Abstract

A double-blind, randomized, controlled, parallel-group prospective trial was conducted to determine whether a dose-response existed for four different levels of docosahexaenoic acid (DHA) supplementation on the cognitive performance of infants. A total of 122 term infants were fed one of four different formulas varying in their DHA composition (0.00%, 0.32%, 0.64% and 0.96% of total fatty acids as DHA) from birth to 12 months. The three DHA-supplemented formulas also contained 0.64% of total fatty acids as arachidonic acid (ARA, 20:4n-6). Infants were tested at 4, 6, and 9 months of age on a visual habituation protocol that yielded both behavioral and psychophysiological indices of attention. Infants in all DHA+ARA-supplemented conditions had lower heart rates than those in the unsupplemented condition; there was no dose-response for this effect. The distribution of time that infants spent in different phases of attention (a cognitive index derived from the convergence of behavioral and cardiac responses) varied as a function of dosage. Infants supplemented at the two lower DHA doses spent proportionately more time engaged in active stimulus processing than infants fed the unsupplemented formula, while infants fed the highest dose were intermediate and did not differ from any other group.

Introduction

The central nervous system (CNS) is highly enriched in docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (ARA, 20:4n-6), but of these two fatty acids, only brain DHA content has been shown to vary as a result of postnatal dietary intake (1, 2). CNS DHA accumulates rapidly during the last intrauterine trimester and in the first two years of life (3, 4). A number of randomized studies of DHA supplementation have been designed with the intent of understanding the functional consequences of increasing postnatal DHA exposure. The majority of these studies have measured visual acuity. In term infant studies, both

positive (5, 6) and null (7–9) effects of postnatal supplementation have been observed, with positive effects typically manifest as an accelerated developmental function for visual acuity during the first year of life.

Learning and cognition are also outcomes of interest given the large amount of DHA that accumulates in the brain, relative to other organs. Indeed DHA has been reported to affect learning and cognition in both animals (10, 11) and humans (12, 13). However, the results of studies using global assessments of early cognitive function (e.g., the Bayley Scales of Infant Development, or childhood IQ tests, such as the Stanford Binet or Weschler tests) as outcomes of long-chain polyunsaturated fatty acid (LCPUFA) supplementation or status are mixed. Investigators have reported benefits on the Brunet-Lezine Scale (14, 15), the Bayley Scales (16), and the Weschler Primary Preschool Scale of Intelligence (17). Null effects have been reported with the Bayley Scales (18) and with the Stanford Binet (19). Both a recent systematic review (20) and a meta-analysis (21) concluded that the Bayley Scales of Infant Development are unaffected by LCPUFA supplementation.

More precise measures of cognition in infancy have long been available from techniques developed for experimental laboratory studies (22). Indeed, measures of attention in infancy tend to be more closely correlated with later cognitive function than outcomes on global tests of early development (23, 24). Moreover, higher DHA exposure in utero has been associated with first year behavior indicative of accelerated attentional development (25) suggesting a potential value for attention as a means of evaluating the effects of LCPUFA supplementation on cognition. Prior randomized clinical trials of postnatal DHA supplementation have not included measures of attention. Furthermore, no previous randomized trial has examined the possibility of a dose-response with respect to the effect of DHA on development, thus inhibiting progress toward the establishment of a standard for DHA intake or supplementation.

Here, we report the results of postnatal LCPUFA supplementation with 3 levels of DHA supplementation on a specific measure of developing cognition; i.e., infant attention and learning in a visual habituation paradigm (26). Along with behavioral indices of attention during visual habituation, we assessed heart rate (HR) and the quality of attention through the conjunction of HR deceleration with visual fixation, which allows the calculation of heart-rate defined phases of attention (27). The inclusion of measures of HR within the cognitive paradigm also allowed for a test of the effects of specific LCPUFA supplementation in infancy on cardiac variables; the extant literature suggests that LCPUFAs (especially omega-3 fatty acids) may affect HR and HR variability through a number of candidate mechanisms (28, 29).

Methods

Data reported here were for planned secondary outcomes specific to one of the two sites involved in the DIAMOND (*DHA Intake And Measurement Of Neural Development*) study (registered as NCT00753818 at www.clinicaltrials.gov), a double-masked, randomized, controlled, parallel-group prospective trial designed primarily to measure sweep visual-evoked potential acuity. The primary outcomes of this trial were red blood cell DHA and ARA in response to formula and visual acuity development. The results have been reported elsewhere, and the report includes a complete description of study design, growth, formula intake and tolerance, red blood cell DHA and ARA in response to formula, and adverse events (30).

Participants

The trial enrolled healthy, term, formula-fed, singleton-birth infants (37–42 weeks gestation; 2490 to 4200 grams birth weight) born in the Kansas City metropolitan area between September 3, 2003 and September 25, 2005. Exclusion criteria included the receipt of human milk within 24 hours of randomization, conditions known to interfere with normal growth (e.g., low birth weight; metabolic anomalies) or development (e.g., maternal chronic infectious, metabolic or renal disease or evidence of alcoholism or substance abuse), poor formula intake, or intolerance to cow's milk infant formula. Informed consent was obtained from all subjects and the study was approved by the Human Subjects Committee at the University of Kansas Medical Center.

Design and Randomization

During the first week of life, infants were randomly assigned to one of four cow's milk-based term infant formulas, which varied only in LCPUFA content. Control infants were fed formula containing no DHA or ARA. Three groups received supplemented formulas varying in DHA. One group received 0.32% of fatty acids from DHA (17 mg/100 kcal), a second received 0.64% (34 mg/100 kcal), and a third received 0.96% (51 mg/100 kcal). All three DHA supplemented formulas included 0.64% of fatty acids (34 mg/100 kcal) from ARA. DHA was derived from single-cell algal oils; ARA from fungal oils (Martek Biosciences, Columbia, MD). Blood level analyses were conducted on the four groups for DHA at 4 and 12 months of age, and have been reported elsewhere (30).

Randomization was performed by and held exclusively by the study sponsor during the conduct of the research. Each of the four formulas had two different codes, for a total of 8 codes. All personnel recruiting infants, parents or guardians, researchers, study monitors, and pediatricians were blind to the infants' study formula group allocation. Infants were fed the study formulas for the first 12 months without limits. Gender was balanced across all groups.

Procedures

Infants were evaluated at the study site at 4, 6, and 9 months of age on a visual habituation protocol that was augmented with simultaneous measurement of HR. In visual habituation, the infant's visual and cardiac responses are assessed to repetitive stimulus presentations; the decline in responses to the stimulus is generally interpreted to indicate learning of the stimulus. Details of the testing situation, stimuli, and recording of infant looking are reported at length elsewhere (25, 31). The stimuli used in habituation tests were static color presentations of adult faces, chosen from a set used in previous research. Infants were habituated to one face at each visit, in a session lasting 5 to 15 minutes in length. The face stimuli used in the study were counterbalanced across ages, so that no infant saw the same stimulus twice.

Testing Sequence—A 20s–30s baseline period was conducted prior to the start of the session, during which HR was collected with no stimulus present. Infants were then habituated to static visual stimuli using an infant-controlled sequence (32), with a criterion of two consecutive looks at a 50% decrement from the previous longest look and a “floating-point” criterion (33). A valid fixation was defined as a look of 1 s or more in duration; fixations were considered to be terminated when the infant looked away for 1 s or more (34). The stimulus was removed after termination of a fixation, and a subsequent interstimulus period of 2s ensued.

Measurement of HR—HR was measured with shielded Ag-AgCl electrodes placed on either side of the infant's chest and grounded with an unshielded electrode on the abdomen.

The infant's electrocardiogram (EKG) was digitized at 250 Hz sample rate. The data acquisition interface also received input from the microcomputer that controlled the timing and presentation of stimuli so that HR could be synchronized with stimulus events and the coding of fixations.

Data Reduction and Statistical Treatment

The time stamp of each infant's R-wave was derived from the digitized EKG and synchronized with time stamps from stimulus events and infant behaviors. Along with the calculation of infant HR during the session, this protocol capitalizes on the fact that infants typically show HR deceleration while looking. This deceleration has been used to derive different types of attention during looking (35); the actual decelerative phase is called *sustained attention* (SA), and has been shown to reflect active engagement with, and processing of, the stimulus (35). The period preceding SA reflects simple *orienting* (OR) to the stimulus, and the period after SA reflects disengagement from the stimulus (*attention termination*, or AT). The derivation of these phases is explicated in detail elsewhere (31). For our purposes, the proportion of time spent in SA was the measure of interest. For purposes of brevity, analyses for OR and AT are not shown here (they were unaffected by Formula) but these phases are represented in Table 3 and Figure 1.

Statistical Methods—As a whole, the trial was powered for the primary outcomes of visual acuity (30). Heart rate and looking variables from the habituation session were subjected to mixed-model factorial analyses (using PASW Statistics 17.0, formerly SPSS) using fixed factors of Formula (4) and Age (3). Age was entered into the model as a repeated factor, subjects as a random factor, and covariance was left unstructured. This analysis uses all available data in longitudinal applications, while allowing for simultaneous age comparisons, assessment of Age \times Formula interactions, and assessment of overall main effects. An accounting of subjects from 4 to 9 months is shown in Table 1.

Results

Three primary measures were analyzed for this study: peak look (i.e., the longest look duration observed during habituation), a behavioral measure taken from the habituation session that is thought to reflect the relative rapidity with which the infant learned or encoded the stimulus (32), the proportion of time spent in sustained attention (averaged across trials), a HR-defined phase of attention, as described above, and (c) mean HR during periods of baseline, pre-looking, and looking (also averaged across trials; the latter being parsed by the three respective phases of attention described above).

Look Duration Measures

The analysis for peak look duration (see Table 2) showed a significant decline in look duration with age, $F(2, 100.912) = 22.542, p < .001$, but no effects of formula.

Sustained Attention

Analyses of the HR-defined phase of sustained attention (also in Table 2) showed significant main effects for both Age and Formula but no significant interactions. The proportion of time spent in SA declined significantly with age, $F(2, 104.743) = 6.971, p = .001$, with SA being significantly higher in the two intermediate doses of DHA (0.32% and 0.64%) relative to controls ($p = .035$ and $p = .005$, respectively). The highest DHA dose (0.96%) did not differ from either controls or the two other doses, and the Age \times Formula interaction did not approach statistical significance.

Infant HR

As expected, infants' HR showed a consistent change with age (all $ps < .001$) for every variable tested during the session; overall, HR in beats per minute (bpm) declined from 146 to 138 to 133 at 4, 6, and 9 months, respectively. In addition, lower HR was observed consistently for all three supplemented groups, relative to controls. A summary figure (see Figure 1) shows mean HR for the four groups across baseline, pre-looking, and looking (including across each of the three HR-defined phases of attention). At each age, the main effects for Formula group ranged from $p < .05$ to $p < .01$ (in no case did any two-way interaction attain significance), with pairwise comparisons showing each of the three supplemented groups 5 to 9 bpm lower than the unsupplemented controls.

Discussion

Positive effects of postnatal DHA supplementation in term infants are typically seen above 0.20% total fatty acids as DHA (14, 16), but concentrations of DHA in human breast milk can vary well beyond these levels, suggesting that systematic tests of doses at higher levels are desirable. The analyses of data from infant psychophysiological responses and on the quality of attention at 4, 6, and 9 months showed significant and positive effects of LCPUFA supplementation on the quality of attention in infants from 4 to 9 months of age.

There were no Formula effects or interactions on the peak look variable from habituation. The age effect observed here for this variable has been routinely reported in prior research (33) and is generally attributed to older infants' more rapid processing of stimuli during habituation (26). The lack of any significant effects involving Formula here contrasts with prior results indicating sensitivity of look duration to LCPUFA status in preterm infants or to maternal LCPUFA status in full-terms (25, 36).

The proportion of time spent in SA, which is the phase of attention most strongly linked to active information processing in human infants (37, 38), was *increased* relative to controls in the 0.32% and 0.64% DHA doses, but not at the highest (0.96%) dose. The finding of increased SA was observed across all ages at which the measure was taken (4, 6 and 9 months). Given that this improvement was not linearly related to DHA dose, we are inclined to posit DHA levels as the source of the effect on SA; since SA at the highest DHA dose was not statistically distinguishable from the two lower doses, however, the contribution of ARA cannot be definitively ruled out, as the power of the study may be less than optimal for comparing individual conditions to one another. If the effect is attributed to DHA, this would represent the first indication that higher doses of DHA may not incur proportional benefit. In a previous observational study, higher maternal DHA status at birth was found to be associated with lower look duration in later infancy (25); within the context of those results, SA was also observed to be lower in infants from high-DHA mothers, which is what one would expect as look duration is reduced. However, in the previous study, DHA status was observed to reduce look duration, in the current one LCPUFA supplementation did not. We have observed that when look duration is reduced across or within sessions, the proportion of SA is reduced, and is generally displaced by OR (39). This appears to be due to the fact that OR represents a latency to decelerate that is fairly constant; in briefer looks, OR takes up a larger proportion of looking, and essentially takes this proportion from SA. The increase in SA in the 0.32% DHA and 0.64% DHA formula conditions is interpreted as the maintenance of engaged cognitive processing in the context of equal amounts of looking; we see this as a positive benefit of supplementation. It is important to note that the recent results of a large longitudinal study show that infants who show reliable age-related decreases in look duration while maintaining high levels of SA across the first year show better performance on language and cognitive outcomes out to age 4 (40).

LCPUFA supplementation also reduced infants' overall HR when measured during the administration of the visual attention task. The main emphasis of the original study was on dose effects for DHA; it was hypothesized that the three DHA-supplemented groups would vary. The fact that manipulation of DHA dose covaried with the presence of ARA in the formula (i.e., the control formula had neither DHA nor ARA) makes interpretation of this effect complicated, as the reduction in HR (relative to the control group) was statistically equivalent for each of the DHA dose levels. As such, we cannot definitively attribute this effect to the sole action of either of these compounds. The positive effect of LCPUFAs on cardiovascular health in rodents and human adults has been known for some time (41, 42), and there have been multiple reports of reductions in HR or increased HR variability as a result of some form of increased n-3 LCPUFA intake (43, 44).

Our finding here is also in accord with the results of a previous clinical trial of fish oil supplementation in infants (45) and a preliminary report on an observational study of DHA intake in infants and toddlers (Pivik RT et al. 2008 Resting heart rate in infants and toddlers: Variations associated with early infant diet and the omega 3 fatty acid DHA. Forty-Eighth Annual Meeting of the Society for Psychophysiological Research, October 2–4, 2008, Austin, Texas, Poster 123), both of which report decreases in HR in relation to DHA status. The pathways through which LCPUFAs influence heart period are not definitively known, although candidate mechanisms include reduced oxygen consumption (46), electrophysiological mediation of the heart rhythm (44), or various forms of autonomic gating originating in the CNS (47, 48). The effect of lowering HR in adult populations is viewed as a positive health outcome and has been suggested to impart positive impacts on affective, cognitive, and behavioral outcomes (48). HR declines systematically with age during infancy (31) so the effect may also represent the acceleration of psychophysiological maturation.

In summary, the current findings add further experimental evidence for the positive health and cognitive effects of LCPUFAs in neurodevelopment in human infants. Further research will necessary to definitively dissociate the effects of AA from DHA on HR and SA; the current work may be constrained by limited power for these particular variables. Future reports will focus on the long-term implications of the improvements in attention observed with moderate DHA supplementation.

Figure 1. Mean HR (collapsed across age) for four formula groups at critical points of interest during the habituation task. Squares represent 0.0% DHA/0.0% ARA (unsupplemented controls); circles represent 0.32% DHA/0.64% ARA; triangles represent 0.64% DHA/0.64% ARA; diamonds represent 0.96% DHA/0.64% ARA.

Table 1

Available data for study conditions across ages tested. "Total" reflects the number of infants within each group. Shown are number of infants successfully tested, and number lost at each age due to fussiness and attrition/missed appointment. "Complete" are the number of infants within each group that successfully completed session *at every age*.

Study Group	Outcome	4 mos	6 mos	9 mos	Complete
0.00% DHA, 0.00% ARA	Successful	24	23	18	15
	Fussy	3	2	5	
	Attrition	4	6	8	
	Total	31			
0.32% DHA, 0.64% ARA	Successful	30	27	23	21
	Fussy	1	1	6	
	Attrition	1	4	3	
	Total	32			
0.64% DHA, 0.64% ARA	Successful	22	23	19	16
	Fussy	4	3	4	
	Attrition	0	0	3	
	Total	26			
0.96% DHA, 0.64% ARA	Successful	28	30	24	20
	Fussy	3	1	4	
	Attrition	2	2	5	
	Total	33			
Sum	Successful	104	103	84	72
	Fussy	11	6	19	
	Attrition	7	13	19	
	Total	122			

Table 2

Estimated means and standard errors (SE; in parentheses) from Age X Group mixed model analyses for peak look (expressed in s), and proportions of time spent in SA.

Variable	Group	4 mo	6 mo	9 mo	Overall Mean
Peak Look	0.00% DHA, 0.00% ARA	33.5 (6.94)	27.7 (5.21)	13.7 (2.27)	25.0 [†] (3.45)
	0.32% DHA, 0.64% ARA	39.0 (6.71)	23.9 (5.02)	14.8 (2.02)	25.9 [†] (3.31)
	0.64% DHA, 0.64% ARA	46.1 (7.46)	18.4 (5.53)	11.6 (2.27)	25.3 [†] (3.66)
	0.96% DHA, 0.64% ARA	33.8 (6.70)	22.6 (4.86)	18.8 (2.05)	25.1 [†] (3.28)
Overall Mean (SE)		38.1 [†] (3.48)	23.1 [†] (2.58)	14.7 [§] (1.08)	25.3 (1.71)
SA	0.00% DHA, 0.00% ARA	.450 (.043)	.420 (.042)	.298 (.045)	.389 [†] (.027)
	0.32% DHA, 0.64% ARA	.528 (.041)	.470 (.041)	.412 (.040)	.470 [†] (.025)
	0.64% DHA, 0.64% ARA	.598 (.046)	.439 (.045)	.461 (.045)	.500 [†] (.028)
	0.96% DHA, 0.64% ARA	.426 (.041)	.473 (.039)	.414 (.040)	.437 [†] (.025)
Overall Mean (SE)		.500 [†] (.021)	.451 [†] (.021)	.396 [‡] (.021)	.449 (.013)

[†] Shared symbols for Group and Age overall means denote values that do not statistically differ from one another within that row or column

[‡] Shared symbols for Group and Age overall means denote values that do not statistically differ from one another within that row or column

[§] Shared symbols for Group and Age overall means denote values that do not statistically differ from one another within that row or column

Table 3

Estimated means and standard errors (in parentheses) from Age X Group analyses for infant HR (expressed in bpm) from each segment of habituation trial. Mixed model main effects for Formula at each point shown are as follows: Baseline, $F(3,104.54) = 3.63, p=.015$; Pre-Looking, $F(3, 108.17) = 2.85, p=.041$; $F(3, 108.45) = 4.13, p=.008$; OR, $F(3, 105.20) = 2.87, p=.040$; SA, $F(3, 109.02) = 3.48, p=.019$; AT, $F(3, 90.96) = 3.28, p=.024$.

HR During:	Formula Condition	Age (mos)		
		4	6	9
Baseline	0.00%DHA/0.00%ARA	150.2 (2.08)	143.0 (1.93)	135.0 (2.80)
