Abstract

Purpose: Item Response Theory (IRT) is a psychometric approach to measurement that uses latent trait abilities (e.g., speech sound production skills) to model performance on individual items that vary by difficulty and discrimination. An IRT analysis was applied to preschooler's productions of the words on the Goldman-Fristoe Test of Articulation-2 (GFTA-2) to identify candidates for a screening measure of speech sound production skills.

Method: The phoneme accuracies from 154 preschoolers, with speech skills on the GFTA-2 ranging from the 1st to above the 90th percentile, were analyzed with a two-parameter logistic model.

Results: A total of 108 of the 232 phonemes from stimuli in the sounds-in-words subtest fit the IRT model. These phonemes, and subgroups of the most difficult of these phonemes, correlated significantly with the children's overall percentile scores on the GFTA-2. Regression equations calculated for the five and ten most difficult phonemes predicted overall percentile score at levels commensurate with other screening measures.

Conclusions: These results suggest that speech production accuracy can be screened effectively with a small number of sounds. They motivate further research towards the development of a screening measure of children's speech sound production skills whose stimuli consist of a limited number of difficult phonemes.

1
2
3
4
5 Screening measures of children’s speech sound production skills typically follow the
6
7 protocol of more comprehensive articulation and phonological tests: children are asked to name
8
9 pictures of familiar items that elicit the range of consonant phonemes that are typically acquired
10
11 during the preschool and early elementary years (e.g., Fluharty, 2001). Pass and fail criteria are
12
13 based on phonetic transcriptions of children's productions. Screening tasks typically weigh each
14
15 phoneme or word equally, regardless of the ages at which they are typically developed or their
16
17 impacts on intelligibility. It is unclear, however, if such a broad-based method is the most
18
19 effective or efficient way to meet the purposes of screening, namely, identifying the need for
20
21 further evaluation or referral to another professional (ASHA, n.d.). It may be that a shorter word
22
23 list, focused on a subset of phonemes in specific word positions, would be better for
24
25 distinguishing children with and without potential speech sound disorders (SSD). One challenge
26
27 to developing an effective screening instrument for SSD is determining which phonemes in
28
29 words best discriminate children with difficulty from those with typical development. The
30
31 present study explored this by applying an Item Response Theory (IRT) analysis to 154
32
33 children’s productions of the sounds-in-words subtest of one commonly used standardized test of
34
35 children's speech production, the Goldman-Fristoe Test of Articulation – 2 (GFTA-2; Goldman
36
37 & Fristoe, 2000).

38
39 IRT is a collection of statistical models that estimate the probability of a person
40
41 answering an item correctly based on an estimate of the person’s underlying latent trait as well as
42
43 item parameters that relate to features such as discrimination, difficulty, and guessing. By
44
45 choosing a particular IRT model, it is possible to better understand how items function, to
46
47 develop tailored assessments, and to use a wide variety of psychometric tools (see de Ayala,
48
49 2009 for basic information on IRT). Although IRT has been primarily used in educational
50
51
52
53
54
55
56
57
58
59
60

1
2
3 assessment and psychological research, IRT has been part of research studies in communication
4
5 sciences and disorders since the 1980s (Baylor et al., 2011), with a notable increase in its
6
7 application over the past 15 years. Recent IRT applications have addressed different aspects of
8
9 assessment including, but are not limited to, examinations of performance differences across
10
11 populations (Baylor et al., 2013; Baylor et al., 2014; Hula, Doyle, McNeil, & Mikolic, 2006;
12
13 Justice, Bowles, & Skibbe, 2006) or multiple forms of the same test (Hoffman, Templin, & Rice,
14
15 2012); the precision, weighting, or validity of items within a test (Baylor, Yorkson, Bamer,
16
17 Britton, & Amtmann, 2010; Chenault, Berger, Kremer, & Anteunis, 2013; Edmonds & Donovan,
18
19 2012; Fergadiotis, Kellough, & Hula, 2015); and the development of a computerized adaptive
20
21 version of an existing test (Hula, Kellough, & Fergadiotis, 2015). In addition, and of particular
22
23 relevance to the present investigation, IRT has successfully assisted the development of
24
25 screening protocols based on existing tests, banks of test items, and previously collected research
26
27 data. This work has addressed a wide range of communicative skills, including expressive
28
29 language skills of Spanish-speaking preschoolers (Guiberson & Rodriguez, 2014); hearing aid
30
31 acceptance, functionality, and use in adults (Chenault, Anteunis, Kremer, & Berger, 2015;
32
33 Demorest, Wark, & Erdman 2011; Mokkink, Knol, van Nispen, & Kramer, 2010); participation
34
35 across communication contexts by adults with a variety of disorders (Baylor et al., 2013); word
36
37 naming in adults with aphasia (del Toro et al., 2011), and vocabulary development in young
38
39 children (Makransky, Dale, Havmose, & Bleses, 2016).
40

45
46
47

48 The current study focused on childhood SSD. Children with SSD present with poor
49
50 speech intelligibility as the result of motoric, linguistic, cognitive, sensory, or unspecified issues.
51
52 Estimates of their prevalence among preschool and elementary aged children range from 2% to
53
54 25% of the general population (Law, Boyle, Harris, Harkness, & Nye, 2000). Clinicians and
55
56
57
58
59
60

1
2
3 researchers identify children with SSD through a combination of standardized tests, spontaneous
4
5 speech samples, and measures to rule out other causes, such as an oral mechanism examination
6
7 to rule out structural anomalies. To date, there have been no published studies examining the use
8
9 of IRT to develop an assessment tool for children with SSD. The present study addresses this
10
11 need through the following research questions. The first focused on the phonemes identified with
12
13 the IRT model. The second and third explored the utility of those phonemes, and subsets of the
14
15 phonemes with the greatest difficulty scores, to serve as a screening measure of children's
16
17 speech sound production skills.
18
19
20
21

- 22 1. Which phonemes within the stimuli of the sounds-in-words subtest of the GFTA-2 would fit
23 within an IRT model?
24
- 25 2. How well do children's performance on the phonemes in the IRT model, and subsets of those
26
27 phonemes, correlate with their percentile score performance on the GFTA-2?
28
29
- 30 3. How strongly can children's percentile score performance on the GFTA-2 and identification
31
32 as having or not having a speech sound disorder be predicted from their performance on the
33
34 phonemes from the IRT model and subsets of those phonemes?
35
36
37
38

39 **Method**

40
41 The participants were 154 monolingual boys and girls between 3 and 7 years of age, with
42
43 and without SSD. This age group was selected because this is an age at which SSD is most likely
44
45 to be diagnosed, and hence which is subject to a high number of speech and language screening
46
47 assessments. The participants' data were collected as part of multiple previous research studies
48
49 conducted by the third and fourth authors (e.g., Munson, Baylis, Krause, & Yim, 2010; Munson
50
51 & Krause, 2016; Storkel & Hoover, 2010; Storkel, Maekawa & Hoover, 2010). All usable data
52
53 were included; No potential participants were specifically included or excluded in order to best
54
55
56
57
58
59
60

1
2
3
4 fit the IRT model. IPA transcriptions were available for each child's productions of the 53 words
5
6 on the sounds-in-words subtest of the GFTA-2. Age and percentile scores, however, were only
7
8 available for 133 of the participants. These children had a mean age of 57.2 months (4 years, 9
9
10 months, \pm 12.73 months) and included 34 3-year-olds, 39 4-year-olds, 44 5-year-olds, 9 6-year-
11
12 olds, and 6 7-year-olds (one child's age was not identified).

13
14
15 The GFTA-2 (Goldman & Fristoe, 2000) was chosen because it is among the most
16
17 widely used standardized tests of children's speech production conducted in used in the 15 years
18
19 prior to this study. Its norming sample includes children with and without SSD between the ages
20
21 of 2 years, 0 months and 21 years, 11 months. Standard scores on the GFTA-2 are based on
22
23 children's performances on the sounds-in-words subtest, in which their productions of target
24
25 phonemes within a picture naming task are scored as correct or incorrect. The GFTA-2 percentile
26
27 score performances of the 133 participants with complete data sets ranged from 1 to 98, with a
28
29 mean of 32.92 (\pm 29.55). The children with SSD included articulatory and phonological issues of
30
31 unknown origin, not secondary to other sensory or cognitive issues or diagnoses such as
32
33 childhood apraxia of speech. As shown in Figure 1, the percentile score performances of these
34
35 children, at each age, reflected the GFTA-2's distribution in which progressively fewer children
36
37 scored at lower ends of the percentile score range. The GFTA-2 was administered and scored
38
39 using its standard method, in which children are prompted to name pictures. Children who do
40
41 not name pictures spontaneously are given a series of progressively greater support until they
42
43 produce the target word. Responses are phonetically transcribed.

44
45
46 Each of the 154 participants' attempts at the 232 individual phonemes included in the
47
48 GFTA-2's sounds-in-words subtest was treated as a separate item, and scored dichotomously as
49
50 correct or incorrect. Because phonemes were nested within individual words (e.g., the /s/ in
51
52
53
54
55
56
57
58
59
60

1
2
3 *house* was discrete from the /s/ in *stars*), consonant clusters were categorized by their constituent
4
5 phonemes (e.g., *stars* included separate entries for /s/, /t/, /ɑ/, /r/, and /z/). Items that were
6
7 answered incorrectly by fewer than 5 participants were eliminated because they did not have
8
9 enough variance for analysis. IRTPro 2.0 was used to fit the two-parameter logistic (2PL) model
10
11 to all 232 items of the test (Paek & Han, 2012). IRTPro is a software package that estimates IRT
12
13 parameters using a variety of possible IRT models. Although there are many models that could
14
15 have been chosen for these data, the 2PL was selected because it allows items to vary on both
16
17 difficulty and discrimination, two features found to be important in modeling items. In addition,
18
19 the 2PL was a reasonable choice given the relatively small sample size. The 2PL model is
20
21 represented by the following formula:
22
23
24
25

$$26 \quad P(u = 1|\theta) = \frac{1}{1 + e^{(-a(\theta-b))}}$$

27
28 where *a* refers to the item *discrimination* (i.e., the strength of the relation of that item to the
29
30 underlying trait), *b* refers to the item *difficulty*, and θ refers to the latent trait being measured by
31
32 the trait. The 2PL formula uses the item parameters (*a* and *b*) in conjunction with the person
33
34 parameter (θ) to predict the probability of answering an item *u* correctly. The parameters, both
35
36 item and person, are estimated via IRTPro using maximum likelihood estimation. An iterative
37
38 process was carried out to estimate item parameters, eliminating items that did not fit the 2PL
39
40 through using the χ^2 goodness-of-fit statistics estimated by IRTPro. After eliminating poor fit
41
42 items, the analysis was re-run, continuing to throw out items until the model fit acceptably well
43
44 (i.e., that there were no items that had significant misfit as judged by IRTPro's χ^2 statistics).
45
46
47
48
49
50
51

52
53 Once the IRT analysis was complete, additional statistical analyses were conducted to
54
55 identify a) the degree to which the model accounted for the children's overall performances on
56
57
58
59
60

the GFTA-2 and b) the predictive accuracy of a subset of phonemes from the model to discriminate children with and without potential SSD.

Results

To test whether the data satisfied the requirement of sufficient unidimensionality, a factor analysis of tetrachoric inter-item correlations was conducted (necessary because the data were dichotomous) and found that the first factor accounted for 31.5% of the variance in the scale. This satisfied the requirement that Reckase (1979) identified that the first factor in an exploratory factor analysis needed to account for at least 25% of the variance to satisfy the unidimensionality assumption of IRT.

The final IRT model consisted of 108 phonemes, which are listed in the Appendix in order from the highest to lowest difficulty score. They included all of the American English consonants, except for /h/ and /ʒ/, and the vowels /i, ɪ, ε, æ, ə, ʌ, ə-, aɪ, aʊ/. The consonants, as a group, occurred in initial and final syllable positions, and as singletons and within clusters. The phonemes in the 2PL model were from 49 of the 53 words on the GFTA-2 (i.e., all words except for *ball*, *house*, *ring*, and *thumb*) and included 47 of the 92 phonemes used to determine percentile scores on the GFTA-2.

The analysis began by exploring which area of the underlying trait, commonly denoted by the Greek letter θ in IRT research, provided the most psychometric information. Information is an IRT-based concept that quantifies the amount of precision provided by the test at varying levels of θ . Traditional measurements of precision, such as standard error of measurement or reliability, assume that the precision is uniform throughout the range of the trait being measured. This assumption is likely untrue for many tests given that some tests are designed to be easy, so that at-risk individuals can be identified, whereas other tests are designed to identify top talent.

Applying IRT to GFTA-2

9

1
2
3 In IRT, the *test information function* allows test users to identify at what range of the trait the test
4 provides precision and at what ranges the test is relatively imprecise. Figure 2 shows the test
5 information function for the 108-item 2PL model. The most information was provided in the
6 negative range of the trait continuum, as demonstrated on the left side of the figure in which the
7 total information values were higher than the standard error, meaning that the test as a whole was
8 able to provide the most precise measurement at the low ability. There was relatively little
9 precision at the high end, as shown on the right side of the figure where the standard error
10 outranked the total information. This suggests that an instrument based on this model would not
11 be able to distinguish well between children with the very best speech sound production skills
12 from those at the upper end of the normal range. The greater precision in the negative range is in
13 line with the goal of using items from the GFTA-2 as a screening test because it emphasizes
14 differentiating children who are functioning below the normal range from those who are within
15 the normal range. To increase measurement precision in the positive range, it would be
16 necessary to write additional items that were high in difficulty and able to discriminate between
17 average and high ability respondents.

34
35
36
37
38
39 Correlations between the percentile scores on the GFTA-2 from the 133 participants with
40 complete data sets and their summed accuracy scores of a) the 92 phonemes used to determine
41 the percentile scores, b) the 108 phonemes in the 2PL model, and c) various subsets of the
42 phonemes in the model with the greatest difficulty scores are presented in Table 1. Significant
43 correlations with GFTA-2 percentile scores were found for each of the groups assessed, with r^2 -
44 values from 0.16 to 0.66. Two sets of multiple regressions were run to determine how well
45 combinations of the percentile score phonemes and each group of 2PL phonemes contributed to
46 the children's GFTA-2 percentile scores. In the first set, the percentile phonemes were entered
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 prior to the 2PL phonemes. As shown in Table 1, all but two of the 2PL groups (the 108 and the
4
5 2 2PL groups) contributed significantly after the effects of the percentile phonemes were
6
7 accounted for ($p \leq 0.05$). In the second set, the 2PL phonemes were entered before the percentile
8
9 score phonemes. In this set, the percentile phonemes accounted for significant additional
10
11 variance after the 1-, 2-, 3-, and 5-phoneme 2PL groups were entered ($p < 0.01$). However, the
12
13 contribution from the percentile phoneme group was not significant after any of the 2PL groups
14
15 with 10 or more phonemes were taken into account ($p > 0.09$).
16
17
18
19

20 The 3-, 5-, and 10-phoneme 2PL groups (see Table 2) were examined as potential
21
22 candidates for a screening measure because they were the smallest 2PL groups that accounted for
23
24 as much variability in GFTA-2 percentile scores as the 92 phonemes used to determine those
25
26 scores ($r^2 = 0.53, 0.62, 0.67, \text{ and } 0.57$ respectively). This process began by calculating separate
27
28 regression equations for each of these groups on the children's GFTA-2 percentile scores. All
29
30 three equations were significant at the 0.05 level ($p < 0.01$). The regression equation for the 3-
31
32 phoneme group was predicted GFTA-2 percentile score = $(12.66 * /s/ \text{ in } stars) + (29.76 * /r/ \text{ in } crying) +$
33
34 $(12.54 * /θ/ \text{ in } bath) + 7.94$. The 5-phoneme group's regression equation was predicted
35
36 GFTA-2 percentile score = $(10.38 * /s/ \text{ in } stars) + (21.53 * /r/ \text{ in } crying) + (12.61 * /θ/ \text{ in } bath) +$
37
38 $(5.11 * /r/ \text{ in } tree) + (13.61 * /ʃ/ \text{ in } fishing) + 1.81$. Finally, the 10-phoneme group's regression
39
40 equation was predicted GFTA-2 percentile score = $(6.42 * /s/ \text{ in } stars) + (6.40 * /r/ \text{ in } crying) +$
41
42 $(6.05 * /θ/ \text{ in } bath) + (-1.19 * /r/ \text{ in } tree) + (12.21 * /ʃ/ \text{ in } fishing) + (7.35 * /r/ \text{ in } brush) + (9.15 * /ð/ \text{ in } feather) +$
43
44 $(9.14 * /ŋ/ \text{ in } monkey) + (16.08 * /r/ \text{ in } rabbit) + (-2.35 * /v/ \text{ in } vacuum) - 0.65$.
45
46
47
48
49
50

51 Each of these equations was then applied to the 133 participants' productions, yielding
52
53 estimated percentile scores. Their utilities as speech screening measures were evaluated by
54
55 calculating sensitivity, specificity, and likelihood ratios for cut off points that best approximated
56
57
58
59
60

1
2
3 1 standard deviation below the mean. Generally, sensitivity and specificity scores $\geq 80\%$,
4
5 positive likelihood ratios ≥ 3 , and negative likelihood ratios ≤ 0.3 are considered preferable
6
7 (Dollaghan, 2007). As shown in Table 3, the 3-phoneme regression equation was better at
8
9 accurately identifying children performing within the average range than those below (sensitivity
10
11 = 62% and specificity = 76%). The 5- and 10-phoneme regression equations outperformed the 3-
12
13 phoneme equation, and showed the opposite pattern (with sensitivities at 84% and 88%, and
14
15 specificities at 74% and 70%, respectively). The likelihood ratio results also favored the 5- and
16
17 10-phoneme regression equations. The positive likelihood ratios were similar for all three
18
19 equations, between 2.56 and 3.26, indicating small to moderate probabilities that the children
20
21 below the cut off score truly had SSD (Dollaghan, 2007). The negative likelihood ratio of 0.50
22
23 for the 3-phoneme equation yielded a mild probability, while the 0.21 and 0.16 results for the 5-
24
25 and 10-phoneme equations, respectively, indicating stronger probabilities that children scoring
26
27 above the cut off did not have SSD (Dollaghan, 2007). To determine if other phonemes within
28
29 the 2PL model would be more accurate, successive blocks of the next 10 and 5 most
30
31 discriminating phonemes across the entire model were run using the same process. The results
32
33 for all of these calculations were similar to those above, with sensitivity scores consistently 20%
34
35 or more lower than specificity scores for the same phonemes.
36
37
38
39
40
41
42

43 Discussion

44
45
46 The 2PL model identified 108 phonemes from the stimuli in the sounds-in-words subtest
47
48 of the GFTA-2 that significantly discriminated performance for preschool and early elementary
49
50 aged children. These included the majority of consonants and vowels in American English, but
51
52 did not strongly overlap with the phonemes used by the GFTA-2 to determine percentile scores.
53
54 This is not surprising, as the test was “designed to provide a controlled sample of a child’s
55
56
57
58
59
60

1
2
3 spontaneous production in words *of the most frequently occurring consonant sounds in Standard*
4
5 *American English* [emphasis added]" (Goldman & Fristoe, 2000, pp. 7). In other words, the
6
7 phonemes assessed by the GFTA-2 were chosen to represent the wide range of consonant
8
9 sounds, not by how well they discriminated performance. In addition, the GFTA-2 scoring
10
11 system weighs each phoneme equally, despite the variations in ages at which they are typically
12
13 developed or their impacts on intelligibility. These features are similar to other tests based on
14
15 classical test theory (e.g., deVellis, 2006).
16
17
18
19

20 In contrast, the 2PL phonemes and their regression equations align more closely with
21
22 item response theory (e.g., Embretson & Reise, 2000) because they include only the phonemes
23
24 with the greatest difficulty scores and each phoneme is individually weighted based on its impact
25
26 on the predicted score. The phonemes that occurred within the ten most difficult items of the
27
28 2PL model were / s, r, θ, ʃ, ð, ŋ, v /. All of these except for / ŋ /, depending on the data source,
29
30 are typically later developing phonemes in American English (e.g., Smit, Hand, Freilinger,
31
32 Bernthal, & Bird, 1990). The ten most difficult words also included the target phonemes in the
33
34 challenging contexts of consonant clusters, medial positions of multisyllabic words, and word
35
36 final position. It is likely that these aspects of the target phonemes' difficulty are what
37
38 contributed to their potential as screening items, and not simply their inclusion within the GFTA-
39
40 2's stimuli. Further, the full 2PL model's inclusion of both easy and difficult phonemes may
41
42 explain why it was more precise at discriminating performance at the lower end of the spectrum
43
44 than the higher end. A measure that consists of only difficult phonemes may be better at
45
46 discriminating performance across the spectrum. Taken together, these results suggest that future
47
48 screening measures of children's speech sound productions skills, whether they are or are not
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 developed from existing tests, should consider stimuli that include difficult phonemes in
4
5 challenging contexts.
6
7

8 The predictive abilities of the 3-, 5-, and 10-phoneme groups were in a positive, but not
9
10 overwhelming, direction. As a group, however, they were within the ranges reported for other
11
12 assessment of child speech and language disorders. Two systematic reviews of screening
13
14 measures of preschooler's speech and language skills (Law, Boyle, Harris, Harkness, & Nye,
15
16 2000; Nelson, Nygern, Walker, & Panoscha, 2006), for example, revealed sensitivity ranges
17
18 from 17 – 100%, and specificity ranges from 14 – 100%. It is noted, however, that approximately
19
20 half of these screening measures identified fell below the suggested 80% lower limits for
21
22 sensitivity or specificity (Dollaghan, 2007). Of the three groups assessed in this study, the one
23
24 with 3 phonemes appears to be the weakest, due to its poorer sensitivity, specificity, and
25
26 likelihood values. The results for the 5- and 10-phoneme groups were both better and fairly
27
28 similar to each other. Caution is advised before directly applying the results of this study to
29
30 clinical or research settings. Because the regression equations were calculated from a subset of
31
32 children used to develop the 2PL model, for example, it is currently unclear how well these
33
34 results will generalize to other children. In addition, the concurrent validity of the 5- and 10-
35
36 phoneme groups with other standardized measures of speech sound production should be
37
38 evaluated. As a result, direct applications of the phonemes and words within the 2PL model to
39
40 speech screening are not recommended without additional research.
41
42
43
44
45
46
47

48 Although successful, the 2PL model was relatively simple, due to its dichotomous
49
50 scoring of item responses. With larger data sets, more flexible models could be used to fit these
51
52 data, including the 3PL model that allows for guessing, and polytomous IRT models that would
53
54 allow graded responses to be scored (see Zickar, 2002). The latter might be useful in
55
56
57
58
59
60

1
2
3 determining whether a scoring system that addresses the specific type of errors (such as
4
5 phonological process or distinctive feature differences) would help improve the measurement. In
6
7 addition, larger sample sizes would allow for us to estimate these more complex models as well
8
9 as model some of the easy items that few children answered incorrectly. Additional areas for
10
11 future exploration on this topic include comparing the results of similar IRT analyses on other
12
13 measures of speech sound production and examining if and how the IRT results may vary across
14
15 age groups.
