sup>18</sup>O<sub>2</sub>-based approach described by Fock & Sültemeyer (1989). Cultures containing colonies and single trichomes were grown in 2.5 l Schott bottles at 25°C and 300 µmol photons m<sup>-2</sup> s<sup>-1</sup> (Biolux; Osram, Garching, Germany). For measurements, <sup>18</sup>O<sub>2</sub> gas (Chemotrade, Düsseldorf, Germany) was dissolved in previously N<sub>2</sub>-bubbled YBCII medium buffered with HEPES (50 mmol l<sup>-1</sup>, pH 8.29 ± 0.06), reaching a final concentration of *c.* 150% air saturation. Cultures concentrated by gentle filtration over a polycarbonate filter, as well as additional colonies picked with a Pasteur pipette, were suspended in the <sup>18</sup>O<sub>2</sub>-enriched medium, reaching a final Chl*a* concentration of 0.41 ± 0.26 µg ml<sup>-1</sup>. The production of <sup>16</sup>O<sub>2</sub> and the uptake of <sup>16</sup>O<sub>2</sub> and <sup>18</sup>O<sub>2</sub> were then monitored in light and dark under three different O<sub>2</sub> concentrations (346 ± 39 µmol l<sup>-1</sup>, 191 ± 51 µmol l<sup>-1</sup> and 101 ± 35 µmol l<sup>-1</sup>) obtained by bubbling with N<sub>2</sub> gas. Samples were stirred during measurements, resulting in disassembly of the colonies. Two replicate light and dark phases lasting *c.* 4 min each were conducted at each O<sub>2</sub> level. O<sub>2</sub> signals were corrected for abiotic consumption and influx of O<sub>2</sub> into the cuvette by subtracting O<sub>2</sub> slopes recorded in abiotic controls at the respective O<sub>2</sub> concentrations. In total, 11 samples containing free-floating trichomes and colonies in various proportions were analyzed. Measurements were performed between 1.5 and 4 h after the beginning of the light phase (except one measurement at 8–9 h after the beginning of the light phase that yielded results that were not different from the others).

### Stable isotope incubations

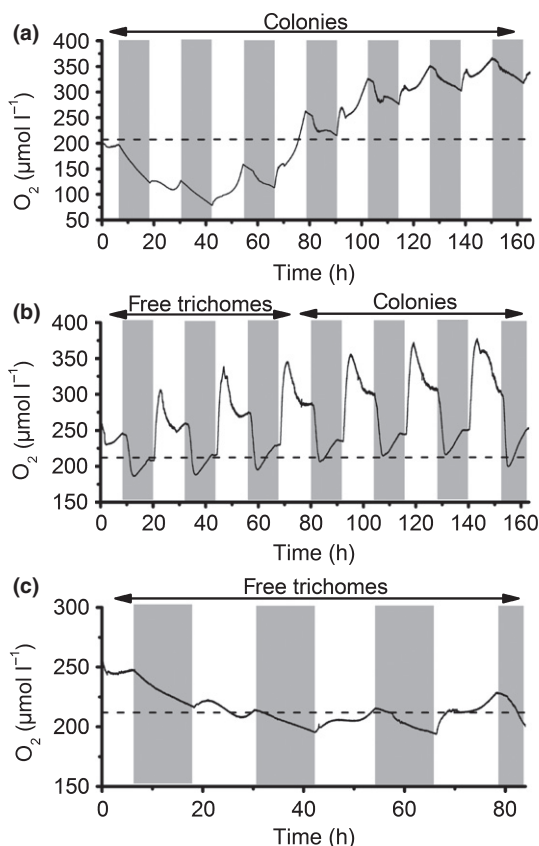

C and N<sub>2</sub> fixation rates of free-floating trichomes and colonies were determined by stable isotope incubations with NaH<sup>13</sup>CO<sub>3</sub> (Sigma Aldrich) and <sup>15</sup>N<sub>2</sub> gas (Cambridge Isotope Laboratories, Tewksbury, MA, USA). To ensure dissolution of <sup>15</sup>N<sub>2</sub> gas, <sup>15</sup>N<sub>2</sub>

and NaH<sup>13</sup>CO<sub>3</sub> were predissolved in YBCII medium for > 12 h before incubations. Final enrichment was 3.44 ± 0.24 atom percent excess (at% excess) for <sup>13</sup>C and 2.2 ± 1.06 at% excess for <sup>15</sup>N, as determined at the end of incubations for each incubation bottle by cavity ring-down spectroscopy (G2201-i; Picarro, Santa Clara, CA, USA) and MIMS (GAM2000; InProcess, Bremen, Germany). O<sub>2</sub> concentrations in the incubation medium were adjusted to low (24 ± 11 µmol l<sup>-1</sup>), ambient (238 ± 13 µmol l<sup>-1</sup>) or high (475 ± 32 µmol l<sup>-1</sup>) levels by bubbling with a mixture of helium and N<sub>2</sub> (20% : 80%, low O<sub>2</sub> treatment), room air (ambient O<sub>2</sub> treatment), or a mixture of O<sub>2</sub> and N<sub>2</sub> (40% : 60%, high O<sub>2</sub> treatment). Subsequently, *Trichodesmium* biomass was transferred to the respective medium and amended with <sup>15</sup>N- and <sup>13</sup>C-enriched stock solutions. For incubations of colonies, approx. 50 colonies per incubation vial were picked from culture bottles with a Pasteur pipette. For incubations of free-floating trichomes, the remaining culture volume was concentrated by filtration over a polycarbonate filter before transfer to the incubation medium. Samples where free-floating trichomes formed colonies during the incubation period, resulting in colony-dominated biomass, were classified as colonies. Incubations were performed in triplicate, in 60 ml serum vials at 25°C and 150 µmol photons m<sup>-2</sup> s<sup>-1</sup> (100–210 µmol photons m<sup>-2</sup> s<sup>-1</sup> in roller tanks), for 11 h starting within 1 h after beginning of the light period. The O<sub>2</sub> concentration in each incubation vial was measured with O<sub>2</sub> microsensors before and after incubations. Vials with single trichomes were gently agitated by hand *c.* 4 times over the incubation period. Vials with colonies were incubated in roller tanks. At the end of the incubation time, cultures were filtered on precombusted GF/F filters and stored at -20°C. Before analysis, filters were acidified in an HCl fume (overnight) to remove all inorganic carbon. Amounts of POC and PON and their isotopic composition were measured by elemental analyser isotope ratio mass spectrometry (EA-IRMS, Delta Plus XP and Flash EA 112; Thermo Fisher Scientific, Waltham, MA, USA). <sup>13</sup>C and <sup>15</sup>N enrichment of the POC and PON relative to the bulk solution was then converted to C and N<sub>2</sub> fixation rates normalized to cellular C and N biomass, respectively, yielding C- and N-specific fixation rates. The dissolved inorganic carbon concentration in incubation vials at the end of the incubation period was never below 1820 µmol l<sup>-1</sup>.

## Results

### Culture characteristics

Single trichomes and colonies co-occurred in the cultures in varying proportions. Cultures generally started forming colonies 1 wk or longer after dilution with fresh medium and stayed in a colony-dominated state for more than a week. Colonies were often formed in high numbers within a short time period, starting with needle- or string-shaped colonies that formed around 200 mostly puff-shaped colonies l<sup>-1</sup> within a day, which were morphologically similar to field-collected puffs. Continuous monitoring of bulk O<sub>2</sub> concentrations within culture vials over

**Fig. 1**  $O_2$  concentrations in the bulk medium of *Trichodesmium* cultures incubated in roller tanks, monitored in three replicate vials (a–c). Dominant morphology (free-floating trichomes or colonies) is indicated above each panel. Note that total biomass differed between vials and changed over time. Dashed lines indicate  $O_2$  concentration at air saturation, and grey shaded areas indicate dark phases (that is, night-time).

several days showed that the cultures were net phototrophic most of the time (Fig. 1). This trend was independent of the relative abundance of colonies vs single trichomes, that is, no changes were observed once cultures went from a single-trichome- to a colony-dominated state (Fig. 1b). Key characteristics of the cultures are summarized in Table 1. pH levels were higher in cultures than in abiotic reference medium ( $t$ -test,  $P < 0.005$ , Table 1), confirming net phototrophic growth. Monitoring of phosphate concentrations in two representative bottles over 8 d showed phosphate consumption. Elemental ratios in biomass were variable, with average values close to the Redfield ratio. POC : PON ratios in samples taken from stable isotope incubations at the end of the light period were higher than those taken *c.* 7 h after the beginning of the light period, and showed no significant difference between colonies and trichomes ( $t$ -test,  $P > 0.05$ , Table 1).

#### Diel variation in bulk $O_2$ concentrations

Continuous measurements of  $O_2$  concentrations in the culture medium revealed strong variations over the diel cycle, both in closed vials (Fig. 1), and in culture flasks with a gas permeable lid (up to  $300 \mu\text{mol l}^{-1}$ ; data not shown). Often, a fast rise in  $O_2$

<sup>§</sup>Samples taken at the end of the photoperiod, average value including colonies and single trichomes incubated under different  $O_2$  concentrations.

concentrations was observed within a short period of 1–3 h in the morning, followed by a slow decrease in  $O_2$  concentrations over several hours (Fig. 1). A second phase of net  $O_2$  evolution followed in most cases 2–4 h before the beginning of the dark phase. Net  $O_2$  evolution over the 12 h light period ranged between  $-3 \mu\text{mol l}^{-1} (12 \text{ h})^{-1}$  (that is, net  $O_2$  consumption) and  $146 \mu\text{mol l}^{-1} (12 \text{ h})^{-1}$ . During the night, a net decrease of  $O_2$  concentrations was observed, sometimes including a short and steep decrease during the first hours of the night. Remarkably, this initial decrease was followed by an increase to air saturation level or above, while the incubation was still in the dark (Fig. 1b). This pattern was confirmed by tracking  $O_2$  concentrations close to the center of single colonies with microsensors over several hours (Supporting Information Fig. S1b,d). In the morning, maximum  $O_2$  concentrations of  $570$  and  $326 \mu\text{mol l}^{-1}$  were observed within colonies (0.5 and 1.3 h after beginning of the light period, respectively; Fig. S1a,c). In the evening, three out of six colonies examined showed elevated  $O_2$  concentrations (e.g.  $450 \mu\text{mol l}^{-1}$  measured 2 h before the beginning of the dark period, Figs 2d, S1). During most of the day, however, colonies were undersaturated with  $O_2$  (Fig. 2a–c) and net photosynthesis calculated from  $O_2$  profiles was negative (Fig. 2e). To shed light on the regulation of  $O_2$  concentrations specifically during this phase of  $O_2$  undersaturation,  $O_2$  microenvironments and cellular gross and net  $O_2$  fluxes were analyzed in more detail during the middle of the day.

#### $O_2$ microenvironments in colonies during the middle of the day

$O_2$  profiles were measured on a total of 13 colonies of different size (250–1500  $\mu\text{m}$  diameter), shape (tufts and puffs), buoyancy and trichome density between 0.45 and 8 h after beginning of the light period, that is, covering the time period of decreasing  $O_2$  evolution rates in the bulk medium (Fig. 1).  $O_2$  concentrations in the center of the colony ranged from anoxic conditions to close to air saturation (Fig. 2a–c). Net  $O_2$  uptake rates ranged from 0.02 to  $26.5 \text{ nmol colony}^{-1} \text{ h}^{-1}$ .  $O_2$  uptake in light was

**Fig. 2** (a–d) Examples of  $O_2$  profiles measured in *Trichodesmium* colonies of different sizes (a,  $0.02\text{ mm}^3$ ; b,  $0.38\text{ mm}^3$ ; c,  $2.4\text{ mm}^3$ ; d,  $0.16\text{ mm}^3$ ) at different light intensities and times of the day (a, 6 h; b, 6 h; c, 7 h; d, 10 h, after the beginning of the light phase). Note the different scale of x-axis. Grey shading indicates approximate position of the colony, dotted lines indicate  $O_2$  concentration at air saturation. (e) Net photosynthesis rates calculated from depth profiles through colonies measured at different times of the day. (f) Net  $O_2$  uptake by colonies in dependence of colony volume. Dashed line indicates diffusion limitation (calculated according to Ploug *et al.*, 1997).

correlated to dark respiration with an  $R^2$  of 0.699 (linear regression). Volume-normalized  $O_2$  uptake was not significantly affected by light intensity ( $t$ -test,  $P > 0.05$ ; Table 2) and colonies undersaturated with  $O_2$  were observed under light intensities up to  $1000\ \mu\text{mol photons m}^{-2}\text{ s}^{-1}$  (Fig. 2b). A comparison of the measured  $O_2$  uptake rates with calculated  $O_2$  diffusion rates into the colony revealed that  $O_2$  uptake in both light and dark ranged up to the predicted maximum rate allowed by diffusive  $O_2$  supply (Fig. 2f). Measurements of chlorophyll fluorescence did not show any spatial patterns of photosynthetic activity along colony transects (data not shown).

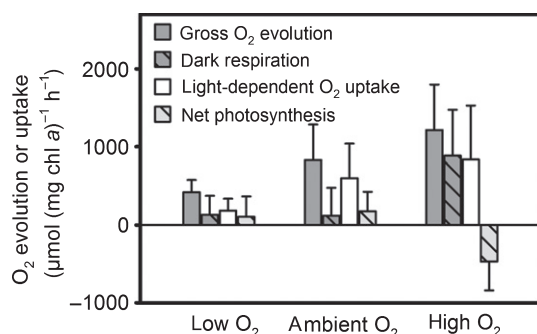

### Cellular $O_2$ fluxes during the middle of the day

Measurements of  $O_2$  fluxes in colonies and single trichomes during late morning/midday using an  $^{18}O_2$ -based MIMS approach yielded net  $O_2$  production rates that were often close to zero or negative (Fig. 3), in line with microsensor measurements performed during this part of the day (Fig. 2). The low net photosynthesis was a result of 4–5 times higher gross  $O_2$  uptake balancing gross  $O_2$  evolution. Dark respiration and light-dependent  $O_2$  uptake (e.g. classical Mehler reaction and/or

**Table 2** Net  $O_2$  uptake rates (mean  $\pm$  SD) by *Trichodesmium* colonies based on  $O_2$  profiles measured at different light intensities at 45 min to 8 h after beginning of the light period.

Light intensity $\mu\text{mol photons m}^{-2}\text{ s}^{-1}$	Net $O_2$ uptake		
	$\text{nmol } O_2 \text{ colony}^{-1} \text{ h}^{-1}$	$\text{nmol mm}^{-3} \text{ h}^{-1}$	
Dark	$4.0 \pm 6.8$	$23 \pm 14$	$n = 14$
200	$2.4 \pm 2.3$	$24 \pm 17$	$n = 16$
500	$1.4 \pm 1.8$	$13 \pm 8$	$n = 8$
1000	$3.1 \pm 3.4$	$15 \pm 1$	$n = 2$

flavoprotein-mediated  $O_2$  uptake) amounted to  $56 \pm 31\%$  and  $42 \pm 63\%$  of gross  $O_2$  evolution, respectively. Measurements under different external  $O_2$  concentrations mimicking the range observed in the center of colonies (e.g. Fig. 2) showed that gross  $O_2$  evolution, dark respiration, and light-dependent  $O_2$  uptake increased with increasing external  $O_2$  concentration, whereas net photosynthesis decreased (analysis of variance (ANOVA),  $P < 0.05$ ; Fig. 3) and was always negative when  $O_2$  concentrations above air saturation were applied. Test measurements revealed that these effects of elevated  $O_2$  levels were reversible; for

**Fig. 3** O<sub>2</sub> production and uptake rates in *Trichodesmium* cultures measured during late morning/midday under different external O<sub>2</sub> concentrations. Cultures contained both colonies and free trichomes. Note that positive values on the y-axis indicate rates of both O<sub>2</sub> evolving and O<sub>2</sub> consuming processes. Light-dependent O<sub>2</sub> uptake is the difference between total O<sub>2</sub> uptake measured in the light and total O<sub>2</sub> uptake measured in the dark. Low O<sub>2</sub>,  $101 \pm 35 \mu\text{mol l}^{-1}$ ; ambient O<sub>2</sub>,  $191 \pm 51 \mu\text{mol l}^{-1}$ ; high O<sub>2</sub>,  $346 \pm 39 \mu\text{mol l}^{-1}$ .  $n = 11$  for low and ambient O<sub>2</sub>,  $n = 7$  for high O<sub>2</sub>. Error bars  $\pm$  SD.

instance, gross O<sub>2</sub> evolution measured under ambient O<sub>2</sub> was not significantly affected by O<sub>2</sub> concentration in the preceding light phase ( $t$ -test,  $P > 0.05$ ,  $n \geq 4$ ; data not shown). The relative amount of colonies and free-floating trichomes did not have consistent effects on O<sub>2</sub> fluxes, with higher dark respiration in colonies than free trichomes observed only under ambient O<sub>2</sub> ( $t$ -test,  $P < 0.05$ ,  $n \geq 4$ ) and higher total O<sub>2</sub> uptake in colonies observed only under low O<sub>2</sub> ( $t$ -test,  $P < 0.05$ ,  $n \geq 4$ ).

### O<sub>2</sub> on the surface of single trichomes

To analyze variability at the level of single cells, O<sub>2</sub> concentrations on the surface of single trichomes were measured with microsensors at a spatial resolution equivalent to  $c. 2\text{--}4$  cells (Fig. 4). O<sub>2</sub> concentrations on the surface of single trichomes as well as in the surrounding agar never deviated more than  $c. 30 \mu\text{mol l}^{-1}$  from air saturation level. Changes in O<sub>2</sub> concentrations on the cell surface when switching between light and dark ranged between 1 and  $8 \mu\text{mol l}^{-1}$  ( $2.8 \pm 1.8 \mu\text{mol l}^{-1}$ , recorded in 27 measurements on a total of nine filaments; examples given in Fig. 4a–c). To test comparability of results from this set-up with those obtained on colonies in the flow system, O<sub>2</sub> concentrations were measured on the surface of a trichome located in the periphery of a tuft-shaped colony, yielding a deviation in light vs dark of  $70 \mu\text{mol l}^{-1}$  (data not shown). In the light, O<sub>2</sub> concentrations on the trichome surface differed by up to  $6 \mu\text{mol l}^{-1}$  between cells/regions within a single trichome (Fig. 4d–f). Distinct areas with lower than average O<sub>2</sub> concentrations were observed in 11 out of the 26 trichomes analyzed. These areas were between 10 and 50 cells long and often located in the middle of trichomes.

### Effects of O<sub>2</sub> concentrations on C and N<sub>2</sub> fixation

N<sub>2</sub> fixation was strongly O<sub>2</sub>-dependent, with a clear inhibition in treatments with air-saturated medium and medium containing elevated O<sub>2</sub> concentrations compared to medium undersaturated in O<sub>2</sub> (two-way ANOVA and Holm–Sidak test,  $P < 0.05$ ;

Fig. 5a). At low O<sub>2</sub> concentrations, representative for minimum O<sub>2</sub> levels observed in the colony center (e.g. Fig. 2), N<sub>2</sub> fixation was increased by a factor of up to 4 compared to ambient O<sub>2</sub> concentrations (Fig. 5a). At elevated O<sub>2</sub> concentrations, representative for maximum O<sub>2</sub> levels observed in the colony center (e.g. Fig. 2), N<sub>2</sub> fixation rates were close to zero (Fig. 5a). Colonies showed lower N<sub>2</sub> fixation rates than free-floating trichomes (two-way ANOVA,  $P < 0.05$ ; Fig. 5a). Pair-wise comparison under each O<sub>2</sub> level showed that this effect was only significant under low O<sub>2</sub> (Holm–Sidak test,  $P < 0.05$ ). Similarly, colonies also showed lower C fixation rates than free-floating trichomes (two-way ANOVA,  $P < 0.05$ ; Fig. 5b), with pair-wise comparison showing a significant difference only under low O<sub>2</sub> (Holm–Sidak test,  $P < 0.05$ ). C fixation was not significantly affected by the O<sub>2</sub> treatment (two-way ANOVA,  $P > 0.05$ ). C-specific O<sub>2</sub> evolution was not significantly affected by the O<sub>2</sub> treatment and was not different between colonies and free-floating trichomes (two-way ANOVA,  $P > 0.05$ ; Fig. 5c).

## Discussion

### Physiological state of the cultures

Several observations indicate net biomass production in the colony-forming cultures in this study. Firstly, the increases in pH and phosphate consumption in the medium demonstrate that the cultures were growing (Table 1). Although brief net heterotrophic phases were observed (e.g. first day in Fig. 1a,c), which could potentially be sustained by uptake of dissolved organic matter accumulated in the medium (Benavides *et al.*, 2017), O<sub>2</sub> concentrations generally increased over the duration of several days, confirming net autotrophy (Fig. 1). Both free-floating trichomes and colonies were able to significantly increase N<sub>2</sub> fixation rates within a day when exposed to reduced O<sub>2</sub> concentrations (Fig. 5a). Colonies formed during the 12 h incubation period had similar N<sub>2</sub> fixation rates as older colonies (data not shown), indicating that ‘old’ colonies were not in a senescent state. These findings are in contrast with a previous report attributing low N<sub>2</sub> fixation rates in colonies of *Trichodesmium* NIBB 1067 to colony formation only during stationary growth phase (Ohki & Fujita, 1988).

C : N and C : Chl *a* ratios in particulate organic matter as well as C and N<sub>2</sub> fixation rates were in a similar order of magnitude as previous data on field-collected *Trichodesmium* colonies (Letelier & Karl, 1998; Eichner *et al.*, 2017). POC : POP ratios were lower than those previously measured in the field (Letelier & Karl, 1998; Orcutt *et al.*, 2013), and similar to P-replete cultures of *Trichodesmium* IMS101 (Spungin *et al.*, 2014), indicating that our cultures were not P-limited.  $F_v/F_m$ , a general indicator for the health status of photosynthetic organisms that is often used to detect iron (Fe) limitation, was higher in our study than previous measurements on free-floating, exponentially growing trichomes of the same strain ( $0.44 \pm 0.11$  (our study) vs  $0.18\text{--}0.35$  (Eichner *et al.*, 2014; measured with a blue LED)), suggesting that colonies were not stressed or severely Fe-depleted. By contrast with a recent laboratory study by Tzubar *et al.* (2018), we

**Fig. 4** Examples of O<sub>2</sub> concentrations measured within c. 3 µm of the surface of single *Trichodesmium* filaments during consecutive light and dark phases (a–c) and while sliding along the trichome with a microsensor (d–f; total duration of the measurement c. 20 min). Grey shaded areas indicate dark phases.

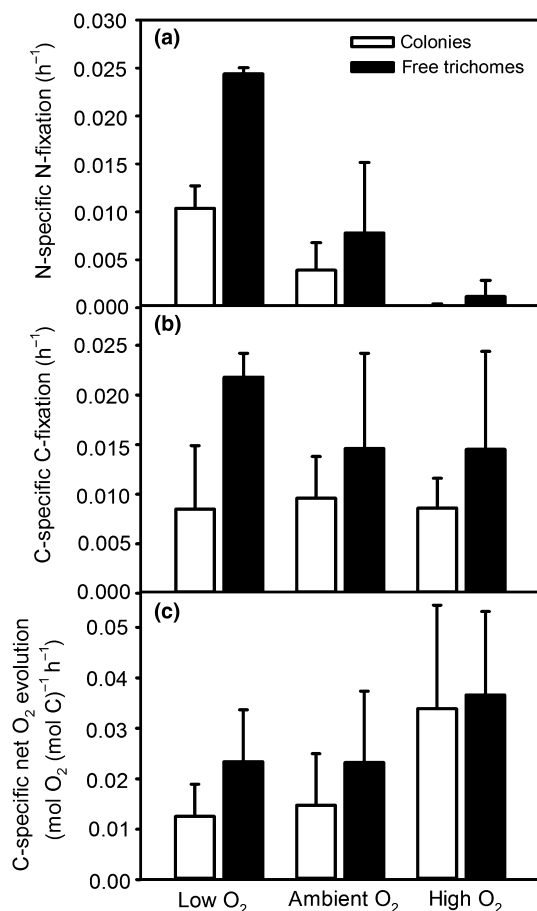

therefore assumed that, in our experiment, colony formation was not induced by P- or Fe-depletion. As we did not observe any differences in abiotic conditions or cellular composition between free-floating trichomes and colonies, the triggers for colony formation could not be identified. As cultures were grown under the same (*macroscale*) conditions, we relate the observed physiological differences to microenvironments within colonies.

#### Variation over the diel cycle

The downregulation of net photosynthesis during the middle of the day (Figs 1, 2e) is in line with previous observations on *Trichodesmium* in the field and laboratory (Berman-Frank *et al.*, 2001; Eichner *et al.*, 2014) and coincides with the peak in N<sub>2</sub> fixation observed 4–5 h after the beginning of the light period in *Trichodesmium* IMS101 (e.g. Kranz *et al.*, 2010; Eichner *et al.*, 2014). The switch from N<sub>2</sub> fixation back to photosynthesis in the afternoon was also reflected in higher POC : PON ratios measured at the end of the light period compared with the afternoon (Table 1), in line with previous observations (Kranz *et al.*, 2009). The magnitude of diel variations in O<sub>2</sub> was exceptionally large, reaching net O<sub>2</sub> uptake during the middle of the day (Figs 1, 2e), whereas previous studies merely showed a reduction of net O<sub>2</sub>

evolution by 40–70% (Berman-Frank *et al.*, 2001; Eichner *et al.*, 2014). To understand the physiological mechanisms leading to this net O<sub>2</sub> uptake during the N<sub>2</sub> fixation phase, we investigated gross O<sub>2</sub> fluxes in this period by MIMS.

These measurements revealed a high ratio of gross to net O<sub>2</sub> evolution comparable with previous field observations on *Trichodesmium* (e.g. Kana, 1993), and exceeding previous estimates for free-floating trichomes of *Trichodesmium* IMS101 under comparable conditions (Kranz *et al.*, 2010; Eichner *et al.*, 2014). Such high O<sub>2</sub> uptake suggests that *Trichodesmium* decreases O<sub>2</sub> concentrations during the day by an upregulation of O<sub>2</sub>-consuming processes such as dark respiration, classical Mehler reaction and/or flavoprotein-mediated O<sub>2</sub> uptake, rather than a downregulation of O<sub>2</sub> evolution. This way, electron transport through the photosynthetic and respiratory transport chain, and therefore proton translocation, is maintained even through the phase of low net O<sub>2</sub> production. This may serve as a means to maintain the production of ATP to support N<sub>2</sub> fixation, and is also in line with the relatively high F<sub>v</sub>/F<sub>m</sub> observed at the same time (Table 1). While O<sub>2</sub> uptake by Mehler reaction does not involve carbon fluxes, the high dark respiration rates observed here require the breakdown of a significant amount of carbohydrates produced in the preceding morning hours. For instance,

**Fig. 5** (a) N<sub>2</sub> fixation, (b) C fixation and (c) O<sub>2</sub> evolution in free-floating trichomes and colonies of *Trichodesmium* measured under different O<sub>2</sub> concentrations in the bulk medium over the duration of the light phase (12 h). Low O<sub>2</sub>, 24 ± 11 μmol l<sup>-1</sup>; ambient O<sub>2</sub>, 238 ± 13 μmol l<sup>-1</sup>; high O<sub>2</sub>, 475 ± 32 μmol l<sup>-1</sup>. n ≥ 3, except for trichomes at low O<sub>2</sub> with n = 2 in (a, b), and colonies at high O<sub>2</sub> with n = 2 in (c). Error bars indicate SD.

maintaining the dark respiration rates observed at high O<sub>2</sub> concentrations (Fig. 3) for 7 h would consume *c.* 30% of the POC at a typical cell density observed in our cultures (200 μmol C l<sup>-1</sup>). In *Crocospaera*, a similar diel cycle including the build-up of carbohydrates during the day and their breakdown at night has been proposed to support the high energy demand related to protecting nitrogenase under ambient O<sub>2</sub> levels (Großkopf & LaRoche, 2012). In *Trichodesmium*, energy and carbon budgets may differ substantially on a single-cell level due to cell specialization, depending on how diazocytes acquire carbohydrates and/or energy equivalents to support respiration and N<sub>2</sub> fixation. As the downregulation of net photosynthesis under elevated O<sub>2</sub> observed during MIMS measurements in the late morning (Fig. 3) was not observed in 12 h incubations (Fig. 5c), it seems to be a transient effect that is outbalanced on a diurnal time scale. It might represent a regulatory response that induces a decrease in O<sub>2</sub> concentrations once a certain threshold is reached during the accumulation of O<sub>2</sub> in the phase of high O<sub>2</sub> evolution in the morning. Such a switch in metabolism towards higher O<sub>2</sub> uptake would ultimately lead to transient O<sub>2</sub> undersaturation (Fig. 2a–c) within colonies, allowing for N<sub>2</sub> fixation to start during midday.

## Impacts of colony formation

Colony formation resulted in pronounced microenvironments with O<sub>2</sub> undersaturation during a large part of the day, reaching nearly anoxic conditions in the center of some of the colonies (Fig. 2a–c). However, as colonies in this study were mostly net phototrophic over a period of several days (Fig. 1), the long phase of O<sub>2</sub> undersaturation must have been outbalanced by a *c.* 10 times shorter phase of strong O<sub>2</sub> supersaturation. Indeed, microsensors revealed O<sub>2</sub> concentrations within colonies of up to 570 μmol l<sup>-1</sup> (Figs S1, 2d). Even under air-equilibrated bulk conditions, O<sub>2</sub> concentrations within colonies therefore temporarily exceeded those supplied in the high O<sub>2</sub> treatment, where N<sub>2</sub> fixation was completely inhibited (Fig. 5a). However, this inhibitory effect of O<sub>2</sub> on N<sub>2</sub> fixation was reversible, as N<sub>2</sub> fixation rates could be increased by exposure to low O<sub>2</sub> concentrations (Fig. 5a), in line with previous studies showing recovery of nitrogenase after exposure to high O<sub>2</sub> (Zehr *et al.*, 1993). Hence, the lowered N<sub>2</sub> fixation in colonies compared with single trichomes is most likely not caused by damage to nitrogenase during the phase of high O<sub>2</sub> accumulation in the morning.

However, elevated O<sub>2</sub> concentrations may lead not only to inactivation or degradation of O<sub>2</sub>-sensitive proteins such as nitrogenase, but also induce damage to other cellular components relevant for both N<sub>2</sub> fixation and C fixation, including lipids, proteins and DNA, through a concurrent increase in reactive oxygen species such as superoxide (e.g. Lesser, 2006). In line with this, high superoxide production by field-collected *Trichodesmium* colonies has been observed (Hansel *et al.*, 2016). Accumulation of O<sub>2</sub> and reactive oxygen species in the colony microenvironment may therefore increase the risk of oxidative stress in colonies compared with single trichomes and might be part of the reason why colonies showed lower N<sub>2</sub> and C fixation rates. The high rates of both gross O<sub>2</sub> evolution and O<sub>2</sub> uptake observed under elevated O<sub>2</sub> concentrations (Fig. 3) might place additional strain on the turnover of the photosynthetic machinery during the periods of elevated O<sub>2</sub> concentrations in colonies.

Moreover, the high rates of photosynthesis during the morning and evening (Fig. 1) may lead to a temporary depletion of carbon dioxide (CO<sub>2</sub>) within the colony microenvironment. In line with this, a correlation of <sup>13</sup>C composition with colony size has been observed in field-collected *Trichodesmium* colonies, which may reflect cellular responses to CO<sub>2</sub> limitation in larger colonies (Tchernov & Lipschultz, 2008). In combination with the concurrently elevated O<sub>2</sub> concentrations, CO<sub>2</sub> depletion is likely to induce photorespiration and therefore lower C fixation rates. While CO<sub>2</sub> depletion can be partly compensated by carbon concentrating mechanisms (CCMs) such as the active uptake of bicarbonate (HCO<sub>3</sub><sup>-</sup>), the elevated energy expenditure for CCMs poses an additional disadvantage for colonies compared with free-floating trichomes. Diffusion limitation in the colony microenvironment therefore involves several negative effects that may counteract the benefits of temporary O<sub>2</sub> depletion for N<sub>2</sub> fixation.

Our combined measurements of N<sub>2</sub> fixation rates and small-scale O<sub>2</sub> gradients contradict the hypothesis of colony formation as a mechanism to foster N<sub>2</sub> fixation by protecting nitrogenase from O<sub>2</sub> (Paerl & Bebout, 1988). Instead, we were able to demonstrate that O<sub>2</sub> undersaturation in the microenvironment (Fig. 2a–c) during the phase of typically highest nitrogenase activity (e.g. Berman-Frank *et al.*, 2001; Eichner *et al.*, 2014) did not result in elevated N<sub>2</sub> fixation rates in colonies (Fig. 5a). Consequently, we suggest that previous observations of higher or similar N<sub>2</sub> fixation rates in colonies compared with free-floating trichomes in the field (Saino & Hattori, 1982; Letelier & Karl, 1998) were not due to O<sub>2</sub> microenvironments, but due to other factors not included in our laboratory setting. These might include positive effects of colony formation on the nutritional status of *Trichodesmium* that are manifested only under nutrient-limited conditions in the field, such as enhanced dust dissolution (Rubin *et al.*, 2011) and more efficient interaction with bacterial associates producing siderophores and/or alkaline phosphatase (Chappell & Webb, 2010; Orcutt *et al.*, 2013; Lee *et al.*, 2017). By excluding these additional factors in our laboratory study under nutrient-replete conditions, we revealed that O<sub>2</sub> microenvironments *per se* did not lead to higher N<sub>2</sub> fixation rates in colonies compared with free-floating trichomes. In addition to microbial interactions and higher nutrient (P and Fe) availability, reduced grazing and efficient vertical movement along light and nutrient gradients (e.g. reviewed by Beardall *et al.*, 2009; Stal, 2017) may contribute to making colony formation a selective advantage in natural ecosystems.

### Intracellular O<sub>2</sub> concentrations

Ultimately, nitrogenase activity is controlled by intracellular O<sub>2</sub> concentrations in the vicinity of the protein rather than extracellular O<sub>2</sub> conditions. On the cell surface of single trichomes, O<sub>2</sub> concentrations were never below 180 μmol l<sup>-1</sup>. Hence, assuming that anoxic conditions are required in the vicinity of nitrogenase for it to function, cells must be able to establish a large gradient in O<sub>2</sub> concentrations across the cell wall. If cells are relatively impermeable, O<sub>2</sub> concentrations may differ strongly between neighboring cells in a trichome, depending on their specific metabolic activity. Our analysis of cell surface O<sub>2</sub> concentrations

on a single-cell level revealed regions with reduced O<sub>2</sub> concentrations (Fig. 4b). While we cannot exclude that these are senescing or dividing cells, it is interesting to note that their occurrence and preferential localization in the center of single trichomes is also in line with the proposed concept of transiently or permanently nonphotosynthetic diazocytes (e.g. Lin *et al.*, 1998; Berman-Frank *et al.*, 2001).

To examine variation in intracellular O<sub>2</sub> in more detail, we modeled the relation between membrane permeability, intracellular O<sub>2</sub> concentrations and respiratory O<sub>2</sub> fluxes based on our data, using a model described in Damm *et al.* (2015; Notes S1). Previous studies examining the interplay of O<sub>2</sub> diffusion, consumption and N<sub>2</sub> fixation in *Trichodesmium* assumed either no or very low ( $1\text{--}7 \times 10^{-1} \text{ m s}^{-1}$ ) diffusion resistance to O<sub>2</sub> for *Trichodesmium* cells (Staal *et al.*, 2003; Milligan *et al.*, 2007). Here, we chose a substantially different approach in that permeability of the cell wall was the ultimate model output. Assuming that nitrogenase can only function under locally anoxic conditions, we calculated the permeability that would be necessary to yield an O<sub>2</sub> concentration close to zero in the center of a diazocyte, based on cell dimensions and respiration rates measured by MIMS (Table 3). Since, strictly speaking, respiration cannot be sustained under anoxic conditions, the optimum intracellular O<sub>2</sub> concentration is most likely to be slightly above zero, and our model output represents a conservative estimate of the required diffusion resistance. As histological studies on *Trichodesmium* indicated that thylakoids are distributed relatively homogeneously in the cytosol (Siddiqui *et al.*, 1992a) we assumed that there was uniform O<sub>2</sub> consumption throughout the cell.

Our model calculations revealed that single cells can achieve anoxic conditions in the center with a cell wall permeability for O<sub>2</sub> between  $2.6 \times 10^{-6}$  and  $4.9 \times 10^{-6} \text{ m s}^{-1}$  if they perform dark respiration at the average rate observed in this study (homogeneous respiration, Table 3). Based on a previous study demonstrating single-cell variation in cytochrome oxidase content that was correlated to nitrogenase content in *Trichodesmium thiebautii* (Bergman *et al.*, 1993), we also considered the effects of a six-fold higher respiration rate in diazocytes compared with vegetative cells, yielding somewhat higher permeability estimates between  $1.6 \times 10^{-5} \text{ m s}^{-1}$  and  $3.1 \times 10^{-5} \text{ m s}^{-1}$  (heterogeneous respiration, Table 3). These estimates exceed a previous one for

**Table 3** Calculated permeability of the cell wall necessary to support anoxia in the interior of a *Trichodesmium* cell, based on measured rates of O<sub>2</sub> uptake (that is, dark respiration), extracellular O<sub>2</sub> concentrations in colonies and cell dimensions (average 5 μm length, 7 μm width).

Respiration distribution	External O <sub>2</sub> (μmol l <sup>-1</sup> )	Average O <sub>2</sub> uptake (fmol cell <sup>-1</sup> h <sup>-1</sup> )	Intensity of O <sub>2</sub> consumption (mol s <sup>-1</sup> m <sup>-3</sup> )	Permeability for O <sub>2</sub> (m s <sup>-1</sup> )	Permeability for CO <sub>2</sub> (m s <sup>-1</sup> )
Homogeneous	329	608	1.49	$4.6 \times 10^{-6}$	$3.7 \times 10^{-6}$
Heterogeneous	329	3648	8.96	$2.9 \times 10^{-5}$	$2.3 \times 10^{-5}$
Homogeneous	187	194	0.48	$2.6 \times 10^{-6}$	$2.1 \times 10^{-6}$
Heterogeneous	187	1164	2.86	$1.6 \times 10^{-5}$	$1.3 \times 10^{-5}$
Homogeneous	101	198	0.49	$4.9 \times 10^{-6}$	$3.9 \times 10^{-6}$
Heterogeneous	101	1188	2.92	$3.1 \times 10^{-5}$	$2.4 \times 10^{-5}$

Scenarios with heterogeneous distribution of respiration assume a six-fold higher respiration rate in diazocytes compared to vegetative cells. Permeability for CO<sub>2</sub> was calculated from O<sub>2</sub> permeability using a conversion factor of 0.7961 according to Ramsing & Gundersen (1994). For further details on the model, please refer to Supporting Information Notes S1.

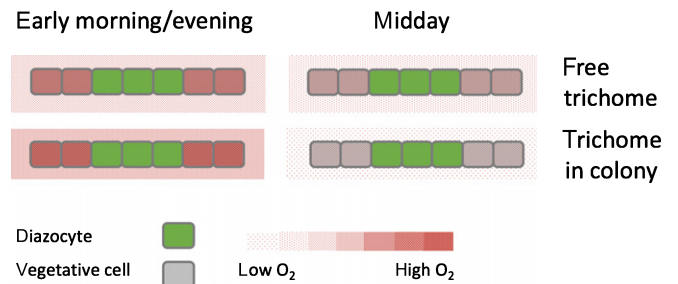

**Table 4** Calculated intracellular O<sub>2</sub> concentrations in *Trichodesmium* under net O<sub>2</sub> producing conditions (representative of early morning or evening), based on measured rates of O<sub>2</sub> production, extracellular O<sub>2</sub> concentrations in colonies, cell dimensions (5 μm length, 7 μm width), and membrane permeability calculated for diazocytes with an anoxic cell interior (Table 3).

Net O <sub>2</sub> production (fmol cell <sup>-1</sup> h <sup>-1</sup> )	External O <sub>2</sub> concentration (μmol l <sup>-1</sup> )	Intensity of O <sub>2</sub> production (mol s <sup>-1</sup> m <sup>-3</sup> )	Permeability for O <sub>2</sub> (m s <sup>-1</sup> )	Intracellular O <sub>2</sub> concentration (μmol l <sup>-1</sup> )
1031	329	2.53	$4.6 \times 10^{-6}$	884
1031	187	2.53	$2.6 \times 10^{-6}$	1166
1031	101	2.53	$4.9 \times 10^{-6}$	623

Cell-specific O<sub>2</sub> production was calculated from a colony-specific measurement assuming 10 000 cells per colony. For further details on the model, please refer to Supporting Information Notes S1.

heterocysts ( $4 \times 10^{-7}$  m s<sup>-1</sup>; Walsby, 1985), in line with the fact that *Trichodesmium* cell walls lack the thick glycolipid layer that acts as a diffusion barrier in heterocysts. In contrast with eukaryotic cells, plasma membranes of *Trichodesmium* are surrounded by a peptidoglycan layer, which was also reported to be more pronounced than in other Gram-negative bacteria (Siddiqui *et al.*, 1992b), and can explain why our estimates for CO<sub>2</sub> permeability (calculated from O<sub>2</sub> permeability according to Ramsing & Gundersen, 1994; Table 3) are lower than estimates for diatoms ( $10^{-3}$  m s<sup>-1</sup>; Hopkinson *et al.*, 2011). Carboxysomes, in turn, with their protein shell acting as a diffusion barrier to CO<sub>2</sub> (e.g. Rae *et al.*, 2013), are expected to have a lower permeability to CO<sub>2</sub> than the plasma membrane and cell wall. Accordingly, our estimates for CO<sub>2</sub> permeability exceeded previous estimates for the cyanobacterium *Synechococcus* that were based on measurements of cellular CO<sub>2</sub> efflux and therefore represent an integrated estimate for the cell wall and carboxysome ( $10^{-6}$ – $10^{-7}$  m s<sup>-1</sup>, Badger *et al.*, 1985;  $10^{-8}$  m s<sup>-1</sup>, Salon *et al.*, 1996).

As there are no indications for differences in membrane permeability between individual *Trichodesmium* cells, anoxic conditions in diazocytes must be accompanied by O<sub>2</sub> accumulation in photosynthesizing cells. Hence, while low permeability favors N<sub>2</sub> fixation in diazotrophic (nonphotosynthetic) cells, it also increases the risk for photorespiration and oxidative stress in vegetative (photosynthetic) cells. Applying membrane permeabilities between  $2.6 \times 10^{-6}$  and  $4.9 \times 10^{-6}$  m s<sup>-1</sup> (calculated for diazocytes as described above; Table 3) and a photosynthesis rate of 1013 fmol cell<sup>-1</sup> h<sup>-1</sup> (based on an O<sub>2</sub> profile measured 10 h into the light period; Fig. 2d), we calculated intracellular O<sub>2</sub> concentrations representative for the net O<sub>2</sub> evolution phase in the morning/evening, yielding concentrations between 623 and 1166 μmol l<sup>-1</sup> (Table 4). Intracellular O<sub>2</sub> concentrations can therefore differ strongly between single cells, depending on their instantaneous rates of photosynthesis and respiration. These rates may change significantly not only over the diel cycle but potentially also as cells switch between N<sub>2</sub>-fixing and non-N<sub>2</sub>-fixing states. The unexpected, transient nighttime increase in O<sub>2</sub> concentrations observed with microsensors within colonies (Fig. S1) and with optodes in the bulk medium in closed vials (Fig. 1b) furthermore suggests that intracellular O<sub>2</sub> dynamics may additionally be influenced by intracellular O<sub>2</sub> reservoirs and/or chemical binding of O<sub>2</sub>, which should be targeted in future research.

**Fig. 6** Conceptual model of intra- and extracellular O<sub>2</sub> concentrations in *Trichodesmium* at different times of the day. Note that (nonphotosynthetic) diazocytes are always anoxic, while O<sub>2</sub> concentrations in vegetative (photosynthetic) cells vary with time of the day and morphology (colony vs free trichomes). Estimates are based on O<sub>2</sub> measurements (by microsensors and membrane inlet mass spectrometry (MIMS)) and model calculations, assuming the same photosynthesis rate and permeability for all cells. Red pattern in and around cells indicates O<sub>2</sub> concentration, grey and green backgrounds indicate vegetative cells and diazocytes, respectively.

Notably, our model calculations demonstrate that O<sub>2</sub> undersaturation on the cell surface is not a prerequisite for anoxic conditions in diazocytes. In fact, anoxic conditions could be achieved within nonphotosynthetic cells even under elevated ambient O<sub>2</sub> concentrations (Table 3). Colony formation as a means to form anoxic microenvironments is therefore not required, explaining why also single trichomes can fix N<sub>2</sub> at high rates (Fig. 5a). More generally, our model results highlight that due to the low permeability of the cell wall, intracellular O<sub>2</sub> concentrations in *Trichodesmium* are largely determined by cellular O<sub>2</sub> fluxes rather than extracellular microenvironments. Importantly, extracellular O<sub>2</sub> microenvironments can, however, indirectly affect intracellular conditions by inducing physiological responses of cellular O<sub>2</sub> fluxes to external O<sub>2</sub> concentrations (Fig. 3).

## Conclusions

In summary, our measurements and model calculations demonstrate strong variations in O<sub>2</sub> concentrations in colony microenvironments and also indicate large variations within single cells (Fig. 6). These were induced by changes in the metabolic activity of *Trichodesmium* over the diel cycle, including high O<sub>2</sub> uptake during midday. Although colonies were undersaturated with O<sub>2</sub> during most of the day, this did not result in higher N<sub>2</sub> fixation

rates by colonies compared with single trichomes, potentially as the O<sub>2</sub> undersaturation over part of the day was accompanied by high extra- and intracellular O<sub>2</sub> concentrations during a short time window in the morning and evening. Based on our model calculations and high resolution microsensors measurements, we hypothesize that the diffusion barrier provided by the cell wall in combination with physiological heterogeneity between single cells allows for anoxic conditions within diazocytes, that is, respiring, nonphotosynthetic cells, under air-saturated bulk conditions (Fig. 6). Hence, O<sub>2</sub> undersaturation in colony microenvironments is not required to support N<sub>2</sub> fixation. Future research should therefore focus on the benefits of colony formation in *Trichodesmium* that outweigh the negative effects on C and N<sub>2</sub> fixation.

## Acknowledgements

We thank the technical assistants in the microsensors group for construction of microsensors and Gabriele Klockgether, Philip Hach and Clarissa Karthäuser for help with EA-IRMS, <sup>13</sup>C-DIC and MIMS measurements. We also thank Laura Wischnewsky for phosphate measurements, as well as Tong Li and Dirk Koopmanns for helpful discussions. Funding was provided by the Alexander von Humboldt Foundation and the Max Planck Society.

## Author contributions

ME, BR, WM and DdB designed the study, ME and SA performed the experiments and analyzed the data, ST performed the model calculations, ME, ST, BR, WM, SA, HP, MMMK and DdB discussed data interpretation and wrote the manuscript.
