4 **Abstract:**  
5

6  
7 This paper presents a multiple-round timber auction simulation, developed in order to study  
8 various configurations of auction design. In this study, simultaneous sequential timber auctions  
9 are modelled and analyzed using agent-based simulation technology. As there are many  
10 individual items in the auction to be sold, the auction designer defines several rounds that are  
11 sequential at pre-defined intervals. At each round, the auction designer announces several  
12 simultaneous auctions. Since bidders are offered different items at each round, a mathematical  
13 linear programming model for selecting the best set of items to bid for is presented. Different  
14 bidding patterns are simulated and compared in various setup configurations. The most advanced  
15 of these strategies are adaptive and use agent-learning capability. The comparisons include the  
16 success rate of winning the auction and the winning price per m<sup>3</sup>. This study suggests an efficient  
17 bidding pattern for bidders to bid in order to achieve to their goal and increase their profit.  
18 Similarly, in order to increase profit, the auctioneer (i.e., the government) needs to control  
19 several auction parameters including the number of auctions per year, the lot size, the auction  
20 periodicity, and the number of bidders. This study also suggests parameters configurations that to  
21 maximize revenue for the auctioneer.

39  
40 **1. Introduction**  
41

42  
43 Environmental pressure to reform forest management practices on public land, as well as drastic  
44 reduction in industrial activity following forest products markets collapse in the United States,  
45 have led to a net decrease in timber sales. At the same time, successful mills or entrepreneurs  
46 complained that access to wood supply was impossible under the Québec forest regime, which  
47 was based on an exclusive long-term licencing system. Moreover, this licensing system made it  
48 difficult to establish a fair price for transactions. In response to these issues, the Québec  
49 government decided to make a portion of the annual wood supply (25%) available through an  
50 auction system, as soon as 2013. With wood available through auction, buyers can access  
51 supplies according to the value of their own forest products market. In such a context, designing  
52 an auction system while preserving a certain level of guaranteed supplies is complex. Different

5 opportunities to new entrepreneurs and assuring a fair financial return for a public asset.  
6  
7

8  
9 In this paper the sealed first-price Auction protocol is considered as the interaction protocol  
10 between the auctioneer agent (i.e., a government agency) and the bidder agents (i.e., forest  
11 products companies). In this type of auction, bidders submit their sealed bids, all at the same  
12 time, without disclosure of the bid content to competitors. After evaluation, the bidder with the  
13 highest bid is announced to pay the proposed price and own the lot. This method of auction is  
14 different from the English auction method, in which each bidder can only bid once at each time.  
15 Further, bidders cannot adjust their proposed bid, since they do not have information about their  
16 competitors' bid. It is therefore more appropriate in this context to use sealed technique in  
17 tendering, such as in mining leases and governmental contracts (Milgrom, 1989).

25

26 Timber auctions aim at selling timber lots via a bidding process. The multiple-round timber  
27 auction is a process, in which the auctioneer announces several different items (i.e., wood lots)  
28 periodically to the bidders. The design of a simulation platform of a wood procurement system  
29 based on a multiple-round auction requires a framework that captures the basic dynamics of that  
30 system. Therefore, agent-based technology is used in this study to design and simulate realistic  
31 agents behaviours and bidding patterns in the context of a multiple-round timber auction.

34  
35  
36  
37

38 In this paper, different combinations of bidding patterns and auction design parameters are  
39 simulated and compared in order to better understand the impacts of various factors of the  
40 auctions outcomes. The results show the combined influence of several auction design  
41 parameters and bidding patterns over both bidders' capacity to achieve procurement target and  
42 the seller's total profit.

47

48 The remaining of the paper proceeds as follows. Section 2 presents the literature review. The  
49 simulation multiple-round auction model is presented in Section 3, followed by the models of the  
50 agents' bidding patterns in Section 4. Section 5 presents the results of experiments designed to  
51 compare and validate the various bidding patterns. Next, Section 6 presents and discusses the  
52 results of experiments designed to specifically study the influence of various auction  
53 configurations. Finally, Section 7 concludes and presents the limitations of this research.

## 2. Theoretical background

Allocating and pricing limited natural resources, such as oil, mineral rights, spectrum, and timber, are two important questions. In order to solve timber allocation problems, many auction models have been used (Mead (1967), Hansen (1985), Paarsch (1991), Elyakime *et al.* (1994, 1997), Baldwin *et al.* (1997), Athey and Levin (2001), Haile (2001), Athey *et al.* (2011)). In practice, formal and informal processes are used to determine the allocation of natural resources. Auctions are an example of formal process for allocating and pricing natural resources. They have generated research interest in economic, marketing and consumer behaviour fields. Auction maximizes the revenue for the seller, while being transparent and competitive method of allocation. An efficient auction design can achieve both an efficient assignment of rights to bidders, and maximizes revenue for the seller (Cramton, 2007).

The auction process contains three main elements: auction issues, auction protocols, and auction strategies. The bidders apply the auction protocols to express clear rules and procedures. These rules are used to send bids, accept or reject proposals, as well as decide when the auction starts and ends. The bidders' preference and the need of the bidder at the time of auction are part of the auction strategies (McAfee and McMillan, 1987).

Multiple-round auctions usually consist of a number of auctions that are announced consecutively or concurrently, dealing with multiple goods (Grossklags *et al.*, 2000). One of the important aspects of analysing this type of auction is to attempt to analyze and predict bidders' behaviour. To achieve this goal, different theoretical and empirical studies have been developed (Kagel, 1995). Many of the studies on bidding in multiple-round auctions involve online auction (Anthony and Jennings 2002, Shehory 2002, Airiau and Sen 2003, Greenwald and Boyan 2005, Gerding 2008, Yue *et al.* 2010).

Similarly, several studies have compared the advantages and disadvantages of sequential auction over simultaneous auction (Weber, 1983, Menezes, 1993). In sequential Auctions, Zeithammer (2004) investigated the bidders' forward-looking behaviour. In forward-looking behaviour, bidders intend to underbid if they expect another auction by the seller to happen in the next round of the auction. Along the same line, Ashenfelter (1989) concludes that in selling multiple items through the auction, the selling price of the each item drops accordingly. Ganuza (2004)

1  
2  
3  
4 studies the sale item information to be revealed by auctioneer in a round of the auction. This  
5 study shows that to have more competition, the auctioneer should publish less information to the  
6 bidders. By using data from Internet auction sites, Pinker *et al.* (2000), and Karuga *et al.* (2005)  
7 studies the number of items to be sold in each round of a sequential auction. However, in these  
8 studies, they did not consider both sequential and simultaneous auction. Furthermore, auction  
9 with resale is one of the aspects that can be considered in multiple round auctions. Lange *et al.*  
10 (2011) investigates changing in the bidding behavior in timber auction with resale compare to the  
11 auction without resale option.  
12  
13  
14  
15  
16  
17  
18

19 Similarly, bidding strategies have been studied in various kinds of auction systems. One such  
20 strategy is Zero-Intelligence-Plus (ZIP) strategy (Gode and Sunder 1993, Cliff and Bruten 1997).  
21 However the advantage of ZIP strategy is unknown over other strategies. In sequential and  
22 simultaneous auctions, Boutilier *et al.* (1999) and Tesauro and Bredlin (2001) investigated  
23 bidding strategies that use history (past auctions). Mathematical functions are widely used by  
24 different strategies to calculate optimal bid(s) value, or to calculate the amount of bid at every  
25 time step for the bidder.  
26  
27  
28  
29  
30  
31  
32

33 The application of multi-agent technology to simulate and study auction systems is generating  
34 increasing interest (Vidal, 2007). Indeed, such a technology allows researchers to study the  
35 interactions among agents and process large amounts of data. Furthermore, multi-agent  
36 simulation enables the modeling of bidders' interactions and bidding strategies in complex  
37 environments. Mehlenbacher (2007) explain that multi-agent simulation has some advantages, as  
38 it does not require simplifying assumptions of mathematical analysis, nor assumptions about  
39 Bayesian Nash equilibrium used by econometric methods.  
40  
41  
42  
43  
44  
45  
46

47 However, although bidding processes have been used in the field of distributed artificial  
48 intelligence, such as in the Contract-Net, the design of a simulation system of auctions requires  
49 to address and overcome challenges. One of these challenges is the randomness of bidders'  
50 preferences (Shoham and Leyton-Brown, 2009 and Vidal, 2007).  
51  
52  
53  
54

55 In order to analyze different bidding strategies in different applications, several studies use  
56 autonomous agents. A software agent is a situated autonomous computer system capable of  
57 sensing and reacting to change in its environment without the direct intervention of a user. As a  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 consequence, a software agent has a certain level of control over its actions. A software agent  
5 can also exhibit goal-directed behaviour by interacting with other agents or humans (Wooldridge  
6 and Jennings, 1994). These agents are autonomous and intelligent software entities that are  
7 designed to conduct different task with minimum human supervision. Andreoni and Miller  
8 (1995) implemented experiments with artificial adaptive agents systems and investigate learning  
9 in auctions. To study the interaction of agents they used genetic algorithm to implement adaptive  
10 learning algorithm. However, their method is not compatible with the context of time pressure,  
11 as many factors should be considered. They explained that adaptive learning is very hard to  
12 investigate in auction. Bapna *et al.* (2003) applied different types of agents to simulate auctions,  
13 aiming to maximize both seller and buyer profit. They introduced agents with virtual behavior  
14 that can play with real human bidders. They also proposed hybrid bidding strategies, which  
15 consist three different bidding strategies.  
16

17  
18 In an auction, bidders need to consider the other participants when they offer their bids. In  
19 contrast, a seller (i.e., the auctioneer) should consider the protocol of the auction, potential  
20 buyers, and other competing sellers in order to sell items with highest profit (Park *et al.* 1999).  
21 Agents use different models to find their best moves (i.e. equilibrium strategies); one model in  
22 game theory is to use a prediction of other bidder's possible moves and payoffs (Kreps, 1990).  
23 Other researchers have reported the design of an agent with ability of predicting opponents move  
24 in the bid, as well as opponents' idea about other participants (Gmytrasiewicz and Durfee, 1995,  
25 Vidal and Durfee, 1996). However, when the model is complex and dynamic with a large  
26 number of bidders, the behaviour modeling of other agents is impossible. Even if some models  
27 exist, using them is difficult and implementation is complex (Park *et al.* 1999).  
28

29  
30 Cramton (2007) studied the design of auctions and highlighted the reason why auction is  
31 appropriate for the allocation of natural resources to individual companies. For instance, the  
32 author claimed that the structure of bidder preference and the competition level are two examples  
33 of settings that determine the best auction format. Simultaneous sealed first-price auction is one  
34 of the best options for a weak competition and for bidders with additive values. It is indeed easy  
35 to implement. It requires no price discovery. It controls weak competition and bidder collusion  
36 (Milgrom 1987). Sealed-bid auction is less disposed to collusion, while in open bidding, bidders

2  
3  
4 use predetermined agreements through their bids. Similarly, sealed-bid auction returns higher  
5 revenues when bidders have different preferences (Maskin and Riley 2000, Klemperer 2002).  
6  
7

8  
9 Athey *et al.* (2011) used some data of timber sales for auction design to compare the results of  
10 open and sealed-bid timber auctions. As an observed outcome, small bidders are attracted more  
11 to sealed-bid timber auctions, which generate greater revenue for the U.S. in some forests.  
12  
13

14  
15 In collaboration with the partner of this project, the *Bureau de mise en marché des bois* of the  
16 Québec government, a simulation platform was developed and implemented in order to study  
17 various configurations of multiple-round sealed-bid timber auctions. This type of auctions  
18 consists of a number of auctions announced at predefined time periods and concurrently (i.e., a  
19 each time period, a set of timber lots are announced simultaneously). It was selected by the  
20 *Bureau de mise en marché des bois* as the Québec timber auction system. The aim of this paper  
21 is to present a multi-agent auction simulation model and the results of various experiments, and  
22 to analyse these results in order to better understand the impacts of these configurations.

### 30 31 **3. Multiple-Round Timber Auction Model**

32  
33 The proposed model contains three main components: the seller (i.e., government), the buyers  
34 (i.e., mills, entrepreneurs), and the auctioneer (i.e., a governmental agency). The auctioneer  
35 manages the publication and general organisation of the auction. The seller wants to sell several  
36 items (i.e., timber lots). The auctioneer announces the items periodically in several rounds of  
37 auctions. In other words, at each round, there are many items to be sold. At the start of each  
38 round, which is decided by the auctioneer, the items for sale in this period are announced. These  
39 items have specific characteristics such as their location, their timber volume, and their species  
40 and quality, which make them different from each other. Once the auctions are initiated, bidders  
41 must decide whether or not they wish to bid on these items, and how much. Because bidders can  
42 be located anywhere, transform different types of timber, and supply different forest products  
43 markets, they have different valuation and interest on each of the items.  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53

54  
55 The design of such an auction system includes several decision variables and parameters. First,  
56 there is a set of items ( $I$ ) that the auctioneer announces to the bidders. Each item  $i$  is unique, with  
57 a specific set of features. In other words, the potential value of each item is different from the  
58 others. In the simulation, these features are randomly assigned to each item. More specifically, it  
59  
60  
61  
62

1  
2  
3  
4 is assumed that each item consists of two species including hardwood and softwood, two  
5 different levels of quality for each species, a predefined volume, a ground slope, and a  
6 geographic location. In other words, each item to be sold is represented by a volume of  
7 hardwood of quality 1, a volume of hardwood of quality 2, a volume of softwood of quality 1, a  
8 volume of softwood of quality 2, a location, and a reserve price. Before the auction, the seller  
9 can measure the reserve price. It is the lowest price the seller is willing to receive from each lot.  
10 However, to calculate this price, many factors should be considered to have an optimal reserve  
11 price. Paarsch (1997) describes how the optimal reserve price in timber auctions can be  
12 measured from some criteria such as volume of timber by species, upset rate of each species,  
13 location, year, and month of the auction. In this simulation, because there is limited information,  
14 the reserve price is set according to the location, the volume of hardwood of quality 1, the  
15 volume of hardwood of quality 2, the volume of softwood of quality 1, the volume of softwood  
16 of quality 2, and the upset rate of each species with different qualities.  
17  
18  
19  
20  
21  
22  
23  
24  
25  
26  
27  
28

29 Next, the simulation model contains different types of agents. Bidder agents, also called bidders  
30 ( $j$ ), participate in the auction and bid for items. Here, three kinds of bidding agents are defined  
31 according to their needs for specific types of products. These three types include the paper mill,  
32 the lumber mill, and the entrepreneur. Paper mills mostly require softwood; lumber mills mainly  
33 need hardwood; and, entrepreneurs are interested in both softwood and hardwood. The  
34 parameters of each bidder include the type of bidder as well as its transformation capacity per  
35 year (i.e., both paper mills and lumber mills), their supply need per year, their location, their  
36 bidding pattern, and their forest products market price. Similarly, in order to study the impacts of  
37 various auction configurations, the proposed simulation model includes also several parameters  
38 such as the number of bidders, the average lot size, the auction periodicity, and the number of  
39 auction per year.  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49

50 At the start of the auction, the auctioneer calls all of the potential bidders. These bidders may not  
51 be interested in all items. Therefore, at each round, several individual items are generated and  
52 announced to the bidders. For each individual item auction, each bidder  $i$  has an entry cost  $k_i$  of  
53 gathering information and entering the auction and a private value for the item  $v_i$  depending on  
54 their valuation of the item. Other factors include distance, supply need, transformation capacity,  
55 and the market price that mills can obtain for their products. Concerning entrepreneurs, their  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 capacity is defined as the forecast of their buyers' aggregated demand. Similarly, their need is  
5 defined as their capacity minus the volume of their past wins.  
6  
7

8  
9 After announcing items and receiving bids, the auctioneer chooses the winner that has offered  
10 the highest price for each item. Some bidders may win one or more items, while others may  
11 obtain none. If the item is not assigned at a specific round, it remains in the set of items to be  
12 sold and is announced again during the next round of the auctions until it is sold. The developed  
13 model allows bidder agents to update their needs in order to reflect changes in their environment.  
14  
15  
16  
17

#### 18 19 **4. Agents' model** 20

21  
22 The design of such a simulation platform requires the modelling of the behaviour and  
23 interactions of two types of agents, namely the auctioneer and the bidders. In sequential  
24 simultaneous timber auctions, bidders face two non-trivial decisions: (1) Which sub-set of items  
25 (i.e., timber lots) is more profitable for them to bid on; and (2) How much should they bid for  
26 each item. The first question depends on the characteristics of the lot and on the supply needs of  
27 the mill. The second depends on their valuation of each lot, as well as on the bidder's bidding  
28 pattern. The design of our simulation platform proposes several elements to address these  
29 questions. The next section explains the auctioneer's and bidders' decision problems and the  
30 processes design to solve and simulate them.  
31  
32  
33  
34  
35  
36  
37  
38

#### 39 **4.1 Auctioneer** 40

41  
42 In a sequential auction, at the start of each round, the auctioneer announces the auction. Once the  
43 auction is closed after a specific time period, the auctioneer identifies the winners. The design of  
44 a simulated auction system requires the auctioneer to consider the potential issues regarding the  
45 auction process and the behaviour of the bidders. One of the key issues in sequential auction is  
46 collusion. For a single unit auction, Graham and Marshall (1987) and Mailath and Zemsky  
47 (1991) address the collusion problem caused by a group of bidders who cooperatively agree to  
48 bid in an auction. Such cooperation usually occurs via meetings outside the auction. By colluding,  
49 bidders collaborate to decrease the level of competition to pay less for the auctioned items.  
50  
51  
52  
53  
54  
55  
56

57 In order to avoid collusion, the *Bureau de mise en marché des bois* proposes in its auction design  
58 that an auction is cancelled if it receives 2 bids or less. In this context, the items for sale are  
59  
60  
61  
62

1  
2  
3  
4 simply offered again during the next rounds of auctions. In many cases, such a constraint  
5 prevents collusion because the probability of collusion is lower when a bidder wants to have an  
6 item at a specific time and the bidder knows there is a chance of cancelling the auction.  
7  
8 Therefore, the bidders prefer participating in the action without collusion and winning the  
9 auction rather than collaborating with others and losing their winning chance. Similarly, mills  
10 belonging to the same corporate group or company are not allowed to bid separately. Another  
11 technique to avoid collusion is simply to increase the number of bidders. Because the auctioneer  
12 has a limited control over the number of bidders (there is indeed a limited number of forest  
13 products companies in the region), bids are allowed from outside of the region.  
14  
15  
16  
17  
18  
19  
20

21 After selecting items to be auctioned, and for a given number of bidders, the auctioneer identifies  
22 the first highest price for each item, as long as the price is higher than the reserve price.  
23 Subsequently, the auctioneer announces the winner and the price paid by the winner. Hence, at  
24 the end of each period, all bidders know the winner of each item and its price. If an item does not  
25 have any winner, the auctioneer offers again that item at the next round of the auction.  
26  
27  
28  
29  
30

## 31 4.2 Bidders

32 For each item  $i$ , bidder  $j$  chooses a value according to its bidding pattern. The value for the item  
33 could be either zero (not interested) or a number equal or larger than the reserve price  $RP_i$ . It is  
34 assumed the bidders know the reserve price of each item. In a single item auction, for each item  $i$ ,  
35 bidder  $j$  has a private value  $v_{i,j}$  for the item, as defined by equation (1).  
36  
37  
38  
39  
40

$$41 \quad v_{i,j} \in [RP_i, MP_{i,j}] \quad (1)$$

42 Equation 1 defines the value interval, where  $MP_{i,j}$  shows the maximum price that bidder  $j$  is  
43 willing to pay for item  $i$ . This price reflects the price that the bidder is prepared to pay to have a  
44 minimum profit from the item. Obviously the farther the item is from the mill the smaller the  
45 maximum price, because of transport costs. According to the characteristics of the item (e.g.,  
46 overall quality of the forest lot), bidders define their maximum prices. For each item  $i$ ,  $V_i$  and  $R_i$   
47 show respectively the volume and the type of item. Furthermore, the distance of the item  $i$  to  
48 bidder agent  $j$  is shown by  $D_{i,j}$ . Equation (2) defines the maximum price  $MP_{i,j}$ .  
49

57  
58  
59  
60  
61  
62  
63  
64  
65

$$MP_{i,j} = V_i(MRP_i - HC_i - D_{i,j}TC_i - PC_{i,j} - PR_{i,j}) \quad (2)$$

$MRP_i$  is the average revenue of the final product generated from item  $i$ .  $HC_i$  is the cost of harvesting item  $i$ .  $D_{i,j}TC_i$  is the total transportation cost. The average processing cost of converting the product  $i$  into the final product of bidder  $j$  is  $PC_{i,j}$ . Finally,  $PR_{i,j}$  is the minimum profit that the company is willing to gain from the item.

#### 4.2.1 Bidders' items selection problem

At each round, bidders are offered many items. They might consequently be interested in more than one item simultaneously. They should therefore decide on which items they want to bid, considering the characteristics of the items, including their species, their size and their quality, as well as the bidders' need and the items' distance to their mills. The distance from a item to the processing facilities must be considered since transportation accounts for a significant share of procurement costs. Also, bidders must also make sure they have the capacity to process (i.e., harvest and transport) the items they bid on. Furthermore, in practice, bidders might be more interested on larger volume items. In other words, when companies have access to more volume in the same location, they need less coordination with other mills or entrepreneurs, who might be interested in buy undesirable species (in case of mixed species lots). Larger volume items might also involves scale economies with respect to harvest cost. Therefore, bidders must weight these parameters and constraints in order to find the best set of items to bid on. A set of such items is referred to as the solution of items to bid on at each round. This best solution represents the mills or entrepreneurs list of items that are the most profitable to bid on. It is expected that bidders bid according to it. In some cases, bidders may have several possible sets of items to bid on. Bidder agents try to find the best solution in their region. The challenge is to establish the option that yields the most profit for them. Two opposite problems may arise from the bidding process. On the one hand, obtaining more than needed induces unnecessary costs for the bidders, such as inventory related costs. On the other hand, bidders can bid on several items and win nothing because they have poorly estimated their value or bid too low. This decision problem is defined by the following binary integer programming model:

$$\text{maximize: } \sum_{i \in I} \frac{V_i}{D_i} x_i \quad (3)$$

$$\text{subject to: } MP_{i,j} x_i > RP_i \quad \forall i \in I \quad (4)$$

$$\sum_{i \in I} V_i x_i < ND_j \quad (5)$$

$$x_i = \{0,1\} \quad \forall i \in I \quad (6)$$

In this model,  $V_i$ ,  $D_i$ , and  $RP_i$  are respectively the volume of item  $i$ , the distance of item  $i$  from the mill, and the reserve price of item  $i$ .  $MP_{i,j}$  is the maximum price that bidder  $j$  is willing to pay for item  $i$ . The need of bidder  $j$  at time  $t$  (i.e., the total volume of wood to acquire) is  $ND_j$ . Binary decision variable  $x_i$  represents whether or not an item is selected.

In this formulation, each bidder assigns a weight to each possible item at each round. The weight is defined as the volume of the item over the distance of the item to the bidder's mill, in order to maximize the volume while minimizing the distance to obtain it. Therefore, the larger the volume and the smaller the distance, the more interesting the item is. Although it is rather simple, this interest indicator provides a good guide for bidders to identify interesting items.

The objective function aims to maximize the total interest of items. The first constraint (4) ensures that the bidder consider only the feasible items, for which the maximum price the bidder is willing to pay is higher than the reserve price of the item. Constraint (5) states that the sum of the selected items is less than its need, in order to avoid bidding on more items than needed. This may include a small buffer to account for lost bids. Equation (6) is the integrity constraint.

#### 4.2.2 Approaches for the bidding patterns

In order to design realistic bidding patterns for simulation purposes, we first developed four pure patterns based on fundamental concepts from the literature that we adapted to the specific problem of forest auctions. Then, we compared and analyzed the performance of these four bidding patterns in order to ultimately develop and hybrid pattern capable of modeling a wide range of bidding behaviours. To do so, we assumed that bidders have information concerning past auction outcomes, including winners and winning prices of all items. In other words, we

1  
2  
3  
4 generally assumed that the information known by bidders is limited to private information and  
5 public information concerning the results of the previous auctions. The behaviour of bidders  
6 during in auctions is called the bidding pattern. Five bidding patterns approaches are presented  
7 hereafter, respectively *random bidding*, *fixed behaviour*, *adaptive*, *learning*, and *adaptive*  
8 *learning*.  
9

#### 10 ***Random bidding approach***

11 In the *random bidding* approach, bidders bid randomly a value between a minimum price (or the  
12 reserve price) and a maximum price. This approach is the most simple pattern as bidders are  
13 inattentive to past auctions or private information and do not follow any particular logic.  
14 Equation (7) describes the random bidding approach. In this equation,  $r$  is a random number  
15 between 0 and 1.  
16  
17  
18  
19  
20  
21  
22  
23  
24  
25

$$26 \quad v_{i,j} = r * (MP_{i,j} - RP_{i,j}) + RP_{i,j} \quad (7)$$

27  
28  
29  
30

#### 31 ***Fixed behaviour approach***

32 The second approach is a slight variation of the random bidding approach. Therefore, in the *fixed*  
33 *behaviour* approach, bidders systematically bid according to their risk averseness, as shown in  
34 equation (8):  
35  
36  
37  
38

$$39 \quad v_{i,j} = K * (MP_{i,j} - RP_{i,j}) + RP_{i,j} \quad (8)$$

40  
41  
42  
43

44 Here,  $k$  is a constant between 0 and 1, which is decided by the bidder before the auction as a  
45 fixed bidding pattern. In other words, if  $k=1$ , then the bidder systematically bid its maximum  
46 value (i.e., risk averse). On the contrary, if  $k=0$ , then the bidder bids her lowest value (i.e., cool-  
47 headed).  
48  
49

#### 50 ***Adaptive approach***

51 Bidders using the random bidding and the fixed behaviour approaches are Zero Intelligent (ZI)  
52 agents (Mathieu *et al.* 2006). In other words, by using any of the first two approaches, bidders  
53 bid ignoring any internal and external information, such as past auctions wins. Although bidders  
54 do not know about other bidders' approaches, they can build a strategy line for themselves using  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

private information. Wei *et al.* (2010) suggest a bidding pattern for multi-round auctions that considers the impact of time on the valuation function. Because we assume that bidders have an annual supply target to achieve in order to supply their mill with a specific type of wood, we exploited this idea to develop an approach that adjusts the valuation function according to the time remaining to achieve that target, but also to the remaining supply need of the bidder at the time of the auction. Indeed, the smaller the remaining time a bidder has to achieve her supply target, or the smaller the percentage of her target she achieved with previous auctions, the more concessions she is likely to make (i.e., the more risk averse she becomes). Consequently, we develop the third approach, namely the *adaptive* approach, in which bidders bid according to their perception of the pressure of the remaining time and supply need. In other words, the adaptive approach is designed to keep the bid value low, and to only increase it when the pressure to achieve the supply target is high.

Therefore, we define the influence of the remaining time to achieve the supply target ( $t$ ) and of the remaining supply need to achieve the target ( $n$ ) as a linear increasing function, defined by equation (9).

$$v_{i,j} = \left( \frac{MP_{i,j} - NP_{i,j}}{2} \right) * \tanh \left( \alpha * \frac{f_1(y)}{f_2(d)} * \frac{f_{j3}(n)}{f_{j4}(c)} - 2 \right) + \left( \frac{MP_{i,j} + NP_{i,j}}{2} \right) \quad (9)$$

Here,  $f_1(y)$  and  $f_2(d)$  are functions representing respectively the whole year (or time period over which the bidder must achieve a specific supply target) and the remaining time until the end of the year (or time period). Next,  $f_{j3}(n)$  and  $f_{j4}(c)$  are functions representing respectively the remaining supply need at the specific time of the auction, and the overall supply target of the bidder. All of these functions are continuously increasing. This valuation reflects a number between the minimum price and the maximum price for an item  $i$  that a bidder  $j$  is willing to pay.

This type of behaviour can be interpreted in the system as adaptive to the perceived pressure of time and supply need, with respect to the bidder's supply target. In other words, at the start of the year, bidders offer near minimum price as they have time to achieve their target. However, if their target is high, their perception of the pressure to achieve it may force them to bid higher. As the auction progresses, bidders have less time and therefore have fewer possibility of winning in the next rounds of auctions. Therefore, while they initially accept the risk of losing and decide to

1  
2  
3  
4 bid less, as time passes without winning, they will choose to bid more, with less profit, in an  
5 attempt to increase the likelihood of winning a bid. Figure 1 shows some examples.  
6  
7  
8  
9

10  
11 In these examples, each point of each line shows a simulated bid at time  $t$  for an item with  
12 minimum and maximum prices of 50 and 70 respectively. At the start of the simulation, the  
13 bidder offers near minimum price as there are still many opportunities to win. As the time  
14 progresses, if the bidder does not win, she incrementally bids higher. Drop points represent a  
15 specific win. When the bidder wins an item which volume represents a higher portion of her  
16 supply target, the drop is larger. When the bidder wins, she starts bidding from drop point, and  
17 gradually increases her bid until it reaches her maximum price or she wins again. Similarly, an  
18 early win of an item has a larger drop point than a late win of the same item, unless the supply  
19 target is achieved by the win. For instance, example 2 shows a bidder that has stopped bidding  
20 because she won sufficient bids early on.

25  
26  
27  
28  
29

### 30 *Learning approach*

31  
32 Recently, agent learning algorithms have reached remarkable outcomes (Vidal, 2007). The  
33 purpose of learning in multi-agent systems is to create some agents, which can use previous  
34 experience for their future bidding (Mitchell, 1997).  
35  
36  
37

38 Learning theory leads to many valuable tools (Mathieu *et al.* 2006). These tools help multi-agent  
39 researchers to find the achievable equilibrium points of a system. At the design stage of a multi-  
40 agent system, designers do not know exactly every condition that agents will encounter during  
41 their operations. Therefore, by adding a learning capability to the agents, designers provide their  
42 agents with the capacity to adapt their behaviour to situations that happen at run time.  
43  
44  
45  
46  
47

48 In sequential auctions, learning is a method that helps bidder agents to build their offers  
49 according to available information. Learning agents use algorithms to analyze available data to  
50 bid more carefully. In order to do this, we propose a learning approach, which aims to estimate  
51 the winning value of an item according to specific parameters, using the results from prior  
52 auctions, including sale prices, the items' lot sizes, and the winners' location. Using the distance  
53 between the winners' mill and the items, the price paid and the characteristics of the items, a  
54 learning bidder agent runs a regression model to estimate the likely value of new items to be  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 auctioned. Such an approach allows bidder agents to identify an ‘average’ winning bidding  
5 pattern based on past auctions. At each round, learning agents computes the coefficient of the  
6 regression function (10), in which  $y_{i,j}$  is the price of item  $i$  estimated by bidder  $j$ ,  $d_{i,j}$  is the  
7 distance of bidder  $j$  to item  $i$ , and  $x_{1,j}$ ,  $x_{2,j}$ ,  $x_{3,j}$  and  $x_{4,j}$  are the volumes of the four species/quality  
8 combination considered in this study.  
9

$$v_{i,j} = y_{i,j} = \beta_0 + \beta_1 d_{i,j} + \beta_2 x_{1,i} + \beta_3 x_{2,i} + \beta_4 x_{3,i} + \beta_5 x_{4,i} \quad (10)$$

### 17 18 *Adaptive learning approach*

19  
20 Out of the four bidding patterns presented above, only the last two strategies proposed some sort  
21 of bidding behaviour that changes over time according to specific, yet different, information  
22 input. The adaptive approach adjusts the valuation function according to bidder's objectives and  
23 the time left to achieve it. The learning approach only adjusts the valuation function according to  
24 past winning conditions. If these two behaviours seem to follow reasonable bidding rationalities,  
25 a rational bidder can adopt any bidding pattern that is between these two. Therefore, we  
26 introduced a fifth approach that is a hybrid of both the third (adaptive) and fourth (learning)  
27 approaches. More specifically, the valuation function of such a bidder is described by the  
28 equation (11).  
29  
30  
31  
32  
33  
34  
35  
36

$$v_{i,j} = \alpha \left( \frac{MP_{i,j} - NP_{i,j}}{2} \right) * \tanh \left( \frac{f_1(y)}{f_2(d)} * \frac{f_3(n)}{f_4(c)} - 2 \right) + \beta \left( \frac{MP_{i,j} + NP_{i,j}}{2} \right) + (1 - \beta) y_{i,j} \quad (11)$$

37  
38 In this equation,  $\alpha$  and  $\beta$  are coefficients defined within [0;1]. With such a hybridisation  
39 mechanism, the pure adaptive and learning bidding patterns can be reproduced. For instance,  
40 when  $\alpha = \beta = 1$ , the bidder behaves like a the pure adaptive bidder. When  $\alpha = \beta = 0$ , the  
41 bidder agent behaves like a the pure learning bidder. This mechanism also allows creating bidder  
42 agents that equally demonstrate both behaviours simultaneously. In other words, when  $\alpha = 1$   
43 and  $\beta = 0$ , the valuation function of the pure learning agent is adjusted by the pressure of target  
44 achievement as with the adaptive behaviour. On the contrary, when  $\alpha = 0$  and  $\beta = 1$ , the hybrid  
45 agent behave simply as a risk neutral bidder agent with a fixed behaviour.

## 5. Experiments

Several experiments were carried out in order to validate and analyze different aspects of the proposed model. The first two experiments were designed specifically to validate the programmed behaviors of the bidder agents. In the first experiment, we compared the four pure bidding patterns and analyse the results to make sure that the overall outcome of each strategies was coherent with their design specificities. Similarly, the second experiment was designed to validate the hybrid approach, and to compare, in a competitive setup, different configurations of hybrid bidder agents (from the pure adaptive to learning).

Next, in a third part, we carried out an experiment to better understand the impacts of various auction design parameters on the outcome of the auction. This experiment was specifically designed with randomly generated populations of hybrid bidder agents. A factorial design plan of 81 scenarios was implemented and simulated in order to understand the impacts of specific auction design parameters, including average lot size, periodicity, number of item sold and number of bidders. The results of this experiment were validated separately with experts from the *Bureau de mise en marché des bois* of the Québec government.

### 5.1 Methodology of experiments

The methodology we used to achieve the objectives of the study includes 3 experiments. In the first two experiments, four different scenarios were simulated. Each scenario is a combination of a number of potential bidders and an average lot size. Scenarios with different number of bidders are used to assess the impact of more or less competition on the auctions outcome, while scenarios with different average lot size are used to assess the impact of the average item size on supply target achievement. In each scenario of the first experiment, there are an equal number of bidder agents using each type of bidding patterns. In the second experiment, we simulated and compared the same four scenarios with a set of bidder agents containing an equal number of each five configurations of hybrid bidder agent, as described in Table 1. Finally, in the third experiment, a factorial design plan was used as the combinations of three levels of average lot size, three levels of periodicity, three levels of number of item sold, and three levels of number of bidders.

## 5.2 Random parameters and common elements

For all experiments, the locations of bidders' mills and sold items are randomly generated. Transportation costs are calculated based on the Euclidian distance between items and mills. Other random parameters were generated by uniform distribution including lot size; volumes of hardwood and softwood of quality 1 and 2 in each item; process cost at each mills; annual production capacity of each bidder's mill; bidders' initial supply targets of each; and market price of each wood product made of hardwood and softwood of quality 1 and 2, for each bidder.

Because each bidder is generally interested in only one combination of species/quality, the market price is different for each combination of species/quality and for each bidder. Therefore, the market price is set to be lower for the species/quality the bidder does not want. It is equivalent to the price of the unprocessed wood in the market, plus transportation cost to the mill. Because market price affects the valuation function through equation 2, if an item contains a large volume of uninteresting species/quality, the resulting bid is lower. This assumption is realistic because we consider that in case of a win, the unused species/quality volumes are sold to other mills without any loss.

A simulation run consists in a 365 time period simulation, in which bidder agents have a unique bidding pattern according to the tested scenario. Each bidder agent is defined by specific public and private parameters including a mill location, a supply target to achieve and a set of cost and revenue functions. In order to obtain a relevant level of statistical significance, each simulation of each experiment was repeated several times. Also, a simple Taboo Search application was programmed in the simulation platform to solve the Bidders' items selection problem described in Section 4.2.1. This algorithm was used by all bidder agents in every simulation.

Next, in order to analyse the influence of specific design parameters, the average sale price per  $m^3$  and the average target achievement of each simulation runs were measured. In the context of public land, the designer of the auction process is interested in both aspects of the auction outcome. More specifically, the average target achievement is a criterion that measures how much bidders are able to fulfill their needs. In other words, it measures the impact of the auction process on the sustainability of mills' economic activities. Target achievement of a bidder is defined as the volumes of all items won by the bidder during the entire simulation over its supply

1  
2  
3  
4 target. Next, the average sale price represents public economical gain from the auction process.  
5  
6 In other words, although the auction process must be designed to generate a large economical  
7  
8 gain in the interest of the public, it cannot do so at the expense of local economic sustainability.  
9

### 10 **5.3 Synthesis of the experiments**

11  
12 As summarized in Table 2, the first part of the experiments focused on the validation of the  
13  
14 agents' behaviours. A total of 280 simulation runs were carried out. The second part studies the  
15  
16 impacts of various auction design parameters on the outcome of the auction. 1900 simulation  
17  
18 runs were carried out and analyzed. The next section presents and discusses the results.  
19  
20  
21  
22  
23

## 24 **6. Results and discussion**

25  
26  
27 This section presents and discusses each experiment. Although more experiments were carried  
28  
29 out during the development phases of the simulation platform, only the results of the mentioned  
30  
31 experiments are analyzed in this paper.  
32

### 33 **6.1 Experiment 1**

34  
35  
36 In this experiment, the average price is first considered to compare the four bidding patterns.  
37  
38 Figure 2 shows the average sale price per m<sup>3</sup> of the four approaches in all tested scenarios.  
39  
40  
41  
42

43 First, we can observe that bidders with strategies 1 and 2 pay, on average, more than the last two  
44  
45 strategies, which is consistent with the development objectives. Indeed, a bidder using pattern 3  
46  
47 (i.e., the adaptive approach) bids systematically low, unless it is under pressure of achieving its  
48  
49 supply target. Similarly, a bidder using the fourth pattern only bids what is likely necessary to  
50  
51 win, and not more. This pattern is also more adapted than the third to achieve lower buying  
52  
53 prices. Indeed, as seen in Figure 2, bidders using approach 3 pay a higher price than the bidders  
54  
55 using approach 4, except in the situation where the competition is lower and the lots are larger  
56  
57 (NB 100, LS 20.000). In this specific case, when an adaptive bidder wins an item, because the  
58  
59 large volume of the item represents a larger portion of its supply target, its next bid will be lower  
60  
61 than if the item represented a smaller portion of its need. Therefore, based on the price paid per  
62  
63  
64  
65

1  
2  
3  
4  $m^3$ , the learning approach is better than all other approaches in almost every configuration.  
5  
6 However, the price in the adaptive approach is almost equivalent to the price in the learning  
7  
8 approach when the competition is low and the lots are bigger. This validates what we intended to  
9  
10 program. Similarly, comparing the first scenario with the second, and the third scenario with the  
11  
12 fourth, we can also observe that price paid seems to be less when items are bigger. This result, to  
13  
14 be confirmed by the fourth experiments, is a first indicator on how to design the auction in order  
15  
16 to maximize revenue from the seller point of view. The second aspect that we analyzed in this  
17  
18 experiments is the average target achievement as seen in Figure 3.

19  
20  
21  
22 Here, the average target achievement displays a similar general trend in all scenarios. Bidders  
23  
24 using approach 2 have the lowest average target achievement. This is caused by the inability of  
25  
26 their pattern to adapt the bid to win an item (not even by generating randomly a high bid like  
27  
28 approach 1). Also, approach 1 and 3 are able to generate a better target achievement than the  
29  
30 other approaches. Although the target achievement of approach 1 and approach 3 are equivalent,  
31  
32 it seems that bidders using approach 1 are only able to obtain a good target achievement by  
33  
34 sometime generating higher winning bids. Therefore, they do so at the expense of their average  
35  
36 paid price, which is much higher than bidders using approach 3 (see Figure 2). On the same  
37  
38 token, bidders using the adaptive approach 3 are able to achieve lower paid price because they  
39  
40 only increase their bids when needed (pressure to achieve the target). These bidders also  
41  
42 outperform the bidders using the learning approach 4, because their bidding patterns controls the  
43  
44 bid so as to improve target achievement, while the learning approach is insensitive to target  
45  
46 achievement. These results, again, validate what we intended to program. .

47  
48 In general, as shown in Figure 2 and Figure 3, bidders using approach 1 and 2 tend to pay higher  
49  
50 for the items in comparison to bidders using approach 3 and 4. This occurs also while they do not  
51  
52 necessarily achieve a better target achievement compared to bidder using approach 3 and 4. As a  
53  
54 result, the learning approach bidders pay less for the item, while the adaptive approach bidders  
55  
56 have a better target achievement. Therefore, according to their objective, bidders should use any  
57  
58 combination of these two approaches. This is why, in the remaining experiments, approach 1 and  
59  
60 2 were abandoned, as they do not try to achieve any particular objective.

## 6.2 Experiment 2

In order to better understand the impacts of combining the adaptive and the learning bidding patterns, we carried out another experiment dedicated to validating this type of hybrid bidder agents. In order to see how this approach performs, we considered and compared 5 combination of the adaptive and learning approaches, with different  $\alpha$  and  $\beta$  as explained in Table 2. Note that the pure adaptive and learning approaches were included in this experiment. As studied in experiment 1, we compared the average price per  $m^3$  and the average target achievement. As shown in Figure 4 and Figure 5, there are no absolute best hybrid bidder agents. However, the performance of the approaches is different in each of the four simulated scenarios. For instance, target achievement (Figure 4) seems generally more correlated to the scenario, than to the type of hybrid combination. However, in more competitive scenarios, the more adaptive the bidder agent is, the (slightly) better its target achievement. In less competitive scenarios, this advantage of the adaptive behaviour seems to fade, especially with respect to the learning bidder agents, which actually perform well, which is rather different from the results of the first experiment. This can be explained by the nature of the competitive game. In other words, the auctions simulated in the second experiment are more competitive than the auctions in the first. Indeed, in the second experiment, all bidder agents present some more or less pronounced capacity to adapt to achieve their supply target objective. However, this was not the case in experiment 1, in which bidder agents using approach 1 and 2 were incapable of adapting to the situation. Therefore, these agents were more prone to loose against more intelligent agents. Consequently, pure adaptive agents were not necessarily better than the hybrid agents from that perspective.

Concerning the average sale price (Figure 5), several observations can be made. First, because an adaptive agent under pressure can offer bids that are higher than necessary to win an item, it is coherent to observe a poor performance of these agents to achieve a good sale price in a competitive game (BN 200, LS 10.000). However, when the game is less competitive (NB 100, LS 20.000), than adaptive agents actually perform well because they are designed to keep their bid as low as possible when not under pressure. This general result can be observed with hybrid agents as well. However, we can noticed that because hybrid 2, 3 and 4 are respectively defined with an incremental decrease of  $\alpha$  from equation (11), and therefore an incremental decrease of

1  
2  
3  
4 the influence of the adaptive behaviour, it is coherent to observe a performance of these agents  
5 that becomes also incrementally further to the performance of the pure adaptive behaviour. In  
6 other words, the less a hybrid agent is influenced by the adaptive behaviour, the less sensitive to  
7 competition it is to achieving good sale prices. This also confirms the findings of the first  
8 experiment, which, compared to the learning approach, the adaptive approach has a stronger  
9 negative impact on the sale price, than it has a positive impact on target achievement.  
10  
11  
12  
13  
14  
15  
16  
17  
18

19 As expected, the observed performance of the different types of hybrid agent is generally  
20 correlated to how much of the pure behaviours they are made of. However, it seems that the  
21 influence of the adaptive behaviour is more significant than the influence of the learning  
22 behaviour, although they all display an almost equally good performance with respect to target  
23 achievement. Therefore we can safely assume that the generation of a population of randomly  
24 generated hybrid agents is representative of a population of rational bidders driven by any  
25 combination of both objectives.  
26  
27  
28  
29  
30  
31

### 32 **6.3 Experiments 3**

34 As discussed earlier, experiment 3 aims to better understand the influence of several auction  
35 design parameters on the outcome the auction. In order to design such an auction, the designer  
36 needs to define the number of auction per year, the average lot size of the items for sale, the  
37 periodicity of the auction, and, as far as possible, influence the number of bidders by, for  
38 instance, selecting lots' location in a strategic manner. These are referred to as the independent  
39 variable. From the seller's point of view, these design parameters should be defined in a way to  
40 maximize the revenue. However, because the seller is also the Québec government, it must make  
41 sure forest companies can operate at sufficient capacity to cover their fixed cost of operation by  
42 allowing them to be supplied with large enough quantity of timber. Therefore, as discussed  
43 previously, both the average price and the target achievement must be studied. These are referred  
44 to as the dependant variables.  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55

56 As explained in the methodological section, experiment 3 is an extensive simulation of 81  
57 different scenarios defined as the combination of various levels of number of bidders, item lot  
58 size, periodicity, and number of items sold as presented in Table 2. Using the data generated by  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 the experiments, we carried out several analyses. First, an analysis of variance presented in the  
5 annexe (Table 3 and Table 4) validates statistically the resulted generated by the simulation  
6 model. For simplification purpose, this analysis only studies the influences of all combinations of  
7 just any two independent variables on both dependant variables. Both ANOVA studies present a  
8 R-square above .95, which indicates a high significant level of statistical confidence. Next, in  
9 order to better understand the combined influence of any two independent variables on the  
10 outcome of the auction, we systematically computed the average target achievement and sale  
11 price for the combination of all levels of all pairs of two design parameters.  
12  
13  
14  
15  
16  
17  
18

19  
20 First, from a general standpoint, all results show systematic opposite effects of all design  
21 parameters on both outcomes. For instance, lot size affects positively target achievement and  
22 negatively sale price (Figure 6). More specifically, when item size gets larger, the sale price per  
23  $m^3$  decreases from \$9 to, sometime, \$4.5, which is rather considerable. This can be explained by  
24 the difference in the quantity of bidders interested in bidding. Indeed, large size items are not  
25 necessarily interesting to bidders with remaining supply needs smaller than the lot size. In other  
26 words, if items lot size are small, then the number of potential bidders for this item increases,  
27 which increases competition. Consequently, more participation in the auction causes more  
28 demand, which in turn affects the sale price. This result presents a limit of the model to be  
29 improved, as it is counter-intuitive for the experts who validated the model. Indeed, in this  
30 model, we consider a fix harvesting cost per  $m^3$ , although in reality, a scale economy can be  
31 gained from harvesting larger items (e.g., less low bed transportation are needed to move  
32 harvesting equipment). Therefore, if a scale economy can be gained from larger items, then  
33 bidders might be willing to pay more to win these items. Although this shortcoming limits our  
34 ability to investigate properly the impact of item size, it does not affect the remaining of the  
35 study insofar as the lot sizes of each simulation configuration are within a limited range. In other  
36 words, within each round of auctions, because the lot sizes are similar, no scale economy is  
37 significantly higher for some items. Therefore, these items are not more interesting from that  
38 perceptive. However, if both small and large items are simultaneously sold within one round of  
39 auctions, then a fix cost of harvesting should be considered.  
40

58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Along the same line, if lot size has a rather clear general influence on both outcomes, this  
5 influence is mitigated to different extent by the other design parameters. For instance, periodicity  
6 (i.e., the delay between two rounds of auctions) has a rather limited influence for values below  
7 15 days. Indeed, as verified in the statistical analysis, there is no significant statistical difference  
8 between the simulation results with a periodicity of 7 days and a periodicity of 15 (Figure 6, a., b.  
9 and Figure 7, a., b., c., d.). However, a periodicity of 30 days between two rounds of auctions  
10 tends to decrease both target achievement and sale price. Therefore, shorter periodicities tend to  
11 be generally more beneficial longer ones. This influence can be explained as follows. When  
12 periodicity increases, while the total number of auctions remains unchanged, the number of items  
13 for sale increases at each round. In other words, there are fewer rounds of auctions, but more  
14 auctions at each round. Consequently, the influence of periodicity on sale price target  
15 achievement can be explained by the fact that bidders can achieve lesser price if they can bid  
16 simultaneously on more items (i.e., more supply quantities per round).  
17  
18

19  
20  
21  
22  
23  
24  
25  
26  
27  
28  
29 Along the same line, and from a general standpoint, the number of auctions affects positively  
30 target achievement, and negatively sale price. Furthermore, it has a mitigating effect on both the  
31 lot size and the number of bidders. More specifically, as the number of auctions decreases, the  
32 influence of lot size (Figure 6, f.) and the influence of the number of bidders (Figure 7, f.) on sale  
33 price are reduced as well. For the same reason, this can be explained by the fact that reduced  
34 supply leads to a higher number of interested bidders, even if the items' lot size is large or the  
35 number of potential bidders is low. This result is interesting because it shows that higher  
36 competition, in other words, a higher number of interested bidders, with respect to a certain level  
37 of supply, leads to a market price that better represents the limit of forest companies to purchase  
38 items.  
39  
40  
41  
42  
43  
44  
45  
46

47  
48 Differently, and as expected, the number of bidders has a positive impact on sale price, but a  
49 negative impact on target achievement, whatever the context ((Figure 6, c., d. and Figure 7, a., b.,  
50 e., f.). This result can be explained as follow. As competition and demand increase, the number  
51 of bids received during each auction is similarly increased, which results in a higher probability  
52 of receiving high value bids. Along the same line, increased competition also reduces the  
53 probability of each forest company to win, and therefore reduces their ability to achieving their  
54 target.  
55  
56  
57

61  
62  
63  
64  
65

1  
2  
3  
4  
5  
6  
7 Finally, we also studied the correlation between the target achievement and the sale price (results  
8 not presented). As it can easily be observed in Figure 6 and Figure 7, this correlation is negative,  
9 which tends to show that both objectives cannot be achieved simultaneously. In other words, it  
10 seems that the government that owns the forest has a dilemma as it can either maximize its  
11 revenue, or support the industry by allowing companies to better achieve their supply target, but  
12 not both.  
13  
14  
15  
16  
17

## 18 19 **7. Conclusion**

20  
21 This paper first proposed theoretical bidding patterns for the design of automated software agents  
22 in the context of natural resource auctions. These bidding patterns were then implemented into a  
23 multi-agent simulation platform, which was used in various simulation contexts in order to  
24 validate these models, as well as to better understand the impact of various auctions design  
25 parameters on the auction performance. This performance was measured through two main  
26 indicators illustrating, on the one hand, the forest companies' ability to achieve their supply  
27 needs (i.e., target achievement), and, on the other hand, the government's ability to generate  
28 revenue from the forest sales (i.e., sales price per m<sup>3</sup>).  
29  
30  
31  
32  
33  
34  
35  
36

37 The analysis of the results first shows that the adaptive and learning bidding patterns have the  
38 best results and achieve their design objectives. They can thus be used as general guidelines in  
39 designing a company's bidding pattern. Next, concerning the design of the auction process, the  
40 results tend to indicate that the government (i.e., the forest owner) cannot simultaneously achieve  
41 high revenue while providing an effective supply channel to forest companies. It is therefore  
42 necessary to find a compromise in order to maintain forest companies' activities, and generate  
43 descent revenue for the public. The results also demonstrate the intuitive impact of the number of  
44 potential bidder on the revenue generated. It also shows that target achievement is improved by  
45 the sales of larger forest lots, while it decreases the average sales price.

Zeithammer, R., 2004. An equilibrium model of a dynamic auction marketplace. Working Paper,  
University of Chicago.

## price per m3 vs. Approach

**Figure 2: Average sale price per m<sup>3</sup> of four approaches in different setup configuration**

# Target achievement

**Figure 3: Average target achievement of four approaches in different setup configurations**

achievement: combined effects of periodicity and lot size

b). Price per m<sup>3</sup>: combined effects of periodicity and lot size

achievement: combined effects of number of bidders and lot size

d). Price per m<sup>3</sup>: combined effects of number of bidders and lot size

achievement: combined effects of periodicity and number of bidders

b). Price per m<sup>3</sup>: combined effects of periodicity and number of bidders

achievement: combined effects of periodicity and number of auctions

d). Price per m<sup>3</sup>: combined effects of periodicity and number of auctions

**Table 1: Defining five configurations by assigning different  $\alpha$  and  $\beta$** 

$\beta \backslash \alpha$	1	0.75	0.5	0.25	0
1	Adaptive approach (1)				
0.75				(4)	
0.5			(3)		
0.25		(2)			
0					Learning Approach (5)

**Table 2: Experimental design specificities**

	<b># of scenarios</b>	<b># of repetitions</b>	<b># of simulation</b>
<b><i>Part 1: Behaviour validation experiments</i></b>			
<b>1</b>	2 parameters, 4 scenarios	Each scenario was repeated 50 times	200
	• number of bidders	2 levels (100 and 200)	
	• average lot size	2 levels (10,000 m <sup>3</sup> and 20,000 m <sup>3</sup> ).	
<b>2</b>	2 parameters, 4 scenarios	Each scenario was repeated 20 times	80
	• number of bidders	2 levels (100 and 200)	
	• average lot size	2 levels (10,000 m <sup>3</sup> and 20,000 m <sup>3</sup> ).	
<b><i>Part 2: Auction design experiments</i></b>			
<b>3</b>	4 parameters, 81 scenarios	Each scenario was repeated 20 times	1620
	• auction periodicity	3 levels (7 days, 15 days and 30 days)	
	• average lot size	3 levels (10.000 m <sup>3</sup> , 15.000 m <sup>3</sup> and 20.000 m <sup>3</sup> ),	
	• number of items sold	3 levels (100, 250 and 500),	
	• number of bidders	3 levels (100, 150 and 200),	

**Table 3: Analysis of variance of Price per m<sup>3</sup>**

*Number of observations* = 1620

*R-squared* = 0.9687

*Root MSE* = .320843

*Adjusted R-squared* = 0.9681
