Abstract

Graphene and its derivatives have been well-known as influential factors in differentiating stem/progenitor cells toward the osteoblastic lineage. However, there have been many controversies in the literature regarding the parameters effect on bone regeneration, including graphene concentration, size, type, dimension, hydrophilicity, functionalization, and composition. This study attempts to produce a comprehensive review regarding the given parameters and their effects on stimulating cell behaviors such as proliferation, viability, attachment and osteogenic differentiation. In this study, a systematic search of MEDLINE database was conducted for *in vitro* studies on the use of graphene and its derivatives for bone tissue engineering from January 2000 to February 2018, organized according to the PRISMA statement. According to reviewed articles, different graphene derivative, including graphene, graphene oxide (GO) and reduced graphene oxide (RGO) with mass ratio ≤ 1.5 wt % for all and concentration up to 50 $\mu\text{g}/\text{mL}$ for graphene and GO, and 60 $\mu\text{g}/\text{mL}$ for RGO, are considered to be safe for most cell types. However, these concentrations highly depend on the types of cells. It was discovered that graphene with lateral size less than 5 μm , along with GO and RGO with lateral dimension less than 1 μm decrease cell viability. In addition, the three-dimensional structure of graphene can promote cell-cell interaction, migration and proliferation. When graphene and its derivatives are incorporated with metals, polymers, and minerals, they frequently show promoted mechanical properties and bioactivity. Last, graphene and its derivatives have been found to increase the surface roughness and porosity, which can highly enhance cell adhesion and differentiation.

INTRODUCTION

Bone tissue engineering (BTE) is a complex and dynamic Strategy that typically requires a bone scaffold for recruitment of stem/progenitor cells, followed by their proliferation, differentiation, matrix formation and remodeling of the bone.¹ Moreover, bone scaffolds are generally made of biomaterials in order to provide proper mechanical support during the stimulation of new bone formation. The desired properties of scaffolds are osteoconductivity, biodegradability, high biocompatibility and mechanical properties and interconnected porosity which are the required properties for fabricating scaffold.² For

decades, carbon-based materials such, as carbon nanotubes (CNT), fullerenes and graphene have been introduced as remarkably promising materials, which have been shown to induce cell attachment, proliferation and differentiation, particularly toward the osteoblastic lineage.³ Graphene is a single atomic layered sheet of conjugated sp²-carbon atoms, attracting attention among all carbon-based materials due to their specific features. These advantageous features of graphene include large surface area, high mechanical strength, great elasticity modulus, unprecedented electricity properties⁴ and potential of providing an interaction site to adsorb various growth factors or other materials that can enhance differentiation.^{3, 5-7}

Graphene derivatives include graphene oxide (GO), reduced graphene oxide (RGO) amine-functionalized graphene oxide (AGO), graphene foams (GFs), graphene nanosheets (GNSs) and graphene quantum dots (GQDs). Among all graphene derivatives, GO and RGO have been widely used in BTE.⁸ Although GO presents reduced electronic and mechanical properties compared to pristine graphene, it has various benefits from a synthetic chemistry aspect.⁹ GO is prepared by oxidation of graphite and has many hydrophilic functional groups, including hydroxyl, carboxyl and epoxy groups, which may cause increased biocompatibility of GO compared to pristine graphene,^{10, 11} however, the other parameters such as concentration, size and dimension should be considered as influential factors in evaluating the toxicity of GO.¹²⁻¹⁴ RGO, produced by removing the oxygen-containing groups of GO, maintains some of the thermal and mechanical properties observed in pristine graphene.¹⁵ Moreover, RGO has a higher capability in electron transferring which may be effective in accelerating differentiation.¹⁶ The properties of graphene-related materials and their great potential to be easily functionalized and combined with biomolecules and biomaterials present several opportunities to design different bio-composites. Thus, in this article we further provide basic information regarding systematic review on the potential of graphene and its ability to produce polymer-, minerals- and metal-composites with modified mechanical properties and enhanced cell differentiation, mineral deposition and bioactivity. We comprehensively evaluated the effect of graphene and its derivatives on osteogenic differentiation of various stem/progenitor cells. Additionally, we further expand our assessment on compatibility of graphene and its derivatives' effect on cell viability, proliferation and attachment. Indeed, this systematic review aims to clarify the limitations in available studies and contribute to designing future preclinical and clinical studies on the use of graphene family for bone regeneration.

METHODS AND MATERIALS

Eligibility criteria

Types of studies

All *in vitro* studies that used graphene and its derivatives for bone regeneration from January 2000 to February 2018 from MEDLINE were included in this review. Included studies were limited to English-language articles. We excluded the abstracts, reviews, letters and thesis.

Types of participants

Participants were any types of graphene, including GO, RGO, AGO, and GQDs prepared in any shape and composition. Additionally, any type of stem/progenitor cells was considered.

Types of interventions

Studies that conducted an osteogenic induction in presence of graphene and its derivatives were included. Studies that used only osteogenic induction as a part of a multilineage characterization test were excluded.

Types of outcome measures

Cell viability and proliferation was reported in *in vitro* studies using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS), deoxynucleic acid (DNA) counting, Cell Counting Kit-8 (CCK-8), mitochondrial activity, Alamar Blue, total protein apoptosis, reactive oxygen species (ROS), and quantitative lactate dehydrogenase (LDH) activity assays. Also, various methods of staining were reported, including 4',6-diamidino-2-phenylindole (DAPI), Calcein AM, F-actin, and live and dead assay. Cellular attachment was reported in *in vitro* studies using fluorescence and microscopic images such as fluorescein isothiocyanate (FITC), DAPI, live and dead, fluorescein diacetate, and scanning electron microscope (SEM).

In addition, differentiation toward the osteoblast lineage was reported in *in vitro* studies using alkaline phosphatase (ALP) activity, western blotting, Wnt pathway, flow cytometric analysis, phosphate assay, calcium (Ca) content and calcium phosphate (CaP) measurement, osteocalcin (OCN) content and gene expression analysis. Furthermore, various methods of staining were utilized, including immunocytochemical (ICC), immunofluorescent, Alizarin Red-S (ARS), Sirius Red (SR) and Von Kossa.

Information source

Our scientific electronic database was MEDLINE (NCBI PubMed and PMC). Further hand search was performed in the following journals: Carbon, Biomedical Nanotechnology, Nature, Nanoscience and Nanotechnology, Nanoscale, ACS Nano and Nanomedicine. Our search was limited to English-language studies dating from January 2000 to February 2018.

An electronic search was performed to select articles relevant to effect of graphene on stem/progenitor cells using the following terms: graphene AND (BTE OR bone regeneration OR osteogenesis OR osteoblast lineage OR osteogenic lineage OR osteogenic differentiation). A search of the selected articles' bibliographies was also performed manually.

Data collection process

Review and data extraction were performed according to the PRISMA flow diagram shown in Figure [1](#). Three independent reviewers performed the initial screening of the selected articles, followed by reviewing the full text of the articles and extraction of all data. Disagreements between the three reviewers were resolved by consensus. In case of no agreement, a fourth reviewer decided. Fourth and fifth authors contributed in the discussion section.

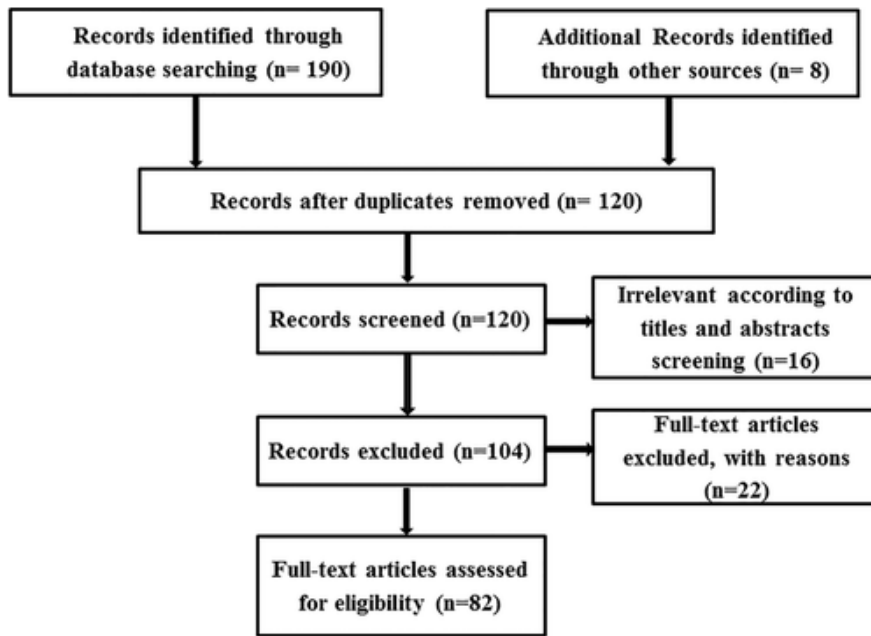

Figure 1 Flow chart of the search strategy.

DATA items

Results and data were extracted from the full text of the articles and tabulated as follows (Table 1): (1) Types of cells used for osteogenesis; (2) chemical composition of graphene and its derivatives used for cell differentiation; (3) types of graphene used in combination with other materials such as metals, metalloids, polymer; (4) size of graphene and its derivatives, including lateral dimension, diameter, and thickness; (5) cultural condition used for cell growth; (6) type of treatment group used for evaluating cell behavior; (7) type of characterization tests conducted for surface characterizing; (8) outcomes of *in vitro* studies, that is, the results of the cell viability, proliferation, attachment and differentiation.

RESULTS

Study selection

The process of article selection and data extraction is illustrated in Figure 1. In the primary search, 190 articles were found from the NCBI PMC and PubMed databases, 3 results from other sources and five other articles also found by hand searching. A total of 120 articles were chosen after duplicates were removed. Then, records were screened and irrelevant studies, according to the titles and abstracts were removed with regards to eligibility criteria, and 104 studies remained. In the next step, the full texts of the 104 selected articles were reviewed and 22 more articles were excluded. Four of the studies were excluded as it described a myogenic, neural and chondrogenic differentiation rather than osteogenic differentiation. Five of the studies were excluded because osteogenesis was only a part of the multilineage differentiation characterization tests. Four studies were excluded because it evaluated osteogenesis only through *in vivo* experiments. Nine other studies were excluded due to only the mechanical strength and its influence on cell proliferation and attachment were investigated, and the osteoability of graphene and its derivatives were not evaluated. Ultimately, a total of 82 articles were included in this systematic review.

Cell sources

The most dominant cell types used in the included articles were mesenchymal stem cells (MSCs), including human adipose-derived stem cells (hADSCs),¹⁷⁻²² Goat ADSCs,²³ human dental pulp stem cells (hDPSCs),²⁴ human alveolar bone marrow stem cells (hABMSCs),²⁵ human periodontal ligament stem cells (hPDLSCs),^{26, 27} and bone MSCs (BMSCs),²⁸⁻³¹ such as human BMSCs^{19, 32-41} (hBMSCs), murine BMSCs (mBMSCs),^{4, 42-49} rabbit BMSCs (rBMSCs),⁵⁰ murine MSCs cell line C3H10T1/2^{51, 52} and Caprine BMSCs (cMBSCs).⁵³

The type of the MSCs in fifteen studies^{19, 32, 36, 40, 54-64} was not defined. Sixteen studies used preosteoblast cells,^{14, 65-79} including mouse osteoblastic cells^{14, 65-74, 77-82} (MC3T3-E1) and rat calvarial osteoprogenitors,⁷⁵ while the type of the preosteoblast cells in one study⁷⁶ was not defined. Five articles^{13, 83-86} used osteoblasts. Immortalized mouse embryonic fibroblasts (iMEFs), immortalized mouse adipose-derived cells (iMADs), immortalized mouse calvarial cells (iCALs)⁸⁷ and human osteosarcoma cell line hMG63^{34, 88-92} were other types of the cells used.

Graphene types

Different types of graphene used in the included studies were pristine graphene,^{19, 20, 23, 24, 27, 28, 32, 35, 41, 46, 52, 55-57, 59, 60, 62, 78, 84, 87, 88, 91, 93} GO,^{13, 14, 17, 21, 22, 26, 29-31, 36-39, 43, 45, 47-51, 53-55, 59, 61, 63, 64, 66-70, 73-76, 79, 82, 85, 89, 90, 92} RGO,^{4, 14, 25, 36, 42, 44, 45, 54, 58, 65, 70-72, 77, 80, 83, 86} AGO,³⁶ GFs,³³ GNSs,³⁴ GQDs,⁹⁴ and nanosized graphene¹⁸ (NGO).

Chemical composition

Different functional groups and materials were used in order to improve the bioactivity of graphene and its derivatives for fabrication of bone regenerative compositions. The materials were metals or metalloids, polymers and mineral substrates. The metal or metalloid category consists of silicon (Si),⁶⁵ zinc oxide (ZnO),⁸⁹ titanate,⁹² strontium (Sr),⁷¹ copper (Cu),^{49, 80} silver (Ag),⁵⁰ titanium (Ti),^{19, 22, 26, 30, 38, 39, 42, 45, 47, 69, 76, 83, 88} Ti alloy (Ti₆Al₄V)²⁸ and nitinol (NiTi).⁵⁷ Polymers include poly(L-lactide) (PLLA),⁴⁶ poly(dopamine) (PDA),⁶⁸ poly(ε-caprolactone) (PCL),^{14, 36, 203} poly(ethylenimine) (PEI),^{37, 82} poly(lactic-coglycolic acid) (PLGA)-tussah,⁶¹ silk fibroin (SF),⁴³ polyethylene terephthalate-based artificial ligament group (PET-ALs),⁷⁸ PLGA,^{55, 63, 81, 91} carrageenan (Car),⁷³ collagen (COL),⁷⁰ chitosan (Ct)/gelatin (Gn),^{21, 74, 75} Ct,^{43, 48, 55} poly-ether-ether-ketone (PEEK),³⁴ tea polyphenol (TP),⁸³ poly(ethylene glycolamine) (PEG)/FITC⁶⁶ and PEG.⁸² The mineral substrates were hydroxyapatite (HAP),^{4, 21, 29, 35, 40, 43, 72, 81, 84} glass (Gl),^{17, 24, 67} calcium silicate (CS),^{56, 60, 86} CaP,⁶⁴ quarts⁷⁹ and vitamin C (VC).⁴¹

Characterization

Synthesized graphene, graphene derivatives and their compositions were chemically characterized using Fourier-transform infrared (FTIR)^{14, 21, 30, 36, 37, 42, 43, 45, 48, 61, 63, 65, 66, 68, 73, 74, 75, 84-86, 91, 92} and raman spectroscopy.^{13, 17-19, 21, 22, 24-28, 32-34, 36, 37, 40-42, 45, 47, 48, 54, 55, 57, 59, 61-65, 68, 69, 71, 72, 75-78, 86-89, 93} Also, morphology and topography of the samples were characterized by SEM,^{4, 13, 20-23, 25, 26, 29, 33-36, 38, 43, 45-56, 58, 60, 61, 63, 65, 66, 70, 71, 73-85, 87, 91, 92} field emission scanning electron microscope (FESEM),^{17, 40, 42, 44, 72, 79, 86, 90, 91} transmission electron microscopy (TEM),^{4, 18, 30, 31, 43, 44, 50, 53, 61, 64, 66, 71, 77, 80, 82, 86, 87, 89-94} and atomic force microscope (AFM).^{14, 17-19, 21, 24-26, 36-40, 42, 45, 47, 49, 53, 54, 59, 62, 69, 70, 77, 79, 80, 82, 89} Surface hydrophobicity of the composites and their chemical environments were evaluated by contact angle (CA) measurements^{14, 20, 28, 36-38, 41, 42, 46, 51, 54, 59, 61, 63, 68-71, 73, 76, 77, 78, 80-82, 88, 91} and X-ray photoelectron spectroscopy (XPS).^{17, 18, 23, 25, 36-38, 41-45, 54, 59, 60, 65, 66, 68, 69, 80, 87-89} Moreover, mineral phase on compositions were investigated by X-ray diffraction (XRD).^{4, 14, 17, 25, 34, 36, 37, 40, 43, 44, 47-49, 52, 60, 67, 70-77, 79-86, 89, 91, 92} Mechanical tests^{4, 14, 20, 21, 34-37, 42, 43, 52, 55, 56, 59, 61, 63, 67, 69, 70,}

78, 81, 86, 88, 91, 92 were employed in the various studies to evaluate mechanical strength. Inductively coupled plasma atomic emission spectrometry (ICP-AES)^{47, 65, 89} and inductively coupled plasma-optical emission spectroscopy (ICP-OES)^{49, 71} were employed to measure the release rate of ions, and inductively coupled plasma-mass spectrometry (ICP-MS)⁶⁴ was utilized to assess the Ca/P ratio. Additional assays and measures used for sample characterization include thermal gravimetric analysis (TGA),^{37, 71, 82, 84, 87} energy dispersive X-ray spectroscopy (EDX),^{33, 38, 50, 67, 73, 74} energy dispersive spectrometer (EDS),^{4, 13, 34, 44, 76, 80} porosity measurement,^{4, 35, 61, 75, 78} electrical tests,^{25, 35, 70} protein adsorption test,^{20, 22, 42, 43, 48, 63, 68, 75, 81, 91} ultraviolet–visible (UV-Vis) spectroscopy,^{49, 69} calcium absorption test,⁷⁰ dynamic light scattering (DLS),^{18, 30, 36, 66, 82} zeta potential (ZP) measurement,^{18, 29, 38, 40, 42, 47, 66} degradation rate measurement,^{48, 71, 75, 91} water absorption,⁷⁵ swelling study,⁷⁵ weight loss measurement,⁶⁰ diametral tensile strength (DTS),⁶⁰ nanoindentation measurements,^{67, 76} photoluminescence (PL) spectra,⁹⁴ elemental analysis experiment,²⁵ magnetometry,²⁵ selected-area electron diffraction (SAED),^{57, 91} wettability evaluation,⁸⁹ roughness evaluation^{14, 28, 89} and PL spectrum.⁹⁴

DISCUSSION

Various biomaterials, including ceramic phosphates and synthetic or natural polymers, have been widely used in BTE;^{2, 95, 96} however, the challenge of these materials matching chemical and material properties of natural bone still remains.⁹⁷ Graphene and its derivatives have specific mechanical, physical, and chemical properties and were shown to facilitate attachment and growth of cells and enhance osteogenic differentiation.¹⁰ In the current review, we conducted the comprehensive review on potential of graphene and its derivatives in promoting cell activities.

Factors affecting the cellular proliferation and viability

Various factors influence the cellular interactions of graphene families, which include graphene concentration, size, type, dimension and composition or functional groups (Fig. 2), as discussed below.⁹⁸

Figure 2 Factors affecting the cellular proliferation and viability.

Concentration of graphene

Despite all the studies regarding the dependence of the toxicity of graphene and its family on concentration, there are no general results about the safe concentration threshold. Many studies⁹⁸⁻¹⁰¹ concluded that concentrations <50 µg/mL of graphene nanoparticles (NPs) are relatively safe for most cell types, and levels higher than this concentration cause intracellular accumulation and high levels of oxidative stress, which is one of the mechanisms playing role in toxicity of carbon nanomaterials (CNMs).⁷⁵ Schinwald et al.¹⁰² studied layered graphene platelets with 1–10 layers at concentrations ≥ 5 µg/mL and found that it notably induced the release of LDH in immortalized human acute monocytic leukemia cells, THP-1, which is representative of loss of membrane integrity. Pristine graphene also induces cytotoxicity in cells by ROS generation through a decrease in potential of mitochondrial membrane and activation of mitochondrial pathway, leading to apoptosis.¹⁰³

Zhang et al.¹⁰⁴ investigated the toxicity of GQDs provided by single reduced graphene sheets (diameter: 5–10 nm) on three progenitor cell types: neurosphere cells (NSCs), pancreatic progenitor cells (PPCs), and cardiac progenitor cells (CPCs). They showed that in the presence of GQDs at 100 µg/mL for 3 days, NSC and CPC cell viability was above 80%, however, the cell viability for PPC was about 65%. All the cell groups were alive after incubation with GQDs at 25 µg/mL, which indicates that GQDs can be used as a beneficial biological platform with low cytotoxicity. Similarly, in a study by Qiu et al.,⁹⁴ a threshold for toxicity of GQDs to MSC cells was established at 50 µg/mL.

GO causes apoptosis of mitochondrial respiration by generating ROS and has a dose-dependent toxic effects on cells.¹⁰⁵ It was shown that GO with concentration of ≤1 µg/mL in culture medium reached 60% of viability of hMSCs, while at concentrations above 10 µg/mL, viability decreased to <20%.⁶⁴ Concentration of 20 and 85 µg/mL were observed to reduce cell viability by 20 and 50%, respectively.¹⁰⁶ In a study by Zancanela et al.,¹³ it was established that after 5 days incubation, osteoblasts with various concentrations of GO (10 to 350 µg/mL), samples with 25 and 50 µg/mL GO yielded greatest cell viability. Mazaheri et al.¹⁰⁷ revealed that 1.5 wt % GO in GO-Ct composites showed a proliferation rate of hMSCs similar to that of pure Ct, while in 3 and 6 wt %, GO cytotoxicity significantly increased. Some studies achieved little toxicity, even at higher concentrations. Based on one study, GO concentration <0.1 mg/mL demonstrated no cytotoxicity to hADSCs.¹⁷ Also, in a study by Chang et al.,¹⁰⁸ even high concentrations of 200 µg/mL GO exhibited about 67% viability of A549 cell after 24 h, and similar results could be achieved even after exposure for 48 and 72 h.

The study done by Talukdar et al.¹⁰⁹ investigating graphene NPs with three different morphologies illustrated that graphene nano-onions (GNOs), graphene oxide nanoribbons (GONRs) and graphene oxide nanoplatelets (GONPs) showed a dose-dependent toxicity. Viability of hBMSCs and hADSCs treated with GNOs, GONRs, and GONPs declined with increasing concentration in the range of 0–300 µg/mL, and concentrations of ≤50 µg/mL were observed to be potentially appropriate. In the similar study, 100 µg/mL of the GONR were reported to present no cytotoxic effect on osteoblasts.⁸⁵ RGO NPs also showed a dose-dependent decrease in cell viability, as concentrations >60 µg/mL seemed to reduce viability.^{58, 110} In a study by Mehrali M et al.,⁸⁶ 1.5 wt % RGO-containing composite displayed the most viable cells compared to CS with 1.0, 0.75, 0.5, 0.25, 0 wt % RGO.

To sum up, different concentrations of graphene and its derivatives have shown different toxicity toward various cell lines, indicating the dependency of the toxic effect of graphene on the type of cells. However, based on the literatures, it can be concluded that, up to 50 µg/mL for Graphene and GO, 60

$\mu\text{g}/\text{mL}$ for RGO, and 1.5 wt % for all^{56, 86, 107} seems to be safest to most of the cells lines. For future studies, we suggest a systematic research on evaluating the safe concentration threshold of graphene derivatives on different cell lines, individually.

Types of graphene

Type of graphene is another important parameter affecting cellular behavior. It was demonstrated that graphene has shown more toxicity compared to GO, as the aggregation of graphene sheet on the membrane of cells can inhibit nutrition transportation.¹⁰⁰ GO is more hydrophilic and biocompatible because of the oxygen-containing groups on its surface. However, some studies report that excess GO might lead to more ROS generation, causing death of cells.¹¹¹ Besides, it was discovered that levels ROS generated by synthesized GO with lower oxygenated degree were much higher than those with more oxygenation.¹¹² Several studies have shown that RGO is more compatible than GO, suggesting reduction may be a means to enhance the compatibility of GO-based biomaterials.^{105, 113} Bengtson et al.¹² revealed that ROS generated by GO was more than the RGO materials. Similarly, it was illustrated that human umbilical vein endothelial cells exposed to 10 $\mu\text{g}/\text{mL}$ GO and RGO with similar lateral sizes showed more viability in the RGO-containing group compared to GO group after 48 h, which revealed less toxicity of RGO than that of GO.

In contrast, some studies revealed that RGO exhibited dramatically higher effect on cell viability due to its hydrophobic features. In all studies mentioned above, graphene derivatives used in aqueous solution while the application of graphene derivatives as a substrate can be considered as an efficient way to overcome the cytotoxicity effect of that.^{54, 114} Akhavan et al.³⁸ reported that graphene (G) sheets grown by chemical vapor deposition showed not only excellent biocompatibility but also improve the cellular attachment of hMSCs. Indeed, the possibility of the aggregation of hydrophobic graphene derivatives on the cell membrane can be readily decreased by doping and coating them on the surface of materials such as Ti⁴² and polydimethylsiloxane (PDMS).⁵⁴ Moreover, the initial attachment between cells and surfaces can be affected by surface chemistry and roughness via ionic forces (directly) and adsorption of proteins (indirectly).¹¹⁵ Therefore, using different graphene derivatives as a substrate can enhance the surface roughness resulting in higher cell proliferation.¹¹⁴ Compared different graphene derivatives, oxygen-containing groups on GO⁴⁵ cause high capacity of protein adsorption through large surface area, intermolecular interactions¹¹⁶ and surface defects that could serve as binding sites for proteins¹⁰⁰ that contribute to cell attachment and viability.⁴⁵

It is important to note that conflicting results observed in comparing GO and RGO can be attributed to their different physical and chemical characteristics or different cell varieties. Conflicting results observed in comparing GO and RGO can be attributed to their different physical and chemical characteristics or different cell varieties.

Size of graphene

Smaller particles are more cytotoxic than larger particles, causing apoptosis through damaging the cellular membrane.¹¹⁷ Akhavan et al.¹⁰¹ treated umbilical cord-derived MSCs with graphene nanoplatelets of four different sizes (11 ± 4 nm, 90 ± 37 nm, 418 ± 56 nm, and 3.8 ± 0.4 μm) each at concentrations in the range of 0.01 to 100 $\mu\text{g}/\text{mL}$. The results showed that after 24 h at treatment with the smallest size, 11 ± 4 nm, and concentration of 100 $\mu\text{g}/\text{mL}$, >50% of the cells declined. In another study, it was demonstrated that microsheets of graphene with lateral dimensions <5 μm can penetrate the plasma membrane of mammalian cells and damage the lipid bilayer.¹¹⁸ Also, a nanosheet of

graphene with lateral dimensions of 100 nm-5 μm has been shown to be easily taken up and accumulate in cells.¹¹⁹ However, a higher uptake of a graphene NPs cannot be the major reason for the observed cytotoxicity.¹⁰⁸ A study by Talukdar et al.¹⁰⁹ demonstrated that in hADSCs treated with different graphene nanoparticles (GONRs, GNOs and GONPs), GONRs have more cytotoxicity than GONPs, while they did not indicate similar cellular uptake trend.

Bengtson et al.¹² discovered that ROS generated by few layered GO and RGO with lateral size above 1 μm were not toxic in FE1 murine lung epithelial cells at concentrations of > 200 $\mu\text{g}/\text{mL}$.

Reviewed studies indicated that graphene with lateral size of <5 μm and GO and RGO with lateral dimension <1 μm show decline in cell viability. In addition, higher uptake of a graphene is not the main reason for the observed cytotoxicity. More studies are underway to better comprehend the differences in cellular uptake of various size of graphene nanoparticles, including their uptake mechanism and the reasons for the observed variation in death of cells.

Dimension

Three-dimensional (3D) structure is known as a promising structure that better mimics the microenvironment and important features of the native extracellular matrix for cells. Kumar et al.¹⁴ investigated the effect incorporation of two-dimensional (2D) and 3D structures has on GO and RGO in PCL. They found that cells in the 3D scaffold had more cell-cell interaction due to their multicellular organization. The macroporous structure of the 3D foams ensured efficient nutrition substance transportation for cells' metabolic demands, which might facilitate cell proliferation.¹⁴ Researchers have demonstrated that 3D structured graphene, compared to 2D, provides larger accessible specific surface areas, interconnected conductive structure and unique surface microstructure,^{120, 121} which might improve cell growth and differentiation.^{122, 123} To further compare the compatibility of 3D and 2D structured graphene, Jiang et al.¹²⁴ synthesized 2D films and 3D foams of graphene and reported that 3D structured foams are more beneficial for migration of neural stem cells. Indeed, the 3D graphene foam could enhance cell migration through stromal-cell derived factor-1 α /CXCR4 signaling pathway, which is essential for the cell migration.^{125, 126} In a study performed by Liu et al.,¹²⁷ the incorporation of GO changes the 3D topography of scaffold by decreasing the fibrous diameter and porosity, which increases cell proliferation. So far, it is indicated that 3D structure of graphene can promote cell-cell interaction, migration and proliferation, however, few studies focused on the influence 3D architecture has on the cell proliferation, which deserves more consideration.

Modification of graphene and its derivatives

Graphene can be functionalized and combined with other biomaterials, which has the potential to influence cell viability and proliferation.¹²⁸ In this review, the effect combination of graphene with these kinds of materials (i.e., metals, polymers and minerals) on cellular behaviors is investigated.

Graphene and metals

Metals are widely utilized in several biomedical applications in pure or alloys forms due to their properties, including toughness, strength, and durability. Graphene has unique physiochemical features, especially its potential for osteogenic induction of stem cells, that make it a promising material for promoting surface modification and bioactive character of metal-based composites.⁴⁸ Several studies^{13, 26, 28, 45, 47, 50, 65, 69, 71, 76, 86, 89, 92} raised a debate regarding the influential role of metals combined with graphene on cell proliferation and viability.

The chemical functionalization of graphene is an efficient way to enhance its dispersibility and viability to generate various functional groups such as amino, hydroxyl, and carboxyl groups on the basal plane and over the edges.¹²⁹ These abundant groups could serve as nucleation sites for metals to anchor and grow through electrostatic and coordinate methods.¹³⁰ Thus, many metals and graphene derivatives composites have been fabricated for biomedical applications, demonstrating synergistic effects over the two individual components.^{131, 132} For example, Kumar et al.⁷¹ prepared RGO decorated with Sr NPs (RGO/Sr), promoting proliferation owing to the release of Sr²⁺ and hydrophilic nature of hybrid nanoparticles. Additionally, it was proven that cell proliferation was improved by RGO coated multipass caliber-rolled Ti alloy of Ti₁₃Nb₁₃Zr (MPCR-TNZ)⁶⁹ compared to MPCR-TNZ and GO-coated Ti compared to Ti-Na²⁶ and Ti.⁷⁶ Graphene sheets can act as substrates for metallic particles and as the storage sites for dissolved metal ions; therefore, preventing the aggregation of metallic particles, decreasing the toxic effects of metallic particles and resulting in the sustained release of metal ions.¹³³ For instance, In studies by Chen S et al.⁶⁵ and Chen J et al.,⁸⁹ the controlled release of ions, including Si (Iv) and Zn, from GO compositions stimulated cell proliferation. Release of >3 µg/mL Zn has been shown to be cytotoxic to cells.¹³⁴ However, GO-COOH, by providing ZnO NPs with anchor sites, prevents the rapid release of Zn and shows a sustained pattern of release without toxicity to the cells.⁸⁹ Likewise, Cu has been shown to improve osteogenic potential, however, since additional Cu in a composite causes oxidative damage,¹³⁵ the amount of Cu used in biomaterials is limited. In a study by Zhang et al.,⁴⁹ in order to release Cu ions moderately and to prevent the cytotoxicity and related adverse effects, GO-Cu nanocomposite was fabricated and deposited on the surface of porous calcium phosphate cement (Cpc) scaffolds. The good initial attachment and growth of rBMSCs on CPC/GO-Cu scaffolds show the successful results of nanocomposite of GO and Cu.

Various nanocomposites of AgNPs anchored onto GO have been successfully prepared. AgNPs can promote the formation of the callus and the reconstruction of bone defects through enhancing osteogenesis of bone cells via induction/activation of TGF-β/bone morphogenetic protein signaling.¹³⁶ However, they are shown the sustained release of a high dose of Ag ions during the degradation process of scaffolds, increasing cytotoxicity. In the study by Zhang et al.,⁵⁰ GNSs with a large number of functional groups, such as -COO⁻ and -OH, combined with AgNPs to form Ag-GO nanocomposites. Release of Ag⁺ from the scaffolds was shown to be well controlled below the concentration range, and scaffolds modified by Ag-GO nanocomposites maintained a high cell proliferation level.⁵⁰

Recently, a surface modification of Ti-based materials and promotion of their biological activities has gained attention of researchers in the field of biomaterial engineering.²⁸ A study performed by Dong et al.⁹² represented that by grafting GO on Ti by functional terminal groups, including -COOH, -NH₂, and -OH, the GO/Titanate OH-grafted composite was found to significantly improve cell viability. This increase in viability is likely due to the fact that -OH groups play a crucial role in modifying the surface to allow attachment of growth factors, proteins, or other biological molecules.⁹² Also, cell proliferation and viability were dramatically greater with Ti-GO than others. In a study by Subbiah et al.,⁷⁶ Fibronectin (Fn)-Ti-GO (i.e., Fn bound onto GO) showed the highest proliferation rate. They observed that the extensive filopodia formation improved cell migration and cell-cell interactions around preosteoblasts on Ti-GO and Fn-Ti-GO. These filopodia connections were dramatically found on the Fn-Ti-GO because of arginine-glycine-aspartic acid (RGD) binding moieties of Fn, which is in charge of cell attachment and proliferation. Similarly, graphene coating on the Ti alloy scaffolds also enhanced cell proliferation due to promoted adsorption of the growth factor of the seeding cells;²⁸ however, in some studies different

observations were reported. In a study by Qiu et al.,⁴⁷ increased layers of graphene coated on Ti showed less cell proliferation, and cells grown on Ti exhibited the greatest proliferation among all GO modified groups after 4 days. Indeed, increasing layer-number of GO resulted in decreased cell proliferation. In addition, Zancanela et al.¹³ showed that presence of GO decreased the osteoblasts' viability on Ti discs, while the viability of cells cultured on the plastic surface in the presence of 25 µg/mL GO increased up to 170% after 21 days.

Based on the most literatures a number of metallic particles and graphene derivatives composites have been prepared for biomedical applications, exhibiting synergistic effects over the two individual components. In addition, GO is one of the important derivatives of graphene used more than other derivatives with metals to result in positive effects on cell viability and proliferation.

Graphene and polymers

Polymer-based materials are widely used for biomedical applications since they are easily shaped and have adjustable chemical properties.¹³⁷⁻¹⁴⁰ However, some of the polymeric materials used in tissue regeneration have to simulate inflammatory reactions, and their degradation might simulate an autocatalytic ester breakdown than can decrease the pH in the microenvironment, causing problems for cell viability and differentiation.¹⁴¹ In order to overcome these limitations, graphene and its derivatives can be incorporated into polymers through different methods to produce composites exhibiting synergistic effects over the two individual components with improved properties.^{34, 36, 37, 46, 52, 61, 63, 66, 68, 70, 73, 75, 78, 91} Recently, graphene-polymer composites have been used for orthopedic applications.^{142, 143} For example, GO in Ct matrix was shown to affect interactions between cells and scaffold leading to improved cell proliferation.¹⁴² Interestingly, a few studies represented that biomaterial surface with multifunctional chemical groups can cause remarkable hemocompatibility and cytocompatibility¹⁴⁴ and affect the physical, chemical and biological features because of the synergetic effect of different chemical functional groups. Thus, the aim of this part is to investigate the effect of functionalized graphene nanoparticles in polymer composites on cell proliferation and viability.

Kumar et al.^{37, 71} investigated the influence of adding different graphene derivatives to polymer on cell behavior. They presented that addition of 3 and 5 wt % of GO, 5 wt % of RGO, and just 1 wt % of AGO in PCL led to a dramatic increase in proliferation compared to PCL only. AGO exhibited higher cell proliferation compared to GO and RGO, respectively, due to its higher chemical functionalization.³⁶ According to recent studies, among various graphene-based substrates, those with greater chemical functional groups generally present enhanced safety profiles.¹⁴⁵⁻¹⁴⁷ It was also reported that adding PEI conjugated GO in PCL was more effective in proliferation than only addition of GO.³⁷ The promoted proliferation on PCL-GO-PEI might be due to the hydrophilic and polycationic properties of PEI conjugated GO.¹⁴⁸

Additionally, in recent studies, incorporation of CNTs and GNSs to promote the mechanical properties of polymer has attracted attention of researchers.¹⁴⁹⁻¹⁵² Feng et al.³⁴ displayed the synergetic effect of CNTs and GNSs on enhancement of mechanical properties, as well as cellular behavior. They showed that a scaffold constructed by combination of HAP-PEEK with GNSs at 0.2 wt % and CNTs at 0.8 wt % had positive influence on cell proliferation with significantly more optical density than other treatment groups. Kaur et al.⁷¹ also investigated the effect of reinforcing PLGA with CNT, graphene nanoplates (GN) and active carbon (AC). They found that cells treated with GN-PLGA showed the highest viability due to its surface functional groups and high protein adsorption that enhanced the cell adhesion and growth.⁷¹

Furthermore, it was observed that GO incorporated in other polymers, including PLGA⁷⁶ and PLGA-tussah silk⁶¹ and also functionalizing Car with GO⁷³ increased the rate of cell proliferation and viability noticeably. This outcome can be attributed to the unique nanotopography of the graphene-reinforced polymer composites with considerable hydrophilicity of surface, which caused expression of various integrins and connexins.^{143, 153}

For biomaterials that have physical interaction with cell membranes, toxicity will probably be generated initially due to the disruption of the membrane integrity, followed by the production of intracellular enzymes (e.g., LDH), and, ultimately, apoptosis or cell death.¹⁵⁴ However, functionalizing RGO with PDA decrease this cytotoxicity, especially during the first days.⁶⁸ While bulk GO stimulated the strongest leakage of LDH, indicative of serious membrane damage, rGO-PDA only mildly affected the cell membrane. All These studies confirm the synergetic effects of graphene derivatives and polymers and enhanced cell proliferation on graphene-polymer composites.

Despite all the reviewed articles indicating positive effect of graphene on cell proliferation, in one study performed by Kanayama et al.,⁷⁰ early cell proliferation was shown to be dramatically inhibited on GO and RGO films coated COL compared to control culture plate, which is attributed to oxidative stress^{155, 156} that stimulates the inhibition of cell viability.

Based on the most reviewed literatures, graphene and its derivatives can be incorporated into polymers to produce composites with multifunctional chemical groups that represent synergistic influences over the two individual components exhibiting improved mechanical properties as well as better cell proliferation and viability. Moreover, it is noteworthy to mention that among various graphene-based substrates in graphene-polymer composites, those with greater chemical functional groups generally demonstrate more safety profiles. There are several opportunities for further development and optimization of graphene-modified polymer composites.

Graphene and minerals

Typically, minerals induce the differentiation of stem cells into osteoblastic lineage.¹⁵⁷⁻¹⁵⁹ However, they are innately brittle, hard to form and exhibit slow resorption rates.^{157, 160} Therefore, the development of strategies that can overcome some of these limitations is of interest for biomaterial studies. Notably, graphene and its derivatives can be incorporated into minerals, resulting in composites with both modified mechanical properties and modified osteogenic potential.

Among various graphene derivatives, GO was utilized in several studies to enhance the mechanical properties of mineral-graphene composites and behaviors of cells, including proliferation, viability and differentiation. For instance, GO–CaP nanocomposite with 0.5 µg/mL GO and 10 µg/mL CaP showed cell viability above 80%,⁶⁴ due to the hydrophilic surface of GO.¹⁰⁶ In a study by Xie et al.,²⁹ cells proliferated higher in the adsorbed Bone Morphogenetic Protein-2 (BMP2)-encapsulated bovine serum albumin (BSA) on GO than in other groups, including GO-tissue culture plates (TCP), BMP2-GO-TCP and pure TCP. Indeed GO modification increased the BMP2-encapsulated BSA adsorption capacity of HAP and TCP scaffolds,²⁹ which can be attributed to the carboxyl groups of GO interacted with the amino groups of the BMP2-encapsulated BSA via electrostatic attraction.⁴⁸ Bioactive glass nanoparticles (BGs) have a great potential to form a bioactive HAP layer and provide powerful surface bonding between bone tissue and implant.^{161, 162} Hence, Fan et al.⁶⁷ produced a novel BGs/GNSs composite scaffold. These scaffolds showed enhanced physical properties of BGs and cell viability of GO by mixing these materials.

They reported that by setting the mass ratio of BGs to GO as 10, cell viability was significantly improved.⁶⁷ Similarly, Xie et al.,⁵⁶ studying graphene reinforced into CS coatings, concluded that compared to pure CS, CS with 1.5 wt % of graphene were more favorable to cell proliferation after 6 days.⁵⁶ Regarding the effect of GO on CS bioactivity, Xie et al.⁴⁸ observed biomineralized octacalcium phosphate (OCP), known as a beneficial agent for cell proliferation,¹⁶³ on the surface of GO-CS scaffold, significantly enhancing cell proliferation. Oyefusi et al.⁸⁴ and Nair et al.^[23] reported that the HAP grafting onto the graphene sheets and incorporating GO nanoflakes into a Gn– HAP matrix enhanced total protein adsorption, as well as cell viability, respectively.

Besides GO, RGO have also been used in some studies to improve the cell viability and mechanical properties of minerals, but there is a controversy in the result of adding RGO on cell viability. CS is a novel biomaterial that causes effective osteoblast-like cell adhesion and proliferation, along with enhancing apatite formation, leading it to become an interesting substrate for hard tissue repair; however, the insufficient strength and toughness of this material is its limitation, which was promoted by RGO. However, adding RGO to CS had no significance influence on cell proliferation,⁸⁶ while in CS/graphene, it was shown that greater contents of graphene caused higher cell proliferation. Among 0, 0.25, 0.5, and 1.0 wt % graphene-containing composites, 1.0 wt % showed the highest cell viability.⁶⁰ In addition to CS, HAP is widely used in BTE because of its similar chemical composition to natural bones.^{164, 165} Nie et al.,⁴ showed that nanohydroxyapatite (nHAP)-incorporated in 3D RGO scaffold dramatically enhances cell behavior as well as mechanical strength, which suggests positive influence of RGO on HAP and vice versa. Among 0, 20, 40, and 80% nHAP-incorporated RGO, 20% nHAP-RGO showed the highest proliferation.⁴ This was confirmed, as Fan et al.¹⁶⁶ illustrated that the growth inhibition and proliferation of cells would be stimulated by over-dosed nHAP, due to its toxicity in terms of surface morphology, porosity, alkalinity feature and nutrient permeation. Finally, as it has been illustrated in most of the cases, the presence of sufficient oxygen functional groups on the surface of GO can make it more favorable to incorporate with different minerals so as to not only promote the mechanical strength but also modified proliferation and viability, which leads to effectively promoted differentiation.

Factors affecting the cellular attachment

Cell adhesion and spread within the scaffold are usually the first steps following seeding of cells onto the biomaterials, and therefore, have a significant effect on modulating the forthcoming cell responses, including cell proliferation and differentiation.⁴⁷ In most reviewed studies, presence of graphene and its derivatives resulted in accelerated cell adhesion and spreading,^{19, 21, 52} yet, there are few studies showing no difference between cell density on GO-coated substrates and noncoated substrate^{62, 79} Besides, in a study by Kanayama et al.,⁷⁰ GO and RGO films were found to show less DNA content compared to controls.

Various factors seem to be effective in cell adhesion and subsequent cell proliferation and differentiation, such as CA, hydrophilicity, functionalization, morphology, size, porosity, layers and roughness (Fig. 3),⁹⁸ as discussed below.

Figure 3 Factors affecting the cellular attachment.

Hydrophilicity, functionalization and roughness

A high CA value indicates the hydrophobicity of the scaffold surface, while a low CA describes the hydrophilicity.⁶⁸ Hydrophilic substrate can provide a surface that allow cells to adhere, spread and grow better on them.⁶⁹ Usually, hydrophilic surfaces lead to the attachment of adhesive proteins, such as Fn and vitronectin, which can facilitate cell adhesion and growth.¹⁶⁷ It was illustrated that the structure of the adsorbed proteins on surfaces with amine and hydroxyl groups helps more integrin bind in osteoblasts, enhancing formation of focal adhesions (FAs) and eventually activating the osteogenic pathways.³⁶ FAs, key factors for adjusting cells adhesion and migration, are a type of adhesive contact between cells and extra cellular matrix (ECM).^{168, 169} Cells cultivated on the GO film were found to have greater FAs compared to that on the uncoated GO materials.¹⁷

Kumar et al.^{36, 37, 71} investigated the effect of graphene derivatives on cell adhesion in three different studies. They indicated that the incorporation of GO and AGO nanoparticles in PCL increased the hydrophilic features of the composite, which can be result of hydrophilic functional groups on GO and AGO surface.¹⁷⁰ In contrast, adding RGO nanoparticles with no oxygen-containing functional groups decreased the hydrophilicity of PCL and did not dramatically influence cell adhesion. However, they reported in another study⁷¹ that decorating RGO with Sr resulted in increased wettability. It was observed that the amine nanoparticles of AGO in PCL tend to better adsorbed cell-adhesive proteins; therefore, AGO-PCL exhibited higher cell attachment compared to GO-PCL and RGO-PCL.³⁶ They also indicated that presence of GO-PEI in the PCL composite improved surface wettability more than addition of GO, and GO functionalized with PEI suggested a synergetic effect of chemical, as well as topographical, improvement for reinforcing cell adhesion and proliferation, particularly on PCL-GO-PEI with the highest content of GO (50 mg).³⁷

In a study by Kaur et al.,⁹¹ the hydrophobicity nature of PLGA is reformed by reinforcing it with carbon materials such as CNT, GN, and AC. Indeed, the oxygen-containing functional groups of these materials have hydrogen bond interactions with the water molecules, which causes the CA value of PLGA to decrease. Furthermore, GN-PLGA and CNT-PLGA were observed to have more hydrophilicity due to the existence of more carboxyl acid groups on their surface. Also, they found that surface roughness of carbon-based materials, as well as van der Waals and electrostatic forces between surface hydrophilic

groups of them, particularly GN, resulted in high protein adsorption playing a remarkable role in improving cell attachment.⁹¹

In a study by Lee et al.,⁵⁹ high adsorption capacity of graphene (up to 8%) and GO (up to 25%) for serum proteins was observed, whereas PDMS-adsorbed serum was just <1% after one day. Serum proteins are known to consist of several extracellular matrix globular proteins and glycoproteins, including albumin and fibronectin.¹⁷¹ Therefore, graphene and GO sheets showed better cell attachment compared to PDMS. For graphene, despite its hydrophobic feature, its π -electron cloud is able to interact with the hydrophobic core of proteins. For hydrophilic GO, the polar groups on the surface can bind to serum proteins through electrostatic connection.⁵⁹ It also has been reported in studies that G and GO have significant loading capacities for DNA and cytochrome C through intermolecular interactions.¹⁷² Li et al.²⁸ also discovered that GO coating promoted cell attachment and early extension of BMSCs on the Ti alloy scaffolds. The mean integrated optical density for vinculin is an important component for cell FAs,¹⁷³ was notably greater for scaffolds coated with GO than groups without GO. This might be due to the higher surface wettability and roughness of the scaffold with graphene coating.

In a recent study by Ren et al.,⁴⁵ BSA was chosen for further investigating the interaction of protein adsorption and cell adhesion. GO-Ti absorbed the highest amount of BSA compared to RGO-Ti. In fact, hydrazine reduction caused elimination of many functional groups, which weakened the electrostatic interaction between BSA and RGO-Ti. In a study by Jia et al.,⁶⁸ the number of MC3T3-E1 cells cultured on RGO-PDA was observed to be more than that on bulk GO due to the presence of PDA on the RGO, leading to decreasing the hydrophobicity of RGO. RGO-PDA showed high potential in adsorbing BSA that grafted to PDA through o-benzoquinone – amine coupling,¹⁵⁴ however, GO had a rougher surface and might have a greater capacity for holding protein. The better cell attachment on RGO-PDA may be due to the special role of PDA in mediating biological activity anchorage and stretching during cell attachment, leading to forming a beneficial matrix for stable adherence.¹⁷⁴⁻¹⁷⁶ In another study, utilizing RGO after incubation of synthesized RGO-MPCR-TNZ in serum protein for 2 hours, which had high CA value due to hydrophobic property of RGO, hydrophobic RGO surface became hydrophilic, and the CA value was dramatically decreased, inducing cell adhesion.⁶⁹

Although several studies have reported improved cell attachment and proliferation on hydrophilic scaffold surfaces, graphene with hydrophobic features can improve the cell adhesion. Similarly, in a study by Duan et al.,⁴⁶ it was illustrated that incorporation of multiwalled carbon nanotubes multiwalled carbon nanotube (MWCNT) and graphene in PLLA resulted in more mBMSCs adhesion, while hydrophobicity was increased compared to pure PLLA scaffolds. Increased hydrophobicity is due to the interaction between hydrophilic groups, including hydroxyl and carboxyl of CNMs, and the hydroxyl or carboxyl end-groups of PLLA through hydrogen bonds, leading to reduction in hydrophilic groups existing on the surface of scaffolds.⁴⁶ It was found that the effect of hydrophilicity of scaffold on cell behavior may depend on cell nature.²

Coating the metal surfaces with carboxyl, hydroxyl and amine functional groups was reported to contribute in enhancement of cell adhesion and proliferation.¹⁷⁷ For instance, coating Cu⁴⁹ and Ti²⁶ with GO could remarkably increase the amount of initial adherent cells. In addition, Subbiah et al.⁷⁶ improved the efficiency of GO-Ti by bonding Fn on GO and reported the expansive filopodia formation around preosteoblasts on the GO-Ti-Fn because of the cell binding moiety, RGD, of Fn that is accountable for cell attachment. Increased number of FA molecules, FA area per cell, and single FA diameter illustrated

that GO-Ti-Fn can be used as a suitable surface for cell adhesion and, consequently, FA formation. Also, Si-O-Si and Si-OH bonds in RGO-aminosilica hybrid were observed by FTIR.⁶⁵ These bonds were found to support the attachment and stimulate the proliferation of cells.^{178, 179} Si-O-Si bond was also found in CS/RGO⁸⁶ and BGs-GNSs composites.⁶⁷ Surface roughness is another important factor playing a significant role in the biological activity of biomaterials. In general, higher roughness provides larger surface areas to interact with protein molecules and cells, which are beneficial for cell adhesion, thereby promoting the biological activity of the biomaterials.^{92, 180-182}

It was demonstrated that the rough topology of a cross-linked GO film increases the tension of the cell scaffold and facilitates the growth of hMSCs.¹⁸³ Kim et al.¹⁵³ discovered that the specific nanomorphology of graphene (i.e., asymmetric nanostructures), as well as its rigidity and roughness, are vital factors for promoting the differentiation of hMSCs. From the studies above, it might be concluded that cell attachment on hydrophilic surfaces, such as GO and AGO, is improved since the hydrophilic surfaces cause much more adsorption of adhesive proteins and formation of FAs. However, moderate hydrophilicity was shown to be better for cell adhesion. Indeed, it was found that the effect of scaffold hydrophilicity on cell behavior is likely to depend on cell nature. Moreover, in most cases, graphene and its derivatives have been found to increase the surface roughness,^{28, 37, 59, 92} which can enhance cell adhesion with some limitations.

Surface area (porosity/pore size)

Porosity and pore size have enormous effects on cellular responses, including cell penetration within the scaffold and differentiation. Studies suggest that macroporosity (i.e., pores >50 μm) enhances osteogenesis through cell migration and blood vessel infiltration.^{184, 185} Microporosity (i.e., pores < 20 μm) is considered to help bone growth into scaffolds by increasing the surface area for protein adsorption,¹⁸⁶ improving ionic solubility in the microenvironment^{187, 188} and providing more adhesion sites for osteoblasts.¹⁸⁴ 3D GFs were seen to be highly porous with individual pore sizes $\geq 100 \mu\text{m}$, providing appropriate surface area for cell attachment.³³

It was also reported that adding GO to the polymer matrix caused decrease in interconnected pore size and provided a massive porous structure.^{61, 189} The optimal pore size in scaffolds to mimic ECM employed in BTE is reported to be in the range of 150–300 μm .¹⁹⁰ In a study by Saravanan et al.,⁷⁵ addition of GO decreased the pore size of scaffold from ≥ 220 to $\leq 180 \mu\text{m}$. Therefore, the presence of interconnective pores in GO-CS-Gn scaffolds supported cell infiltration, nutrient transfer and metabolic waste elimination. Furthermore, in a study by Nie et al.,⁴ it was obvious that number of cells adhered to 20% nHAP-incorporated RGO was much more than that on 40% nHAP-RGO and 80% nHAP-RGO scaffolds. This can be attributed to porous structure of RGO scaffold, which can be changed by incorporating different contents of nHAP. However, in some studies, no significant influence of graphene on porosity was observed. Zhang et al.,⁵⁰ showed that the Ag-GO on β -TCP surfaces had no significant influences on the porosity of the scaffolds. Finally, it can be reported that porous structure of graphene and its family provides appropriate surface area for cell attachment and spreading, and therefore enhances osteogenesis through cell migration and blood vessel infiltration.

Factors affecting the cellular osteogenic differentiation

Graphene has been found to not only influence cell attachment, migration, and proliferation, but also promote the differentiation of stem cells to different lineages (Fig. 4).^{114, 191, 192}

Figure 4 Factors affecting the cellular osteogenic differentiation.

Graphene and its derivatives' properties affecting osteogenesis

Several studies confirm the osteopromotive activity of graphene,^{24, 57, 59, 93} GO,^{33, 62, 79, 192} RGO^{58, 77} and GQDs.⁹⁴ It was demonstrated that cells cultured on graphene exhibit higher levels of mineralization and significantly up-regulated osteogenic genes and proteins, including Runx-related transcription factor 2 (Runx2), COL and OCN,²⁴ even without the use of osteogenic medium (OM).^{33, 62} The mechanisms of how graphene affects stem cell behavior remains unknown. It seems cooperation of factors, such as nanoscale structure, high stiffness, roughness, oxygen-contained functional groups, and absorption of biomolecules on graphene and its family, prepare suitable environments for cell behavior regulation such as attachment, proliferation, and differentiation.¹⁷

In the presence of osteogenic inducers, it was revealed that the mineralization of MSCs cultured on graphene was more enhanced than on GO and the PDMS control. Graphene adsorbed the remarkably higher amount of dexamethasone (Dex) and β -glycerolphosphate compared to GO and PDMS, which can be attributed to the π - π bond between the aromatic structure of Dex and the graphene structure.⁵⁹ Dex is a synthetic glucocorticoid changing the expression levels of many proteins and enzymes demanded during osteogenesis.^{193, 194} In fact, graphene increasing the local concentration of Dex on its surface increases mineralization and causes fast and influential cell differentiation. In addition, in the study by Ren et al.,⁴⁵ GO-Ti samples showed larger adsorption of Dex compared to RGO-Ti samples. The ALP activity, mineralization and osteopontin (OPN) and OCN expression of Dex-GO-Ti was more than Dex-RGO-Ti and Dex-Control. However, GO-Ti and RGO-Ti in the absence of Dex were found to not influence ALP activity effectively.⁴⁵ Dex is not the only chemical that is in charge of directing cells to osteogenic differentiation, but it has a synergistic effect with β -glycerolphosphate, binding to graphene by H-bonding and intracellular ALP enzyme for mineralization.⁵⁹ Besides, it has been proven that ascorbic acid (AA) influences mainly postdifferentiation,¹⁹⁵ and GO, which has a high density of oxygen functionalities,

showed greater degree of H-binding with AA compared to graphene. ALP, an early and quantitative osteoblastic differentiation marker, is a significant factor in formation of hard tissue. ALP helps in declining the concentration of extracellular pyrophosphate, which inhibits mineralization and increases the inorganic phosphate concentration to enhance mineral formation.⁵⁹

Another factor that may influence osteogenic differentiation is graphene morphology. Talukdar et al.¹⁰⁹ investigated the graphene NPs with three different morphologies: GNOs, GONRs, and GONPs. Greater ALP activity was observed after treatment of hBMSCs with 10 µg/mL GONR. In a similar study by Ricci et al.,⁸⁵ up to 100 µg/mL of GONR seemed to not dramatically change gene expression of ALP, OCN, OPN and Runx2, whereas higher concentrations (200 µg/mL) showed reduction in expression of genes, playing a critical role in bone regeneration process.

Several studies reported that RGO can induce osteogenic differentiation individually. For example, in a study by Jin et al.,⁵⁸ the amount of ALP synthesized after 14 days and mineralized nodule after 21 days by the cells on RGO NPs was found to be significantly higher than those of the other groups without RGO NPs. Indeed, π -electron cloud of graphene and its derivatives cause interactions with the inner hydrophobic core of proteins.⁵⁹ Also, because of the H-bonding and electrostatic interactions, graphene allows the noncovalent binding of proteins and osteogenic inducers on its surface.¹⁹⁵ Interestingly, the 3D-rGO film was observed to offer a faster osteogenic differentiation of MC3T3-E1 compared to RGO, indicating the 3D structure is beneficial for osteogenic differentiation.^{14, 77}

Although graphene can enhance osteogenesis, it can be chemically modified or combined with other materials to further induce its osteopromotive activity, such as other carbon-based materials, hydrogels, metals, minerals or polymers. Recently, it has been shown that graphene combined with single-walled carbon nanotube (SWCNT) exhibited better mineralization rather than administration of graphene and SWCNT alone. The G/SWCNT hybrids increased the level of expression genes of OCN, OPN, and Runx2 in a dose-dependent manner. The G-SWCNT hybrids at a concentration of 10 µg/mL after 14 days illustrated the greatest mineralization. It has been reported that graphene and SWCNTs exhibited high surface area in the G-SWCNT hybrids, which led to greater adsorption of osteogenic inducers and proteins from the culture medium. Hydrogel was found to enhance the strength and flexibility of graphene film.⁹³ Lyu et al.²⁰ utilized the self-supporting graphene hydrogel (SGH) film for cell seeding and reported the greater levels of the OCN, ALP, BMP2, and Runx2 genes expression, as well as higher ALP activity and mineralization on SGH compared to graphene and carbon films. These findings might attributed to two factors; first, the wrinkled and rippled nanostructure of SGH surface showed significantly higher protein absorption rate, such as BSA molecules compared to other carbonaceous films; second, the SGH film indicated higher hydrophilic surface, which is a vital factor for protein interactions with the surface.

All the results above confirmed the capability of graphene and its different derivatives in improving osteogenesis of stem cells.

Modification of graphene and its derivatives

Incorporation of graphene and its families in the materials utilized for bone reconstruction—metals, polymers and minerals—promotes osteoconductivity via stimulating bio-mineralization as well as cellular osteogenesis, as discussed below.

Graphene and metals

Several studies have utilized metals with graphene.^{13, 26, 28, 38, 39, 45, 47-49, 65, 71, 76, 89, 92} GO is widely reported as an efficient adsorbent for metal NPs.^{196, 197} In studies by Chen S et al.⁶⁵ and Chen J et al.,⁸⁹ controlled release of Si (Iv)⁶⁵ and Zn⁸⁹ ions from GO composition were reported, which can be attributed to the negatively charged surface of GO contributing to the stability of the positively charged metallic ions.¹⁹⁸ Chen J et al.⁸⁹ showed that synthesized carboxylated GO (GO-COOH) offers anchor sites for ZnO NPs to prevent ZnO NPs from releasing rapidly. Thus, GO caused sustained release of Zn ions for a relatively long-term, which was shown to enhance ALP activity and OCN secretion. It was reported that a proper dose of zinc ions could promote cell proliferation and differentiation,⁸⁹ while a high concentration of Zn ions might cause cytotoxic reactions.¹⁹⁹ This promotion could be due to the mitogen-activated protein kinase (MAPK) pathway.⁸⁹ Zn ions induce formation of osteoblastic COL, therefore increase the binding of osteoblasts to matrix integrins, which activate the MAPK pathway. This pathway transduces signals to phosphorylate to ALP and Runx2, which then bind to the promoter region of the OCN gene.

Many studies^{26, 38, 39, 47, 76} used titanium incorporated with graphene for enhanced osteogenesis. It is proven that surface roughness and hydrophilicity of Ti can affect differential Wnt pathways and signaling molecules, leading to the osteogenic differentiation.²⁰⁰ Studies by Zhou et al.²⁶ and Subbiah et al.⁷⁶ suggested that the level of gene expression of collagen type I (COL-I) and OCN were more up-regulated on GO-Ti substrate than on Na-Ti²⁶ or Ti.⁷⁶ In addition, binding Fn onto GO-Ti composition led to the higher levels of osteogenesis than GO-Ti substrate, which was confirmed by ALP activity and ARS staining.⁷⁶ Likewise, in a recent study by Li et al.,²⁸ GO coating on Ti alloy significantly promoted the osteogenesis, which might be attributed to the outstanding surface activity of graphene that increases the capacity of adsorption of the growth factors of the seeding cells to GO-Ti alloy. Zancanela and collaborations¹³ reported that in a situation demanding Ti, such as in prostheses and implants, the use of GO might promote mineralized nodule formation, biomineralization, and accelerate bone formation.

La et al.^{38, 39} evaluated the bioactivity of BMP2 released from Ti and Ti-GO-substrates. The notable higher level of expression of OCN and ALP was observed in the groups with GO, due to the better conformational stability, greater bioactivity, and increased local concentration of BMP2 on the Ti-GO surface. This increase can be due to the interactions between π -electron clouds in the GO and the inner hydrophobic cores of BMP2, and electrostatic interaction between negatively charged carboxylic groups of GO and the positively charged BMP2. In fact, GO caused sustained release of BMP2, which both play significant role in bone formation.

In another recent study by Qiu et al.,⁴⁷ the effect of varying numbers of layers of GO deposited on Ti on osteogenesis was investigated. With increasing the layer-number of GO, wrinkling as well as roughness may promote the cell-material interactions and improve the osteogenic differentiation, though, as stated earlier, increase in thickness or number of layers could reduce cell adhesion and proliferation.

In a study by Dong et al.,⁹² the surface chemistry of GO was optimized by constructing -COOH, -OH and -NH₂ terminals through covalent bonding, then grafting these GO sheets on Titanate. This study showed that the scaffold terminated with -OH groups significantly enhanced differentiation compared to those with other terminated groups. The scaffold terminated with -COOH showed less effect on osteogenesis due to the fact that it induced ROS by contributing electrons to oxygen molecules as a result of its high ZP in cell culture medium.

Kumar et al.⁷¹ illustrated that the incorporation of RGO decorated with Sr in PCL was found to have enhanced mineral deposited compared to PCL-RGO composites and neat PCL. These differences were more evident as the amount of the hybrid RGO-Sr particles increased.⁷¹ The Sr ions were found to be beneficial for improving differentiation, even in the absence of osteogenic inducers,²⁰¹ since these ions contribute to the activation of calcium sensing receptors and osteoblast markers.^{202, 203}

Zhang et al.⁴⁹ illustrated that GO and GO-Cu used to coat the Cpc enhanced ALP expression and OCN. GO-Cu was found to be more influential than GO. Moreover, they reported that use of GO, and especially GO-Cu, boosted the activation of Hif-1 α through the Erk1/2 signaling pathway causing higher expression of vascular endothelial growth factor (VEGF) and BMP2, two principal regulation factors of osteogenesis. In addition, Ag NPs have exhibited a special property to effectively enhance the osteogenesis of mBMSCs at concentrations of 5–10 μ M.^{136, 204} Zhang et al.⁵⁰ discovered the controlled release of Ag⁺ from the Ag-GO- β -TCP, with concentration below the concentration range. GO has showed high adsorptive ability for AgNPs due to the hydrophilic features and high specific surface area of GO. This adsorption could enhance the osteoinductivity properties of biomimetic GO scaffolds.⁴⁸ At short term, Ag was seen to inhibit proliferation of bone cells at the defect sites. However, at a long-term, scaffolds can promote BMSC differentiation toward the osteogenic lineage.

Most of the studies included in this section have provided evidence that incorporation of metals and graphene promote the differentiation of stem cells. Also, graphene has been shown to help sustained release of metals.

Graphene and polymers

Several included papers^{14, 34, 36, 37, 46, 52, 61-63, 66, 68-70, 73, 75, 78, 90, 91} investigated the different polymers improved by graphene and its derivatives or vice versa.

Four included studies have reported a successful use of Gn as a modifying agent. Indeed, Gn improved the HAP nucleation through its negatively charged carboxylate groups existing on its surface.⁷⁴ Liu et al.⁷⁴ used Gn functionalized GO to mimic charged proteins existing in ECM and observed a higher amount of ALP activity, as well as fibrous organic bundles for GO-Gn compared to GO and Gl. In the study performed by Saravanan et al.,⁷⁵ the addition of GO at the concentration of 0.25% in Ct-Gn scaffolds improved apatite deposition, as confirmed by XRD. The -NH₂ and C=O functional groups of Ct were reported to contribute to bio-mineralization.⁴⁸

Zou et al.⁸⁷ demonstrated that Gn-derived graphene/laponite (GL) powder enhanced osteodifferentiation due to the physical stresses induced on cells, as a result of the surface topographic, stiffness and roughness of graphene sheet.⁸⁷ Furthermore, the GL-powder promoted matrix mineralization of the cells by increasing BMP9-induced osteogenesis; BMP9 is one of the most potent to induce MSC osteogenic differentiation.

Two polymers of PET-based artificial ligaments with low known bioactivity⁷⁸ and nHAP/PA66⁵² were promoted by graphene and showed more osteoability represented by notably up-regulated expression of ALP and OCN compared to polymers alone. This can be attributed to graphene enhancing the adsorption of the growth factors and chemicals containing benzene rings, such as β -glycerophosphate and Dex.⁵² Also, the electric characteristics of CNMs may be a significant factor in this improvement.²⁰⁵

Nayak et al.⁶² compared the effect of common growth factors (BMP2) and graphene on osteogenesis. Without BMP2, graphene coating dramatically increased differentiation of all substrates (glass slide, Si/SiO₂, PET and PDMS), while this increase was more pronounced with the stiffer substrate (glass slide and Si/SiO₂). On the other hand, in the presence of BMP2, it was observed that coating graphene on the stiffer substrates did not further improve the production of calcium deposits, but a clear dramatic increase was seen on the softer materials, PET and PDMS. This again represents that graphene itself has a significant role in the osteogenesis of hMSCs.

A study done by Kumar et al.³⁷ illustrated that the PCL-GO-PEI exhibited more mineralization and ALP activity compared to the PCL-GO and neat PCL. The greatest graphene and GO-PEI content (5 wt %) in the PCL-GO5 and PCL-GO-PEI5 exhibited highest mineralized deposition. This increase for the PCL-GO-PEI may be rooted in the fact that the GO-PEI is rich in amine and oxygen-containing functional groups, which have been proved to promote FAs^{206, 207} and adsorption of the osteogenic inducers (β -glycerol phosphate, Dex and AA), followed by the PCL-GO and, finally, neat PCL. They showed in another study³⁶ that composition of 5 wt % of AGO (PCL-AGO5) and 5 wt % of GO (PCL-GO5) with PCL exhibited 40 and 25% higher mineralization than neat PCL, respectively. It was observed that mineral deposition increased with increase in content of GO and AGO in PCL. The more mineralized deposits, such as HAP, calcium and phosphorous, on the PCL-AGO5 may be due to the fact that the combination of AGO and PCL proposed both amine and carboxyl functional groups, which led to better mineralization.

In one study by Jia et al.,⁶⁸ ALP expression, COL secretion and Ca²⁺ content on PDA-functionalized RGO, and particularly on bulk GO, was improved compared to that on commercial pure titanium (cpTi). For RGO-PDA, it can be stated that the amine groups of PDA cause great interaction with the graphene, as well as provide active sites for mineral ions, therefore improving apatite nucleation and growth.²⁰⁸ For bulk GO, beside polar groups in its structure, the special topographical ridges known as “graphene patterns” deserve consideration as they provide biophysical cues for greater improvement in osteogenesis. Furthermore, micropatterned geometries of graphene were illustrated to be influential in stem cell differentiation.¹⁸ Another article by Kanayama et al.,⁷⁰ comparing GO and RGO films coated COL, displayed that cells adhered to RGO illustrated the highest ALP activity, due to high adsorption of Ca²⁺ on RGO rather than that on GO. This significantly high Ca²⁺ accumulation on RGO can be attributed to AA used as reducing agent that was adsorbed onto the GO surface and interacts well with Ca²⁺. On the other hand, Kumar et al.¹⁴ demonstrated that functionalized groups on the GO surface and its tendency toward adsorbing osteoinductive factors led to better mineralization compared to nonfunctionalized RGO. As there are distinct results from comparing osteoability of GO and RGO, generalization in this case is not acceptable.

Using Car could enhance the bioactivity of GO, as it was shown that cells cultured on the GO-Car exhibited greater levels of ALP activity, along with increased mineral deposits consisting of COL fibers and some matrix vesicles, loaded with CaP crystals, than those on the GO and glass. Also, the Ca and P contents and calcium deposition of GO-Car film were significantly more than the GO film. This is because of the carrageenan's effect on cell proliferation and differentiation, and the improved nucleation of HAP due to sulfate groups on GO-Car surface, which promote the calcium binding.⁷³

In some studies^{20, 36, 37, 64, 69, 71, 109} it was represented that cells cultured in osteogenic media, mostly supplemented with osteogenic factors such as Dex, ascorbate, and β -glycerolphosphate,⁵⁹ illustrated improved osteogenesis in comparison with cells cultured in nonosteogenic media. For example, cells

cultured on MPCR-TNZ, RGO-MPCR-TNZ, and Dex-RGO-MPCR-TNZ in nonosteogenic media suggested relatively inadequate osteogenic tendency compared to that in osteogenic media.⁶⁹ On the other hand, seldom different results have been reported. For instance, in one study by Elkhenany et al.,⁵³ cells cultivated on GO in growth medium showed notably greater alizarin red content compared to cells grown on GO in the presence of the differentiation medium.

Reviewed studies suggest that graphene and its derivatives, due to their unique features and remarkable osteability, are good choices to not only overcome polymer limitation but also improve their osteoconductive effects.

Graphene and minerals

An alternative strategy for improving the osteogenic potential of stem cells is to utilize mineral materials with graphene family.^{4, 20, 21, 29, 40, 41, 48, 56, 60, 64, 72, 74, 75, 86, 87}

In three other studies,^{56, 60, 86} CS was utilized as a mineral agent. Si is known as a principal component of the CS and has a mitogenic effect on human osteoblast cells,²⁰⁹ acting via the insulin-like growth factor II.²¹⁰ Si ions released from materials have been shown to stimulate differentiation, gene expression and proliferation, which can be considered as evaluation criteria for bioactivity.^{210, 211} Mehrali et al.⁸⁶ demonstrated that Si concentrations in simulated body fluid, level of ALP activity, and the amount of HAP formed on the surface of composites increase with increase in RGO content. In CS-RGO composites, CS – 1 wt % RGO composite has the best performance among other groups: 0.25, 0.5, 0.75 and 1.5 wt % of RGO. Similarly, it was reported that the expression level of ALP, OCN, and OPN enhanced with increasing graphene content in graphene-CS composites.^{56, 60}

In some studies, HAP is utilized with 3D-graphene³⁵ and RGO.^{4, 40, 72} The expression level of OCN, OPN, and COL-I enhanced in both composites, while in the former this expression mainly remained less than that in HAP.³⁵ It was found that HAP and RGO have an interactive effect on the early and late osteogenic differentiation markers. Therefore, cells exposed to RGO-HAP exhibited higher osteogenesis.^{40, 72} For nHAP-RGO, despite up-regulated relative expression of Runx2 with using 20% nHAP-RGO scaffold, its value initially enhanced to the maximum at day 7, after which it dropped down at day 14. This observation might be due to the role of the Runx2 as a key transcription factor to launch early osteogenesis.⁴ Oyefusi et al.⁸⁴ also grafted HAP onto the surface of graphene sheets and treated cells with various concentrations (200 and 400 ng/mL) of them at different temperatures (34 and 39°C). Interestingly, they found that G-HAP400 at 39°C showed higher OCN expression than G-HAP400 at 34°C, and the opposite occurred for GO-HAP200.

Incorporation of GO in CaP exhibited great levels of ALP activities and OCN expression, as well as high calcification compared to GO and CaP individually, which suggests synergistic contribution of GO and CaP to promoted osteogenesis.⁶⁴ This increase can be attributed to not only increased connection between the intracellular FA complexes of the cells and the CaP on GO–CaP composite,²¹² but also to higher stiffness of these composites than solely GO or CaP.²¹³ It is reported that increased stiffness of materials leads to improve a mechano-transduction influence for differentiation regulation.²¹⁴

Recently, Xie et al.^{29, 48} utilized GO nanolayer to provide anchor sites for the immobilization of BMP2-encapsulated BSA (Nps) on HAP and TCP. Nps-GO-HAP scaffold showed the highest ALP activity compared to BMP2-GO-TCP, GO-TCP and pure TCP. This scaffold provided a nanostructure with charge-balanced surface, achieved by negative charged GO, positive charged Nps, and long-term sustained

release of BMP2. All of these factors synergistically enhance the BMSCs proliferation and differentiation. Moreover, the results of ALP assay show that the immobilization of BMP2 on the surfaces of GO-modified CaP scaffolds improve their osteoinductivity.

Although the utilization of graphene family and minerals can improve the osteogenic differentiation of stem cells individually, it seems that the combination of these materials may provide better features to induce and enhance cell differentiation.

LIMITATIONS

Several limitations were found in the included articles, which deserve to be considered:

1. Some studies did not investigate cell attachment, even though it has an important role modulating the forthcoming cell responses, like cell differentiation.⁴⁷
2. Since the cytotoxicity of graphene and its derivatives impose serious limitation on biomedical application, evaluation of viability and proliferation of cells exposed to them is very important, however, some studies did not evaluate this kind of cell response. In addition, MTT assay performed in 21 included studies was discovered to be not successful in predicting the toxicity of graphene and its derivatives due to the spontaneous reduction of MTT by them, leading to a false positive signal.¹⁰⁰ Therefore, to evaluate the toxicity of graphene, it is much better to use alternate assays, such as water-soluble tetrazolium salt (WST-8) assay,⁵⁸ ROS assay,⁴¹ CCK-8 assay^{52, 76, 77, 79} and DNA counting^{25, 36, 37, 71}
3. In nine included studies the type of the MSCs, and in one study, type of the preosteoblast cells were not defined.
4. Size (i.e., thickness and lateral dimension), topography of graphene surface (roughness) and hydrophilicity of graphene (CA) are the important factors affecting the graphene bioactivity, were not measured in some studies.
5. In most of the included studies, C/O ratio of graphene, indicative of oxidation state, was not determined as a significant criteria, which made it impossible to make a reasonable comparison between studies.

CONCLUSIONS

The current review is systematic review regarding the effect of graphene and its derivatives on cell osteogenic differentiation. Despite the limitations in the included studies, which made the comparison difficult, some general conclusions can be drawn:

1. Different concentration of graphene and its derivatives have shown different toxicity toward various cell lines, demonstrating the dependency of the toxic effect of graphene on the type of cells. However, based on the literatures, it can be concluded that, up to 50 µg/mL for Graphene and GO, 60 µg/mL for RGO, and 1.5 wt% for all seems to be safest to most of the cells lines.
2. GO seems to be more biocompatible than graphene, while the conflicting results were observed in comparing GO with RGO.
3. Graphene with lateral size less than 5µm and GO or RGO with lateral dimension less than 1 µm showed decline in cell viability.
4. Graphene and its derivatives incorporated with metals, polymers, and minerals showed promoted mechanical properties and bioactivity, in most cases.

5. Graphene and its derivatives have been found to increase the surface roughness, which can highly enhance cell adhesion and differentiation.
6. Graphene exhibits better osteogenic differentiation result compared to GO, but making comparison between osteogenic potential of GO and RGO is not feasible to precisely due to the contradictory reports.
