Dynamic interplay between H-current and M-current controls motoneuron hyperexcitability in amyotrophic lateral sclerosis

Abstract

Amyotrophic lateral sclerosis (ALS) is a type of motor neuron disease (MND) in which humans lose motor functions due to progressive loss of motoneurons in the cortex, brainstem, and spinal cord. In patients and in animal models of MND it has been observed that there is a change in the properties of motoneurons, termed neuronal hyperexcitability, which is an exaggerated response of the neurons to a stimulus. Previous studies suggested neuronal excitability is one of the leading causes for neuronal loss, however the factors that instigate excitability in neurons over the course of disease onset and progression are not well understood, as these studies have looked mainly at embryonic or early postnatal stages (pre-symptomatic). As hyperexcitability is not a static phenomenon, the aim of this study was to assess the overall excitability of upper motoneurons during disease progression, specifically focusing on their oscillatory behavior and capabilities to fire repetitively. Our results suggest that increases in the intrinsic excitability of motoneurons are a global phenomenon of aging, however the cellular mechanisms that underlie this hyperexcitability are distinct in SOD1^{G93A} ALS mice compared with wild-type controls. The ionic mechanism driving increased excitability involves alterations of the expression levels of HCN and KCNQ channel genes leading to a complex dynamic of H-current and M-current activation. Moreover, we show a negative correlation between the disease onset and disease progression, which correlates with a decrease in the expression level of HCN and KCNQ channels. These findings provide a potential explanation for the increased vulnerability of motoneurons to ALS with aging.

Abstract

Amyotrophic lateral sclerosis (ALS) is a type of motor neuron disease (MND) in which humans lose motor functions due to progressive loss of motoneurons in the cortex, brainstem, and spinal cord. In patients and in animal models of MND it has been observed that there is a change in the properties of motoneurons, termed neuronal hyperexcitability, which is an exaggerated response of the neurons to a stimulus. Previous studies suggested neuronal excitability is one of the leading causes for neuronal loss, however the factors that instigate excitability in neurons over the course of disease onset and progression are not well understood, as these studies have looked mainly at embryonic or early postnatal stages (pre-symptomatic). As hyperexcitability is not a static phenomenon, the aim of this study was to assess the overall excitability of upper motoneurons during disease progression, specifically focusing on their oscillatory behavior and capabilities to fire repetitively. Our results suggest that increases in the intrinsic excitability of motoneurons are a global phenomenon of aging, however the cellular mechanisms that underlie this hyperexcitability are distinct in *SOD1^{G93A}* ALS mice compared with wild-type controls. The ionic mechanism driving increased excitability involves alterations of the expression levels of *HCN* and *KCNQ* channel genes leading to a complex dynamic of H-current and M-current activation. Moreover, we show a negative correlation between the disease onset and disease progression, which correlates with a decrease in the expression level of *HCN* and *KCNQ* channels. These findings provide a potential explanation for the increased vulnerability of motoneurons to ALS with aging.

Introduction

Motor neuron disease and excitability

Amyotrophic lateral sclerosis (ALS) is the most prevalent form of motor neuron disease (MND) and is characterized by a progressive loss of both upper and lower motor neurons, leading to paralysis and ultimately

death due to a respiratory failure, often within 3–5 years from diagnosis. In the absence of a unifying mechanism that leads to the clinical symptoms, multiple processes have been found to be instrumental in disease progression. One of the most prominent changes in MND patients is an increased excitability of motoneurons, leading to fasciculation, cramps, hyperreflexia, and spasticity in MND patients¹. Due to these symptoms, it has been hypothesized that neuronal hyperexcitability mediated by glutamate excitotoxicity is a leading cause for neuronal loss during MND, reviewed by ref.². However, recent studies have challenged this concept, questioning the impact of increased cellular excitability on neuronal

survival³, and influence on excitability symptoms^{4,5}. Moreover, recent in vivo studies showed that adult spinal motoneurons are not hyperexcitable⁶, and that fast fatigable lower motoneurons, which are most vulnerable in amyotrophic lateral sclerosis mouse models, display hypoexcitability and loss of repetitive firing rather than hyperexcitability prior to degeneration⁷.

SOD1 mouse model

Familial ALS (fALS) accounts for approximately 5–10% of all ALS cases. The first discovery linked to fALS was a mutation in the ubiquitously expressed Cu–Zn superoxide dismutase (SOD1) enzyme, which catalyzes the dismutation of superoxide anions (O_2^-) to oxygen and H_2O_2 ⁸. Indeed, mutant SOD1 has been found to cause malfunction of many cellular pathways and processes, including excitotoxicity and mitochondrial stress, which leads to cell death⁹. Identification of SOD1 mutations in ALS led to the development of several mouse models, including a transgenic mouse that expresses multiple copies of a mutated form of human SOD1 (SOD1^{G93A}), and that develops a progressive ALS with many similarities to the human disease¹⁰.

Aims of study

Neuronal excitability is not a static phenomenon but rather shows a pattern of progression in a spatiotemporal aspect¹, in which the biophysiological properties of motoneurons change with age. Therefore, it is essential to distinguish between physiological alterations in cellular excitability that are simply due to normal aging and alterations that are caused by the progression of the disease. Previous studies examining hyperexcitability in ALS mouse models have used mainly embryonic or early postnatal stage neurons, which has made it difficult to assess the role of hyperexcitability in normal aging. Hence, the aim of this study was to monitor the physiological properties of upper motoneurons during aging, as well as in different stages of the disease, which is crucial for our understanding of the mechanisms leading to motoneuron degeneration.

Results

To assess cellular alterations occurring during the progression of ALS, we recorded the electrophysiological properties of upper motoneurons (UMNs) residing in layer 5b of the motor cortex of transgenic mice expressing the mutated human *SOD1* gene (SOD1^{G93A}) and their wildtype littermate controls¹⁰. Mice were divided into two different age groups, corresponding to definite disease stages. The first group consisted of SOD1 mice at the age of 70–80 days (average of 73 ± 1 days). Although previous reports indicate that these mice show cellular differences as early as a few days^{3,11}, our mouse colony at this age

were still lacking behavioral phenotypes or any motor dysfunction, so we named them the ‘Young SOD1’ group ($n = 19$). The second group, ‘Aged SOD1’ were SOD1 mice at the age of 5–7 months, which showed symptoms of ALS (Symptomatic group, $n = 55$), including rigid paralysis and minimal joint movement of the limbs, corresponding to neurological score (NS) 2 as described by refs. ^{12,13}. As controls for normal aging, we used age-matched littermates named ‘Young Control’ ($n = 21$) and ‘Aged Control’ ($n = 53$), which neither express the mutant human SOD1 enzyme, nor show any symptoms.

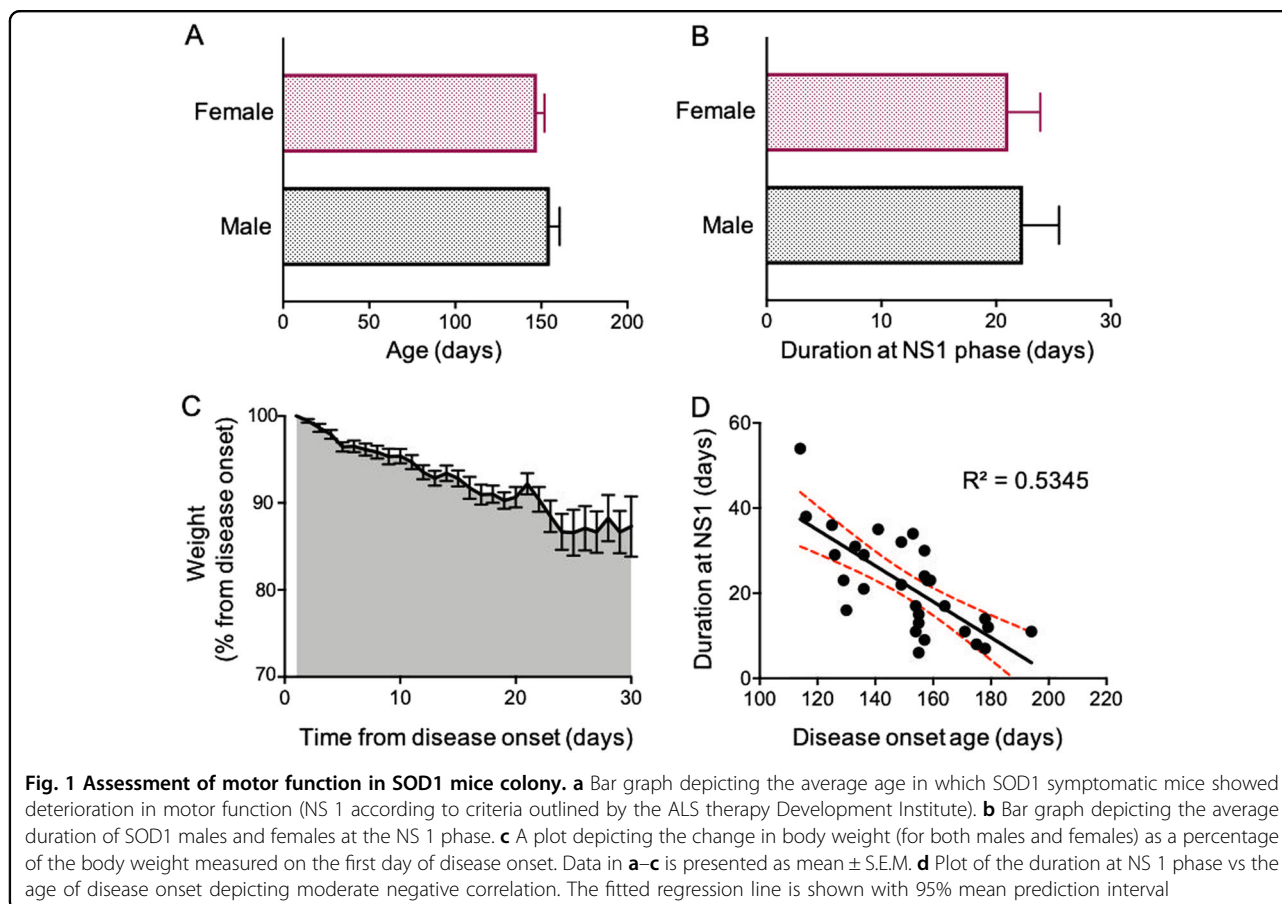

Characteristics of our mouse colony

Our mouse colony consisted of 55 symptomatic mice, 28 males and 27 females. While the average age in which females started showing deterioration in motor function (NS 1; corresponding to motor weakness—depicted as partial collapse of leg extension or trembling of hind legs during tail suspension) was 147 ± 4 days, the males started showing symptoms at the age of 155 ± 5 days (Fig. 1a). On average, SOD1 mice reached NS 2 after 168 ± 2 days, (no significant differences between genders, student *t*-test), which is longer than the period of 17–20 weeks published in previous reports^{10,14}. Moreover, the deterioration rate from the first onset of the symptoms until the mice reached NS 2 was longer than previously described, averaging 21 ± 2 days in females and 22 ± 3 days in males (Fig. 1b). These alterations in motor function were accompanied with weight loss (Fig. 1c), as previously described by other studies^{12,14}.

Intriguingly, there was a moderate negative correlation between the disease onset (the age at which the mice first showed symptoms of motor impairment (NS 1)) and the duration in which the mice stayed at the NS 1 phase before progressing to NS 2 (Fig. 1d). These changes in disease progression from previous studies are most likely attributed to a decrease in the relative copy number of the expressed human *SOD1* transgene, (6.2 ± 0.2 , see¹²) compared with the original SOD1G93A mouse line^{10,15} that reportedly had a gene copy number of 18 ± 2.6 .

Cortical motoneurons from symptomatic SOD1 mice are hyperexcitable

To assess alterations in the intrinsic properties of cortical motoneurons during disease progression, we have recorded the passive and active electrophysiological properties of pyramidal neurons residing in layer 5b of the primary motor cortex (M1). Layer 5 pyramidal neurons are heterogenous and consist of various types of motoneurons, including corticospinal and corticostriatal motoneurons, which display different electrophysiological properties^{16–19}. Two of the most prominent features of corticospinal neurons are their distinct laminar location in layer 5b of the motor cortex and relatively high Sag

amplitude, ranging from 10 to 40%, as previously reported by refs. ^{16–19}. Although previous reports showed that the overall excitability profile of all cortical neurons increased in SOD1 mice^{4,20}, to reduce bias selection of the recorded neurons, only pyramidal neurons residing in layer 5b and expressing a Sag amplitude higher than 10% were included in the analysis (Supplementary Fig. 1). The impact of aging and SOD1 mutation on cortical motoneuron excitability was assessed using two-way analysis of variance (ANOVA), followed by a Tukey's post hoc test. Table 1 summarizes the significant impact of aging, the SOD1 mutation and the interaction between these factors, on the intrinsic membrane properties of cortical motoneurons.

On average, the resting membrane potential of layer 5b pyramidal neurons recorded from the primary motor cortex (M1) was comparable between all groups tested ($p > 0.05$; two-way ANOVA, Fig. 2b). Conversely, the excitability of pyramidal neurons from aged SOD1 symptomatic mice was higher than young SOD1 pre-symptomatic mice, depicted as a significant decrease ($F_{(1,65)} = 40.93$, $P < 0.0001$ for the factor aging and $F_{(1,65)} = 4.586$, $P < 0.01$ for the factor interactions, two-way ANOVA) in the spike rheo-

base, respectively, $p < 0.01$, two-way ANOVA with Tukey's post hoc test; Fig. 2c) and a trend for increased input resistance (from 193 ± 21 M Ω in 'Young SOD1' to 218 ± 30 M Ω in 'Aged SOD1'; Fig. 2d). The increase in cellular excitability was also significant in age-matched controls, as the rheo-base significantly decreased from 161 ± 18 pA ($n = 12$) in the 'Young control' group to 48 ± 17 pA in the 'Aged control' group ($n = 11$, $F_{(1,65)} = 4.586$, $p < 0.001$, two-way ANOVA with Tukey's post hoc test). However, closer investigation into the relationship between the rheo-base current and the overall input conductance suggested that the excitability profile of cortical motoneurons was higher in the SOD1 mice than their aged-matched controls (depicted as a lower gain of slope, Fig. 2e, f), indicating an impactful involvement of the SOD1 mutation, which interacts with normal aging (Table 1).

Neuronal spiking activity is determined by a complex interaction of voltage dependent inward and outward currents, and underlies the execution of neuronal output which contributes significantly to network behavior²¹. As muscle movement is defined by the firing rate of motoneurons, and one of the hallmarks of ALS is a loss of the ability of lower motoneurons to fire repetitively^{6,7}, we measured the firing frequency-current (F-I) curves

Table 1 Age and SOD1 mutation affects the intrinsic properties of cortical motoneurons

	Rin	Rheobase	Sag amplitude	mAHP	HCN1	HCN2	HCN3	KCNQ2	KCNQ3	KCNQ5
Aging	*	****			****	**		****	**	*
SOD1 Mutation			***		***	*	*	**	**	**
Interaction		*		*						

Intrinsic properties of cortical motoneurons change during normal aging and are affected by the SOD1 mutation. Significance levels presented as * $p < 0.05$, ** $p < 0.005$, *** $p < 0.001$, **** $p < 0.0001$; Reported P -values are by two-way ANOVA with factors 'age' (black asterisks), 'SOD1 mutation' (blue asterisks) and interaction between factors (red asterisks)

(Fig. 3a–c), as well as the oscillatory behavior (Fig. 4) of cortical motoneurons. Our results showed that the average gain of the spiking F-I curves of motoneurons from symptomatic “aged SOD1” mice was significantly higher ($F_{(1, 57)} = 9.442, P < 0.001$, two-way ANOVA) than pre-symptomatic “young SOD1” motoneurons (0.09 ± 0.01 Hz/pA, $n = 21$ vs. 0.05 ± 0.01 Hz/pA, $n = 21$ respectively; $p < 0.05$; two-way ANOVA with Tukey’s post hoc test; Fig. 3c, d), indicating an increased excitability and ability to fire at higher frequencies. However, there was a trend

for an increase in the average gain of F-I curves recorded from aged controls compared with young controls (Fig. 3b), though this did not reach statistical significance.

Neurons act as resonators that on the one hand respond preferentially to inputs at a certain frequency, and on the other affect the network oscillatory activity²². Neuronal resonance frequency is determined by the interplay of passive and active properties^{23,24}, mainly slowly activating K^+ current and a fast-persistent Na^+ current²⁵, and affects spike propagation and adaptation²³. Our results

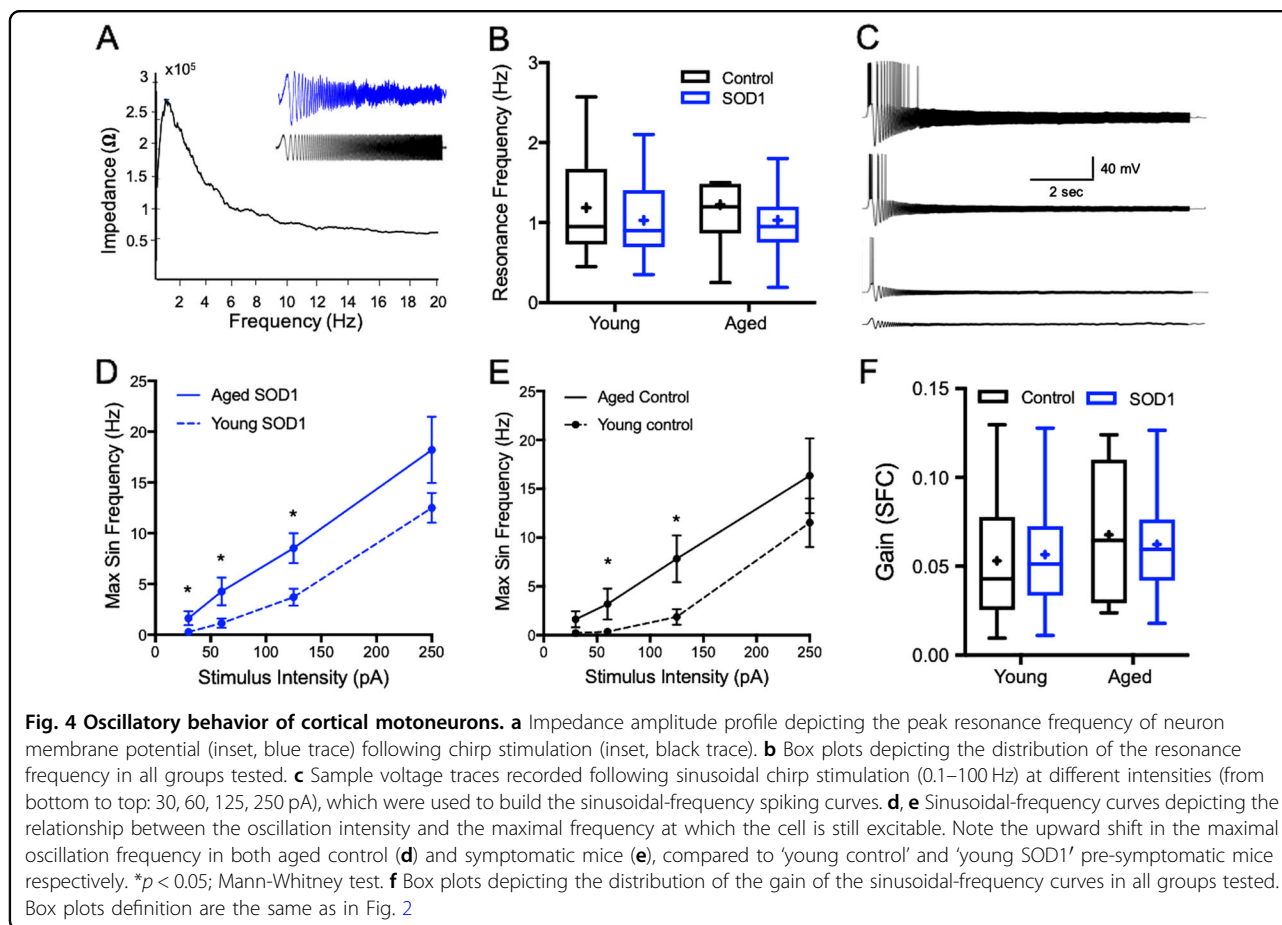

show that the average resonance frequency of the cortical motoneurons recorded remained stable and neither change due to normal aging nor during disease progression (Fig. 4a, b).

In order to evaluate the relationship between membrane oscillation frequencies and spike threshold, we injected sinusoidal currents at different intensities (30–250 pA chirp current) at increasing frequencies (0.1–100 Hz; Fig. 4c). This protocol detects neuronal excitability at instantaneous sinusoidal frequencies and allows an evaluation of the relationship between neuronal excitability and oscillatory behavior, depicted by the Frequency-Spiking Curve (SFC, Fig. 4d, e). Analysis of the sinusoidal frequency curves of upper motoneurons suggest that following low amplitude sinusoidal stimulation (≤ 125 pA), motoneurons from both 'aged control' mice and 'aged SOD1' symptomatic mice were able to fire action potentials at higher oscillations frequencies than young mice (7.8 ± 2.3 Hz ($n = 8$) and 8.5 ± 1.4 Hz ($n = 23$) vs. 1.8 ± 0.8 Hz ($n = 12$) and 3.7 ± 0.8 Hz ($n = 22$), respectively; $U = 17$, $p < 0.01$ for control and $U = 128$, $p < 0.001$ for SOD1, Mann-Whitney's two-tailed U -test, Fig. 4d, e). However, no significant alterations were identified at higher amplitudes (>125 pA), indicating a differential impact of aging on the maximal firing frequency.

Moreover, no differences were observed between the gain of SFCs recorded from SOD1 mice and their age-matched controls (Fig. 4f). Together these results suggest that the intrinsic alterations controlling the maximal frequency at which neurons were still able to fire action potentials, were limited to lower spiking frequencies and were simply due to the physiological impact of aging.

Cortical neurons lose their capability of repetitive firing in pre-symptomatic stages

Previous reports suggested that in ALS, neurons lose their capability of repetitive firing, and once symptoms of ALS appear, a substantial amount of motoneurons may have already degenerated²⁶. This implies that most neuronal death occurs during the pre-symptomatic stages and progress with time. For this reason, we compared the spiking activity of all pyramidal neurons recorded in layer 5 of the motor cortex. In order to assess neuronal firing patterns, we injected increasing step currents greater than $>150\%$ of rheobase amplitude. All recorded upper motoneurons from young controls showed repetitive firing (Fig. 5a), however 23.0% of upper motoneurons recorded from the 'young SOD1' pre-symptomatic mice, lost their capability of repetitive firing. In comparison, only 7.9% of neurons from the 'aged SOD1' symptomatic group lost

their capability of repetitive firing, while 21.4% of aged controls showed similar features (Fig. 5a). This suggests that at least two-thirds of the neurons that had lost their ability to fire repetitively in the pre-symptomatic stage had been lost by the symptomatic stage of the disease. Further analysis of the spiking properties showed that while the spike amplitude and spike width at half amplitude (SWHA) were similar among all groups (Fig. 5b, c), the medium after hyperpolarization (mAHP; Fig. 5d), which is mediated by small conductance potassium channels²⁷, as well as muscarinic and HCN channels^{28,29}, increased significantly from 2.5 ± 0.4 mV ($n = 10$) in ‘aged control’ mice to 4.5 ± 0.5 mV ($n = 24$) in ‘aged SOD1’ symptomatic mice ($F_{(1,60)} = 6.15$, $p < 0.05$; two-way ANOVA followed by Tukey’s post hoc test, Fig. 5e). This increase was absent in young mice, suggesting it is specifically attributed to the disease progression in SOD1 symptomatic mice ($F_{(1,60)} = 6.15$, $P < 0.05$, two way ANOVA).

To assess the ionic mechanisms underlying the alterations in neuronal firing patterns and mAHP we measured the impact of H-current (I_h) and M-current (I_m) on neuronal excitability during disease progression. The H-current is activated by hyperpolarization of the resting

membrane potential and mediated by hyperpolarization-activated cyclic nucleotide-gated (HCN) channels, which are permeable for both Na^+ and K^+ ions and therefore have an equilibrium potential of -30 mV. This current affects the neuron oscillatory activity, responsiveness to inhibitory synaptic potentials (IPSPs) and resting membrane potential³⁰. Analysis of the hyperpolarization-‘Sag’ amplitude (Fig. 5d), mainly mediated by the H-current (I_h), identified a significant increase in the Sag amplitude ($F_{(1,64)} = 15.33$, $P < 0.001$, two way ANOVA), which was mainly caused by aging (Fig. 5f, Table 1). However, an increase in I_h conductance is usually accompanied by depolarization of the resting membrane potential and a decrease in input resistance, which we did not observe (see Fig. 2), suggesting other processes may be superimposing and masking our results. For these reasons, we repeated the recordings with a selective antagonist of the non-inactivating K^+ channels mediating the M-current (I_m), XE991³¹. These recordings indicated a significant increase in the Sag amplitude and overall excitability of motoneurons following I_m inactivation, across all groups ($p < 0.01$, $t = 3.22$, $df = 14$ for young SOD1; $p < 0.01$, $t = 27$, $df = 1$ for aged control and $p < 0.05$, $t = 2.57$, $df = 10$ for aged SOD1, two tailed paired student t -test, Fig. 6a).

Moreover, examination of the F-I curves following inhibition of the M-current led to an upward shift of the F-I curve of motoneurons recorded from both 'young SOD1' and 'aged SOD1' mice, suggesting enhanced excitability (Fig. 6b, c). In contrast, application of the Kv7 K^+ channel opener, retigabine, did not affect the F-I curve of motoneurons recorded from 'young SOD1' pre-symptomatic mice (Fig. 6b, green markers), yet reduced the excitability of motoneurons recorded from 'aged SOD1' symptomatic mice (Fig. 6c). The relative change in Sag amplitude following I_m inhibition was highest in 'young SOD1' pre-symptomatic mice (average increase of $57 \pm 25\%$ compared with $28 \pm 17\%$ in 'aged SOD1' symptomatic mice), consistent with the significantly higher expression levels of *KCNQ2* ($F_{(1, 28)} = 21.08$, $P < 0.0001$ for aging and $F_{(1, 28)} = 7.64$, $P < 0.01$ for mutation) and *KCNQ3* ($F_{(1, 28)} = 11.92$, $P < 0.001$ for aging and $F_{(1, 28)} = 10.29$, $P < 0.001$ for mutation) channel genes in the motor cortex of 'young SOD1' mice (compared with symptomatic 'aged SOD1' animals; $p < 0.05$, two way ANOVA with Tukey's post hoc test, Fig. 6d). Further analysis of the expression level of

HCN channel genes in the motor cortex of all groups tested identified a significant decrease of *HCN1* channel expression during both normal aging ($F_{(1, 26)} = 33.9$, $p < 0.0001$, two-way ANOVA) and disease progression ($F_{(1, 26)} = 13.84$, $p < 0.001$, two-way ANOVA, Fig. 6e, Table 1), yet the expression level in SOD1 mice was significantly higher than their littermate controls. Intriguingly, the expression pattern of *HCN1*, *KCNQ2*, and *KCNQ3* channels was similar, depicting a significant decrease with age, but greater expression in SOD1 mice (Fig. 6d, e), underpinning the differential impact of I_m on cortical motoneurons during symptomatic and pre-symptomatic stages. Together our data thus identifies a complex dynamic between H-current and M-current in aging and in ALS.

Discussion

ALS is a multi-factorial disease, however increasing evidence suggests that hyperexcitability, which is thought to develop in the motor cortex, is the underlying mechanism leading to loss of motoneurons^{1,32,33}. The

source of cortical hyperexcitability can be either via alterations in intrinsic properties of upper motoneurons, extrinsic circuitry processes that affect the inhibition-excitation balance³⁴, or via modulation of glial activity^{9,35}. However, a recent study that investigated the correlation between selective loss of corticospinal neurons and their excitability showed that alterations in cortical excitability are not cell-type specific, but rather a global phenomenon

of the motor cortex. Indeed both excitatory and inhibitory neurons exhibited increases in intrinsic excitability, which were provisional to the disease stage and counterbalanced by the cortical circuit⁴.

Here, we assessed the intrinsic cellular properties of cortical motoneurons during disease progression in *in vitro* slice preparations, which provides mechanical stability and fine control of the extracellular environment.

Our results suggest that alteration of the intrinsic excitability of cortical motoneurons is a characteristic phenomenon of aging in this mouse model, as indicated by the decrease in spike rheobase in both SOD1 symptomatic mice and their age-matched controls (Fig. 2c). However, two-way analysis of variance showed that the SOD1 mutation affects cellular processes that increase the excitability profile of cortical motoneurons and interact with normal aging, as summarized in Table 1. Moreover, the overall increase in excitability of cortical motoneurons from SOD1 mice suggest that the degree of augmented excitability is higher in SOD1 mice compared with their age-matched littermate controls, as indicated by the declined slope of the rheobase-conductance curves (Fig. 2e, f).

Neuronal firing properties form the basis for the neural code, which regulates numerous operations of the central nervous system, including motor control and complex cognitive processes³⁶. A key feature of spiking neurons is their capability to act as resonators that amplify inputs at certain preferential frequencies, shaping their firing patterns²³. The H-current, mediated by hyperpolarization-activated cyclic nucleotide-gated cation channels, affects neuron resonance behavior, as well as synaptic and dendritic integration, thus regulating spiking output and overall motor control³⁷. Indeed, computational models show that enhancement of I_h may control the rate of rhythmic oscillations in neural networks³⁸, and recent reports showed that upper motoneurons express high levels of I_h ¹⁹. In that regard, our results indicate that the expression level of HCN channels was higher in mice expressing the SOD1 mutation (compared with age-matched controls, Fig. 6e), which surprisingly was not accompanied by an increase in the resonance frequency (Fig. 4b), nor a decrease in the overall input resistance as might be expected. This counterintuitive result suggests that the increase in I_h is superimposed with other mechanisms that mask its function. One candidate that is active during subthreshold membrane potential is the M-current, which forms a non-inactivating outward K^+ current.

H-current and *M-current* have biophysiological properties that counterbalance each other, reviewed by ref. ³⁹. While activation of I_h leads to membrane depolarization and increased excitability, activation of *M-current*, mediated by four subunits of the K_v7 (*KCNQ*) K^+ channel family⁴⁰, will do the opposite. In general, we found that the expression level of *HCN1*, *HCN2*, and *HCN3* mRNA, as well as *KCNQ2*, *KCNQ3*, and *KCNQ5* channels in the motor cortex decreased with age and disease progression, yet were higher in SOD1 mice than their age-matched controls (Fig. 6b, e). Moreover, the expression level of these channels was gender independent, as no differences were recorded between males and females.

Our results suggest there is a differential impact of K_v7 channel activity during disease progression, as the increase in the Sag amplitude following I_m inactivation with XE991 was much greater in the 'young SOD1' pre-symptomatic mice than in the symptomatic mice (paired *t*-test, Fig. 6a). Hence, these results suggest that the enhancement of I_h during aging could be caused essentially by reduced activity of K_v7 channels (Fig. 6). As both M-current and H-current are mediated by voltage gated channels, yet they have different activation curves, this means that their combined impact on intrinsic excitability of motoneurons is complex and varies between different types of neurons and age. While M-current consistently drives K^+ outflow and thus hyperpolarization, once active, it counterbalances the inward Na^+ flow of the I_h current³⁹, leading to the low Sag amplitude seen in young animals (Fig. 5f). Moreover, the reduced M-current in symptomatic mice ('Aged SOD1' compared with pre-symptomatic 'Young SOD1' mice) could explain the slight trend for increased overall input resistance (Fig. 2). Consistent with our results, Milan and colleagues found a complex age-related dynamic of the cholinergic system in the spinal cord that appeared completely disrupted in SOD1 motoneurons⁴¹. Moreover, a recent report showed that the K_v7 channel activator retigabine, which increases K_v7 channel opening and stabilizes the resting membrane potential, both blocks the hyperexcitability and improves motor neuron survival in vitro, when tested in SOD1 ALS patient motor neurons in cell culture⁴². Consistent with this, our results show that application of retigabine had an inhibitory impact on motoneuron excitability, and a greater effect on motoneurons in the symptomatic 'aged SOD1' than the pre-symptomatic 'young SOD1' mice (compare 6B and 6C).

Overall, our findings provide insights into the intrinsic physiological properties of cortical motoneurons underlying cortical hyperexcitability, a common phenotype in MND. Despite controversy as to the underlying mechanisms leading to cortical hyperexcitability, it is paramount to emphasize that neuronal intrinsic excitability is not a static phenomenon, and is *constantly changing during normal aging*, as well as different pathologies¹. However, the nature of these properties will determine the transformation of neural signals into active movement, and knowledge about alterations in these properties is an essential step in unraveling new therapeutic targets. Moreover, the negative correlation between disease onset and disease progression (Fig. 1d) might be due to age-dependent compensatory mechanisms for functional motor control, in which the capacity for compensation decreases with age. This compensatory mechanism might involve molecular mechanisms that slow the neurodegenerative process, reviewed by ref. ⁴³, or recruitment of other neurons leading to a greater

activation of the network involved in motor control, as suggested by ref. ⁴⁴ for Huntington's disease. Nevertheless, these observations provide insight into potential therapeutic targets that could alleviate disease symptoms or progression.

Conclusions

We have identified increased neuronal excitability in 'normal' aging in cortical motor neurons and a distinct mechanism for aberrant hyperexcitability beyond 'normal' aging in a mouse model of ALS. These changes are mediated by a dynamic interplay between H-current and M-current and provides a potential explanation for increased vulnerability of motor neurons to ALS with aging.

Material and Methods

Animals

Transgenic SOD1 mice (SOD1^{G93A})1Gur/J were originally from the colony held by Justin Yerbury (University of Wollongong, NSW, Australia). Mice were bred and maintained on the B6SJL background by breeding mSOD1 transgenic males with non-transgenic females in a rotational scheme. All animals handled with standard conditions of temperature, humidity, 12 h light/dark cycle, free access to food and water, and without any intended stress stimuli. All experiments were approved and performed in accordance with Western Sydney University committee for animal use and care guidelines (Animal Research Authority #A11789).

Slice preparation

Animals were deeply anesthetized by inhalation of isoflurane (5%). Following anesthesia, mice were transcardially perfused with ice-cold HEPES-buffered N-methyl glucamine-artificial cerebrospinal fluid (aCSF) solution containing in mM: 2.5 KCl; 1.25 NaH₂PO₄; 25 NaHCO₃; 25 D-glucose; 10 MgSO₄; 92 NMDG (N-methyl glucamine); 0.5 CaCl₂; 20 HEPES; 2 Thiourea; 5 Na-ascorbate; 3 Na-pyruvate (NMDG-ACSF), until the outflow solution was clear. After perfusion, the mice were decapitated, and their brains were quickly removed and placed into ice-cold aCSF containing (in mM): 125 NaCl, 2.5 KCl, 1 MgCl₂, 1.25 NaH₂PO₄, 2 CaCl₂, 25 NaHCO₃, 25 glucose, and saturated with carbogen (95% O₂–5% CO₂ mixture; pH 7.4). Parasagittal brain slices (300 μm thick) were cut with a vibrating microtome (Leica VT1200S) and transferred to the BraincubatorTM (PaYo Scientific, Sydney; <http://braincubator.com.au>), as reported previously⁴⁵. The Braincubator is an incubation system that closely monitors and controls pH, carbogen flow, and temperature, as well as irradiating bacteria through a separate UV chamber^{46,47}. Slices were initially incubated for 12 min at 35 °C, after which they were allowed to cool to 15–16 °C

and kept in the BraincubatorTM for at least 30 min before any measurement⁴⁸.

Electrophysiological recording and stimulation

The recording chamber was mounted on an Olympus BX-51 microscope equipped with IR/DIC optics. Following incubation in the BraincubatorTM, slices were mounted in the recording chamber for a minimum of 15 min, to allow them to warm up to room temperature (~22 °C), and were constantly perfused at a rate of 2–3 ml/min with carbogenated aCSF, as reported previously⁴⁹. Whole-cell intracellular recordings from layer V pyramidal neurons in the motor cortex were obtained with patch pipettes (5–7 MΩ) containing (in mM): 130 K-Methansulfate, 10 HEPES, 0.05 EGTA, 7 KCl, 0.5 Na₂GTP, 2 Na₂ATP, 2 MgATP, 7 phosphocreatine, and titrated with KOH to pH 7.2 (~285 mOsm). Voltages were recorded in current clamp mode using a multiclamp 700B dual patch-clamp amplifier (Molecular Devices), digitally sampled at 30–50 kHz, filtered at 10 kHz, and analyzed off-line using pClamp 10 software²³. Membrane properties were obtained before and after bath application of the KCNQ/K_{v7} channel blocker XE991 (3 μM) or the KCNQ/K_{v7} enhancer retigabine (10 μM), as previously reported³¹. Cells were considered stable and suitable for analysis if the input resistance did not change more than 20% during the baseline recordings, before any treatment.

The Sag potential was measured following injection of hyperpolarizing current steps (–50 to –150, 1 s, Fig. 5d) and determined as the difference between the minimum peak potential and the steady state potential, as previously described^{19,37}. Sag potentials were normalized to their respective peak deflection from resting membrane potential, and only neurons with Sag potentials greater than 10% were included in the analysis.

Suprathreshold sinusoidal stimulus protocol

In order to evaluate alterations in suprathreshold oscillation frequencies under different conditions, 10-s stimulating protocols of sinusoidal current (chirp stimulation), in which there was a linear increase in the frequency from 0.1 to 100 Hz, were designed at 30, 60, 125, and 250 pA, using the pClamp 10 software suite (Molecular devices, Sunnyvale, CA).

Spectrum impedance analysis

To measure the resonance frequency of individual neurons, a 20-s subthreshold sinusoidal current at 10 pA, with a linear increase in frequency from 0.1 to 20 Hz (chirp stimulation) was applied through the recording electrode, as previously described²³. The resonance frequency was determined as the peak in the impedance amplitude profile (ZAP) generated by dividing the Fourier transforms of the voltage signal by that of the current

Table 2 List of qPCR primers

Target	Forward primer (5'–3')	Reverse primer (5'–3')	Product size (bp)	Annealing temp. (°C)	Primerbank ID or source

signal, as previously described by ref. ²⁵. The voltage recordings were recorded in millivolts and the current signal recorded in picoamps and adjusted accordingly such that the resulting complex impedance can be measured in Ohms.

qRT-PCR

Halved mouse motor cortices for qRT-PCR analysis were stored in 0.5 mL RNAlater Solution (Ambion) at -80°C . RNA was extracted using the Qiagen RNeasy Plus Mini Kit, with tissue samples blotted to remove excess RNAlater Solution before being snap-frozen in liquid nitrogen. Tissues were homogenized using a mini-pestle followed by disruption by passing through a 21 G needle 5 times and extraction as per kit instructions, with RNA eluted in 30 μL volume. RNA yield was determined using a NanoDrop 2000/2000c Spectrophotometer (Thermo Fisher Scientific) and 1 μg of RNA was used per 20 μL cDNA synthesis reaction, using the Tetro cDNA Synthesis Kit (Bioline) with Oligo (dT)₁₈ primer. An equivalent dilution of RNA was prepared in water and stored at -20°C for inclusion in qRT-PCR experiments to assess RNA preparations for genomic contamination (“no RT” control). The SensiFAST™ SYBR No-ROX Kit (Bioline) was employed for qRT-PCR, with 20 μL reactions performed in triplicate. Intron-spanning primers (Table 2; synthesized by Sigma-Aldrich) were selected from PrimerBank⁵⁰ or designed in-house and evaluated via BLAST and Ensembl searches. Reactions contained 0.4 μM final concentration of each primer, along with 50 ng of cDNA. Negative controls included water (NTC) and the “no reverse transcriptase” RNA samples. Three-step cycling was carried out on a QuantStudio 5 Real-Time PCR System (Thermo Fisher Scientific) with conditions of 95°C for 2 min, then 40 amplification cycles of 95°C for 5 s, $57\text{--}63^{\circ}\text{C}$ (primer-dependent; Table 2) for 10 s, and 72°C

for 20 s, followed by a single melt cycle of 95°C for 15 s, 60°C for 1 min, then increasing to 95°C at a rate of $0.1^{\circ}\text{C}/\text{s}$. The threshold was automatically set by the QuantStudio Design and Analysis Software (v1.4.3) and the Ct was calculated as the average of the three replicates. The Ct values for transcripts of interest were normalized to the average of the two reference genes, *Ccdc127* and *Hprt* (Table 2).

Statistical analysis

Unless stated, data is reported as mean \pm S.E.M. Statistical comparisons were performed with Prism 7 (GraphPad Software; San Diego, CA) using two-way ANOVA followed by Tukey's post hoc test, or two-tailed paired student *t*-test as detailed in the text. Data in figures are presented in two levels. Asterisks above a dashed line represent the significance levels of the impact of “Age” (black), ‘SOD1 Mutation’ (blue), and level of interaction (red). Asterisks below the dashed line represent significance levels between groups following Tukey's post hoc test. * $p < 0.05$; ** $p < 0.005$; *** $p < 0.001$; **** $p < 0.0001$. For the box and whisker plots, the box upper and lower limits are the 25th and 75th quartiles, respectively. The whiskers depicting the lowest and highest data points, while the +sign represents the mean and the horizontal line through the box is the median. Resonance frequency analysis was performed using custom code written in Matlab (Mathworks). Probability values <0.05 were considered statistically significant.
