We have continued our study of symmetric and asymmetric fission of intermediate-mass nuclei using 190 MeV protons. A three-detector ΔE -E counter telescope, consisting of a common-anode ΔE ion chamber (~ 12.6 torr isobutane) and three large area, 300 mm^2 , Si(SB) detectors (in gas) in coincidence with a three-detector Si(SB) array was used to provide approximate fragment Z identification as well as fragment energies (TKE). This, together with fragment TOF relative to the beam r.f. ($\Delta t = 0.5 \text{ ns}$) provides Z and A identification. The TKE is used to separate contaminants.

Figure 1. Ion-chamber - Si(SB) detector spectrum of ΔE -E for coincident p+Ce fission fragments ($E_p = 190 \text{ MeV}$) gated on the fission peak in TKE. The calculated contours for various fragment Z values are indicated.

Two new elements were studied (Nd and Dy), together with new targets of masses (Ce and Er) studied previously without the ΔE -E detector.¹ A ΔE -E spectrum for Ce is shown in Fig. 1. This appears to be consistent with the unusually symmetric fission mass distribution $140 \rightarrow 50(Z \approx 20) + 80(Z \approx 35) + \dots$ deduced previously.^{1,3} Likewise mass (and Z) distributions for other targets near $A = 140$ (Nd and Dy) exhibit broad and/or double-peaked mass distributions (Fig. 2). This is indicative of a trend towards broad, asymmetric fission as $A \rightarrow 100$ which is predicted by the liquid drop model (BG point). Recent studies⁴ at $E_p = 1 \text{ GeV}$ also indicate such behavior (Fig. 3).

We have also obtained angular correlations (using the coincidence data) and angular distributions (using singles data and plastic track detectors). Further studies using a 200 MeV ^3He beam have been approved, which will permit investigation of the region $A < 140$, yet still with relatively low angular momentum and mass transfer.
