## Abstract:

The efforts of the European Commission to reduce regional inequalities over its territory continues to attract the attention of researchers. The purpose of this paper is to perform an exploratory investigation of the relationship between the spatial distribution of regional income and of regional development funds among 145 European regions over 1989-1999. Using a set of tools of spatial statistics, we first detect the presence of global and local spatial autocorrelation in the distribution of regional per capita incomes, traducing that rich (poor) regions tend to be clustered close to other rich (poor) regions, and in the distribution of regional growth rate and regional funds. Second, the results of LISA statistics conclude to the presence of spatial heterogeneity in the form of two spatial clusters of rich and poor regions over the decade, highlighting the persistence of a significant core-periphery pattern among European regions. Finally, an exploratory analysis reveals a negative correlation between growth and initial income, that tends to indicate  $\beta$ -convergence. A positive relationship between regional growth and structural funds is identified among the significant results as well. Only Andalucia, Galicia and Sterea Ellada show atypical linkages. These results suggest that further research should include spatial effects and the distribution of regional funds in the spatial econometric estimation of regional convergence in Europe.

---

<sup>1</sup> This paper has been written while I was a Fulbright Visiting-Researcher at the Regional Economics Applications Laboratory, University of Illinois at Urbana-Champaign (USA). I have benefited from useful comments of the participants of the 49<sup>th</sup> Annual North American Meeting of the RSAI and the participants of the 42<sup>nd</sup> Annual Meeting of the WRSA. I would like to thank most especially Julie Le Gallo, Phil Rees and two anonymous referees for their valuable suggestions. Financial support from the Région Aquitaine (France) is gratefully acknowledged.

## 1 Introduction

The phenomenon of persistent income disparities among European regions has been widely studied in the literature, using  $\beta$ -convergence<sup>2</sup> models, most of the time based on neo-classical specifications (Esteban, 1994; Neven and Gouyette, 1995). Together with  $\sigma$ -convergence,<sup>3</sup> these concepts have been criticized for several econometric problems they bring about, like Galton's fallacy problem, and their inadequacy to explain economic polarization, persistent poverty and clustering (Quah, 1993). In contrast, the concepts of convergence clubs (Durlauf and Johnson, 1995; Chatterji, 1992; Quah, 1996) and core-periphery (Krugman, 1991a, 1991b; Fujita *et al.*, 1999) are compatible with the existence of multiple, locally stable steady state equilibria that are more relevant in the European regional case.

Another often-raised criticism comes from the fact that the majority of these empirical tests of regional income convergence are based on the same hypotheses as the ones underlying international income convergence: regions are considered as isolated entities, as if their geographical location and potential interregional linkages did not matter. Only recently, with the development of the appropriate tools of spatial statistics and spatial econometrics (Anselin, 1988, 2001; Anselin and Berra, 1998), has the role of spatial effects been considered in empirical works. These tools have been applied to regional convergence in the United-States (Rey and Montouri, 1999; Rey, 2001), in Europe (Fingleton, 1999 and 2001; Baumont *et al.*, 2002; Bivand and Brunstad, 2002), in China (Ying, 2000), in Brazil (Magalhães *et al.*, 2000), in Chile (Aroca *et al.*, 2000) and Turkey (Gezici and Hewings, 2002). The underlying idea, based on economic geographic theories and growth theories, is that forces that are driving the relocation/agglomeration process and hence generating an even/uneven regional development may be attributed to such factors as productivity

---

<sup>2</sup>  $\beta$ -convergence occurs when the poor regions tend to grow faster than the rich ones.

<sup>3</sup>  $\sigma$ -convergence occurs when there is a reduction in the standard deviation of regional incomes.

(Hirschman, 1958), transportation infrastructures (Krugman and Venables, 1995, 1996), technology and knowledge spillovers (Martin and Ottaviano, 1999), factor mobility (Krugman, 1991a, b; Puga, 1999), each of which has an explicit geographic component. Since geographic spillover effects influence the patterns of regional development, it is highly probable that these influences exhibit a non-random distinctive geographic pattern. Applied to the spatial distribution of income, evidence reveals that the rich (poor) regions have a propensity to be clustered close to other rich (poor) regions.

However, the European Commission considers regional imbalances unacceptable on distributional (spatial equity) and political grounds. The successive enlargements of the European Community to less developed countries have made regional disparities so prominent that 68% of structural funds are now devoted to the least developed regions (objective 1). Structural funds are the most important instruments of the European regional development policy with Ecu 154.5 billion (at 1994 prices) allocated over 1994-1999. However, their impact on regional development is not yet clear: most of the structural funds finance public infrastructures that are supposed to enhance cohesion among European regions (Aschauer, 1989). Many of these investments finance transportation infrastructures that result in a decrease in transportation costs, thereby potentially altering the locational attractiveness of regions. As a result, the benefits from these investments do not necessarily remain to benefit only the region in which they are implemented (Martin, 2000; Vickerman, 1996).

The purpose of this paper is to apply some newly developed techniques of spatial analysis to investigate the ability of the European Commission to favor cohesion through its regional policy. To this end, we perform an exploratory analysis of the relationship between the spatial distribution of per capita GDP and regional funds among 145 European regions over the period 1989-1999, a decade that corresponds to the first two programming periods in

which European regional development policy was developed.. The paper proceeds as follows: section 2 describes the linkages between regional funds and even/uneven regional development. Section 3 presents the data. In section 4, we perform the exploratory spatial data analysis of the distribution of regional per capita GDP, of structural funds and of additional funds. The paper concludes with a summary and some closing remarks.

## **2. Impact of structural funds on the spatial distribution of income**

European regional assistance over the 1989-1999 period dealt with six different objectives, the most important of which, with 68% of total structural funds devoted to this objective, was the objective 1, designed to address the economic development of the least prosperous regions. NUTS II level regions<sup>1</sup> were eligible under this objective when their per capita GDP (in PPP, Purchasing Power Parity) was below 75% of the Community average. The other objectives were respectively devoted to the regions affected by industrial crisis (objective 2), by long-term unemployment (objective 3), the adaptation of the labor force (objective 4), agricultural structures (objectives 5a and 5b) and low density regions (objective 6). Objective 1 affected about 50 NUTS II level regions, and included the Mezzogiorno in Italy, all regions of Greece, Ireland and Portugal, and about two third of the Spanish regions. With regards to the type of projects financed, one third of structural funds (Ecu 77 billion at 1999 prices) were devoted to transportation infrastructures, while the rest supported human-capital enhancement and the productive sector directly. Transportation infrastructures have also been strongly supported through one half of the cohesion funds (Ecu 8 billion at 1999 prices), the second main instrument of regional policies, allocated since 1994 to Spain, Portugal, Greece and Ireland. They will not be formally included in the rest of the analysis since they

---

<sup>1</sup> NUTS: Nomenclature of Territorial Units for Statistics. The Commission uses as regional statistical concept the spatial classification established by Eurostat on the basis of national administrative units. Europe can therefore be shared either in 77 NUTS I level regions, or 211 NUTS II, 1031 NUTS III, 1074 NUTS IV or 98433 NUTS V. Regional objectives are however mostly designated at either NUTS II or NUTS III level regions.

are allocated at the national but not regional level, and since there are no data to reveal their regional distribution. For the European Commission, that has the goal of achieving the European Single Market, transportation infrastructures play a key role in the efforts to reduce the lack of cohesion among members.

However, from a theoretical as well as empirical point of view, their impact on regional development is not clear. On the one hand the endogenous growth models *à la* Aschauer (1989) and Barro (1990) predict that if public infrastructures are an input in the production function, then policies financing new public infrastructures increase the marginal product of private capital, fostering both capital accumulation and growth. On the other hand, the economic geography theoretical perspectives developed by Martin and Rogers (1995) and Martin (2000) demonstrate that when transportation infrastructures are financed, they affect the process of industry location and lead to involuntary effects. Financing intra-regional transport infrastructures in the poorest regions increases the probability of firms locating there, but reduces the country's aggregate growth rate and increases regional income inequalities. On the other hand, interregional transport infrastructures foster aggregate growth, but lead to greater concentration in the core. Moreover, an increasing part of the new transport infrastructures planned for the development of the trans-European network tend to be built within and between core regions, where transport demand is the highest (Vickerman, 1991, 1996). Only the regions that belong to the main network will gain in accessibility, whereas the regions that do not belong to it or are located at the edge of it will not.

The relationship between gain in accessibility and economic development in peripheral regions is not clear and requires further research, since it depends on the specific dependence on transport cost in each sector. There is no doubt that gains in accessibility due to interregional transport infrastructures will always be relatively higher in the core region than in the peripheral one (Vickerman *et al.*, 1999; Venables and Gasiorek, 1999). Peripheral

regions have generally lower unit costs than core regions and this advantage may attract activities to locate there. However, this attraction also depends on the level of transport infrastructure, the lack of which impedes the development of growth potential in the periphery, but the improvement of which does not necessarily promote its growth.

Three other points confirm that the allocation of regional funds does not necessarily promote regional development. First, a firm located in the targeted region does not necessarily undertake the construction of new infrastructures. As a result, a part of the value added of a project in one region may first benefit another location. Secondly, beyond this apparent desire to reduce interregional income inequalities, the EU aid is not necessarily correlated with the development gap or development potential. As pointed out by Fayolle and Lecuyer (2000), only objective 1 was devoted to the poorest regions. Objectives 2 and 3, even if they handle lower amounts, concern aid for industry restructuring that affect mostly regions that were formerly prosperous. Finally, a particular project is never implemented without additional regional or national financing. This is the principle of additionality that would preclude regions presenting dubious projects<sup>4</sup>. There is a bias introduced through this principle which comes from the fact that poor regions often have problems to match the European aid, whereas the aid can be tripled or quadrupled in regions with medium or high income levels, as they have more fiscal capacity to complement structural funds (Martin, 1998).

### **3 Data**

The regional per capita GDP series in Ecu current prices come from the database New Cronos Regio by Eurostat. This is the official database used by the European Commission

---

<sup>4</sup> Community funds support up to 75% of total public expenditure in NUTS regions, the rest depends on national or regional additionality in order to avoid regions present unviable projects. The ceilings vary according to the objective concerned: objective 1 finances a maximum 75% of the total cost, but 80% in cohesion countries (Spain, Portugal, Greece and Ireland) and 85% in the most remote regions and the outlying Greek islands. The other objectives financed a maximum 50% of the total cost.

for its evaluation of regional convergence. We use the logarithms of the per capita GDP of each region over the 1989-1999 period in constant prices. Our sample is composed of 145 regions at NUTS II level (Nomenclature of Territorial Units for Statistics) over 12 EU countries:

- Belgium: 11 regions
- Denmark: 1 region
- Germany: 30 regions. Berlin and the nine former East German regions are excluded due to historical reasons
- Greece: 13 regions
- Spain: 16 regions, as we exclude the remote islands: Las Palmas, Santa Cruz de Tenerife Canary Islands and Ceuta y Mellila.
- France: 22 regions
- Ireland: 2 regions
- Italy: 20 regions
- Netherlands: 12 regions
- Portugal: 5 regions. The Azores and Madeira are excluded because of their geographical distance
- United Kingdom: 12 regions. In the case of the UK, we use regions at the NUTS I level, because NUTS II regions are not used as governmental units, they are merely statistical inventions of the EU Commission and the UK government.
- Luxembourg: 1 region

We do not include Austria, Finland and Sweden since they joined the EU only in 1995. The choice of studying European regions at the NUTS II level is purely based on regional development policies consideration. The data on structural funds come from the publications

of the Commission. The period under study covers the two first programming periods: the data over 1989-1993 are from “*Community structural interventions*”, *Statistical report n°3 and 4*, (July and Dec., 1992)<sup>5</sup> and for 1994-1999, from *The 11<sup>th</sup> annual report on the structural funds*. The data represent the total payments plus the total engagements of the European Commission at the date of publishing the 11<sup>th</sup> report. Some of the funds were allocated to 6 German NUTS I regions and 2 Belgian NUTS I regions. We therefore disaggregate these funds at the NUTS II level with respect to their objective and their redistribution pattern<sup>6</sup>. With regard to the total cost of Community projects, we apply the same methodology and take also into account the fact that the richer NUTS 2 regions within the NUTS 1 region have more facility to accompany Community funds. This modification enables the bias introduced by additional funds to be considered in the formal analysis. Since these data are not annually available and we want to consider funds relatively to the local population, data are divided by the number of inhabitant (average over 1989-1999) for each region and expressed in constant prices. As we have seen in the previous section, structural funds are just a part of the financing of public infrastructures in lagging regions. Since national and regional co-financings also support Community investments, we will also consider the total cost of Community projects over the same period.

We are aware that our empirical results could be affected by missing regions and by the use of different levels of spatial aggregation. The choice of the spatial aggregation influences the magnitude of various measures of association. In the literature, this problem is referred to the modifiable areal unit problem (MAUP) (see Openshaw and Taylor, 1979), and also considered as an example of ecological fallacy (Anselin and Cho, 2000). Messner and Anselin (2001) add that scale is important as well. If the scale and spatial extent of units of observations for the data do not match up the scale and spatial extent of the studied process,

---

<sup>5</sup> The author would like to thank Jacky Fayolle and Anne Lecuyer for providing this dataset.

<sup>6</sup> The disaggregating methodology is available upon request.

then it may result in a statistical problem wherein spatially correlated and/or heteroskedastic error structures occur. For instance, the area of Castilla-y-Leon (in Spain) is 585 times greater than the one of Brussels (Belgium), but both are official NUTS II regions (Casellas and Galley, 1999). Moreover, per capita growth in open formal NUTS 2 regions may reflect characteristics of neighboring regions. Boldrin and Canova (2001) discuss the problems linked to measuring a variable on a territorial unit that is artificially defined and in which people are free to move. They give the example of the city of Hamburg, a NUTS II level region with high per capita income, in which half the population of the whole Hamburg metropolitan area lives in the nearby NUTS II level regions of Schleswig-Holstein and Lower Saxony, commuting to Hamburg for work. As a result, the value added in Hamburg is overstated by 20% relative to its effective population, while those of Schleswig-Holstein (value added equals 102% of EU average) and Lower Saxony (104%) are understated. This is similar for Ile de France (160%) and Bassin Parisien (92.7%), Comunidad de Madrid (101%) and its two neighboring Castillas (66 and 76%).

#### **4 Exploratory spatial data analysis (ESDA)**

ESDA is a set of techniques used to describe and visualize spatial distributions, identify atypical locations or spatial outliers, discover patterns of spatial association, clusters or hot spots, and suggest spatial regimes or other forms of spatial heterogeneity (Anselin, 1988, 1999; Messner and Anselin, 2001; Haining, 1990)

##### **4.1- Mapping the distributions**

We start the analysis with the figure 1<sup>7</sup>. It is a choropleth map displaying the distribution of regional per capita GDP level in 1989 relative to the European average. A clear core-

---

<sup>7</sup> All figures have been realized using ArcView GIS 3.2 (Esri).

periphery pattern appears in this map, with the core (the darker color) composed of the richest regions, whereas the peripheral regions are also the poorest ones. Four different categories are presented. The first one includes the regions of Ireland, Portugal, Greece, the majority of the Spanish regions and six southern Italian ones with per capita GDP below 75% of the European average in 1989 (objective 1). The other categories show the distribution of regional income below the average but superior to 75% (75%-100%), higher than the average (100%-150%) and strongly greater than the average (>150%). Three regions had an exceptionally greater level of income than the overall distribution (greater than 1.5 interquartile ranges), thus are considered as outliers. These are the regions of Hamburg and Darmstadt in Germany, and Ile-de-France in France. These results are partly due to significant commuting from their neighboring regions, as was noted earlier for the case of Hamburg.

<<insert figure 1 here>>

The core-periphery pattern in 1999 is still apparent and since there have been few changes, a separate figure is not included. Only the situation of the two Irish regions has clearly improved in comparison with the initial year. Actually the Irish per capita GDP has been greater than the EU average since 1997.

Figure 2 displays the distribution (in quartile) of the sum of structural funds on the average regional GDP over 1989-1999. As expected, the poor and peripheral regions are the ones that benefited the most from Community support. Note that two core regions (Hainaut in Belgium and Flevoland in Netherlands) belong to the most assisted regions as well. They even received more structural assistance than Attiki (Greece) or some Portuguese or Spanish regions. The explanation lies in the facts that the two regions received significant structural funds, but under objective 2 (for regions in industrial decline), whereas the poor Portuguese and Spanish regions received assistance only under objective 1. As explained in section 2,

structural assistance is not only based on the objective of reducing income gaps. We do not perform an analysis of detecting outliers since the map makes clear that the poor and peripheral regions received exceptionally high levels of structural funds compared to the sample mean.

<<insert figure 2 here>>

Figure 3 presents the ratio total project cost on structural funds (in quartile). The greater is this ratio, the greater is the regional or national co-financing in the total investment. In the poorest regions (first quartile), the total cost is until 2.2 times higher than the level of structural funds. It means that the region itself has to pay an amount equal to 1.2 times the level of structural funds. While peripheral regions are just able to double the Community support (first quartile), the wealthiest northern Spanish regions and numerous core regions succeed in providing from 2.5 to 6.4 times the amount committed by structural funds (upper quartile).

<< insert figure 3 here>>

The range of each category defined in the previous maps is rather large, and these maps do not allow reveal whether the spatial distribution of this variable is significantly persistent over the period. Moreover, they are also limited in the ability to identify any of the significant spatial effects that were introduced in the introduction.

#### **4.2 Determination of the spatial weight matrix**

Before going further in the spatial analysis of regional income distribution, some comments need to be made about the spatial weight matrix that will be employed in the analysis. In the European context, the presence of islands such as the United-Kingdom, Ireland or Corsica impedes adoption of simple contiguity matrices, since the weight matrix would include rows and columns with only zeros for these regions. Since unconnected observations are

eliminated from the results of the global statistics, this would change the sample size and the interpretation of the statistical inference. Following the recommendations of Anselin (1996) and Anselin and Bera (1998), we choose to base them on pure geographical distance, as the exogeneity of geographical distance is unambiguous<sup>8</sup>. More precisely, we use the great circle distance between regional centroids. By using the great circle distance, dependence can be considered in any direction. Following Le Gallo and Ertur (2003), we base our weight matrices on the  $k = 10, 15, 20$  nearest neighbors. The form of the spatial weight matrix is the following:

$$\begin{cases} w_{ij}(k) = 0 \text{ if } i = j \\ w_{ij}(k) = 1 \text{ if } d_{ij} \leq D_i(k) \text{ and } w_{ij}^*(k) = w_{ij}(k) / \sum_j w_{ij}(k) \\ w_{ij}(k) = 0 \text{ if } d_{ij} > D_i(k) \end{cases} \quad \text{for } k = 10, 15, 20 \quad (1)$$

where  $d_{ij}$  is the great circle distance between centroids of region  $i$  and  $j$ .  $D_i(k)$  is the critical cut-off distance defined for each region  $i$ , above which interactions are assumed to be negligible. In other words,  $D_i(k)$  is the  $k^{\text{th}}$  order smallest distance between regions  $i$  and  $j$  such that each region  $i$  has exactly  $k$  neighbors. Each matrix is row standardized so that it is relative and not absolute distance that matters, yielding the matrix  $w^*$ . It is worth mentioning that in the European context, the minimum number of nearest neighbors that guarantees international connections between all regions is  $k=7$ , otherwise the Greek regions would not be linked to Italy at all. With  $k=10$ , Ireland is connected to the UK, which in turn is connected to the whole continent; and the islands of Sicilia, Sardegna, Corsica are connected

---

<sup>8</sup> In the case of European regions, it could be attractive to base these weights on the channels of communication between regions, such as roads and railways (see Bodson and Peeters, 1975). However, as pointed out by Anselin and Bera (1998), “indicators for the socioeconomic weights should be chosen with great care to ensure their exogeneity, unless their endogeneity is considered explicitly in the model specification”.

to the continental French regions. When the number of  $k$ -nearest neighbors increases, the share of international interconnections increases as well.

### 4.3- Moran' $I$

We begin the analysis of the spatial distribution of regional income and regional funds by examining Moran's  $I$  statistics to capture the global spatial autocorrelation of the variables of interest. For each variable, the degree of linear association between its value at one location and the spatially weighted average of neighboring values is provided. We use a permutation approach with 10000 permutations (Anselin, 1995)<sup>9</sup>. Formally, for each variable of interest, the Moran's  $I$  is given by:

$$I_t = \frac{\sum_{i=1}^n \sum_{j=1}^n w_{ij}^*(k) x_{it} x_{jt}}{\sum_{i=1}^n \sum_{j=1}^n x_{it} x_{jt}} \quad (2)$$

where  $w_{ij}^*$  is the (row-standardized) degree of connection between the spatial units  $i$  and  $j$  and  $x_{it}$  is the variable of interest in region  $i$  at year  $t$  (measured as a deviation from the mean value for that year). Values of  $I$  larger (smaller) than the expected value  $E(I) = -1/(n-1)$  indicate positive (negative) spatial autocorrelation. In our case,  $E(I) = -0.00694$ .

<<insert table 1 here>>

The results in table 1 report the value of Moran's  $I$  and of the standard deviation for all the variables.<sup>10</sup> Moran's  $I$  statistics are positive and significant ( $p$ -value = 0.0001) for all variables. For the regional per capita income, it means that the rich (poor) regions have a

<sup>9</sup> We use the SpaceStat 1.91 software to realize all the computations (Anselin, 1999).

<sup>10</sup> The results are similar to those found with the Geary's  $c$  statistics. Complete results are available upon request.

propensity to be clustered close to other rich (poor) regions. We note that the values of the statistics seem stable over the period, but they are higher over the 1993-1995 period, one that corresponds to greater integration after the 1992 Maastricht Treaty. The distribution of the regional per capita GDP in Europe is therefore certainly not random. With the same idea, objective (non-objective) regions, i.e. regions with high (low) structural funds, have a propensity to be close to other objective (non-objective) regions. The extent of Moran's  $I$  statistics reveals a higher clustering of regions with similar structural funds than with similar Community projects, for all weight matrices. Differences among values of Community projects seem smaller than among structural funds according to the standard deviation as well. One explanation is that the last ones have structural purposes, therefore their amount and location are targeted. On the contrary, the first ones depend more on national/regional contributions that easily complement Community support in the rich regions. Results also display a clustering of regions with high (slow) growth rates. The Moran's  $I$  can detect global spatial autocorrelation, but it is not able to identify local patterns of spatial association, such as local spatial clusters or local spatial outliers of high (low) values that are statistically significant. Identifying the groups of regions belonging to clustering of high (low) values of per capita income is based on the results of a Moran scatterplot.

#### **4.4 Moran's scatterplot**

The idea of the Moran scatterplot, suggested by Anselin (1996), is to display the per capita income for each region (on the horizontal axis) against the standardized spatial weighted average (average of the neighbors' per capita income, also called spatial lag) on the vertical axis. As pointed out by Anselin (1999), expressing the variables in standardized form (i.e. with mean zero and standard deviation equal to one) allows assessment of both the global spatial association, since the slope of the line is the Moran's  $I$  coefficient, and local spatial

association (the quadrant in the scatterplot). The Moran scatterplot is therefore divided into four different quadrants corresponding to the four types of local spatial association between a region and its neighbors:

- quadrant I (on the top right corner) displays the regions with a high per capita income (above the average) surrounded by regions with high per capita income (above the average). This quadrant is usually noted HH.
- quadrant II (on the top left corner) shows the regions with low value surrounded by regions with high values. This quadrant is usually noted LH.
- quadrant III (on the bottom left) displays the regions with low value surrounded by regions with low values, and is noted LL.
- quadrant IV (on the bottom right) shows the regions with high value surrounded by regions with low values. It is noted HL.

Regions located in quadrants I and III refer to positive spatial autocorrelation, the spatial clustering of similar values, whereas quadrants II and IV represent negative spatial autocorrelation, the spatial clustering of dissimilar values.

<<insert figure 4 >>

Figure 4 displays the Moran scatterplots of regional per capita GDP for 1989, with  $k=10$  nearest neighbors. Positive spatial autocorrelation, detected by the value of Moran's  $I$ , is reflected by the fact that most of the regions are located in quadrant I and III. Compared to the situation in the final period<sup>11</sup>, most of the regions that belong to quadrant I (III) in 1989 also belong to quadrant I (III) in 1999. However, there are some exceptions such as the two Irish regions that were LL at the initial year and are HH (Dublin) or LH (Border) at the final year. This reflects the rapid development of Ireland over the decade. Other signs of

---

<sup>11</sup> Complete results available upon request.

development concern three Belgian regions (Luxembourg, Brabant-Wallon, Antwerpen) and Yorkshire and the Humber (UK) which go from LH-type to HH-type.

On the contrary, signs of decline may be seen in one Italian region (Abruzzo) that moves from HH-type to LL-type, Picardie (France), Trier and Lüneburg (Germany) and Drenthe (Netherlands) that move from HH- to LH-type. The Moran scatterplot also enables identification of regions with higher spatial instability for both years (HL-type and LH-type): Aquitaine in France (HL), whereas Corse, Languedoc-Roussillon, Limousin (France), Wales, North-East (UK), Namur, Hainaut (Belgium), Flevoland and Friesland (Netherlands) are LH-type. This implies that the spatial distribution of regional income is more complicated than the simple core-periphery framework previously noticed in the choropleth maps. Le Gallo and Ertur (2003) reached the same conclusions for 138 European regions over 1980-1995.

The same method is applied to structural funds and Community projects total costs as well. The results for structural funds are presented in figure 5. Here again, most of the regions are located in quadrants I and III. Regions in I (III) are basically the regions that were in III (I) in figure 4, reflecting the efforts at promoting cohesion by the Commission. However, the regions Madrid (Spain), Norte and Lisboa and Vale do Tejo (Portugal) were LL-type for their income in 1989 and 1999, but are LH for both structural funds and Community funds because they are among the richest of the Iberian Peninsula. The region of Dublin in Ireland is by far the first beneficiary of the allocation of structural funds and Community projects (it is not displayed in the figure). To a lesser extent, this is also true for the Greek region Voreio Aigaio and the Spanish Extremadura.

<<insert figure 5>>

The last three columns of table 2 present the scatterplot quadrants for total structural funds over the average income 89-99, Community projects total costs over the average income 89-99 and additional funds. The results for additional funds confirm that the rich regions are

more able to complement structural funds whereas the poor ones cannot. In Spain for instance, the regions of Navarra, La Rioja and Cataluña have significant additions to the Community funds, which may be a reason for increasing disparities among Spanish regions (Fayolle and Lecuyer, 2000).

<<insert table 2>>

#### 4.5 LISA (Local Indicator of Spatial Association)

The previous scatterplots display a slight modification of the overall structure of spatial autocorrelation between the initial and the final year. For instance, some regions that were HH in the initial year belong to another quadrant in the final year. We therefore calculate LISA statistics for each observation to obtain an indication of the extent to which there has been significant spatial clustering of similar values around that observation. Moreover, the sum of LISAs for all observations is proportional to a global indicator of spatial association (Anselin, 1995). Since we use a row-standardized matrix, the average of local Moran statistics is equal to the global Moran's  $I$  statistics. LISA statistics are used for the detection of significant local spatial clusters (also called "hot spots") as well as for the diagnostics of local instability, significant outliers and spatial regimes. Anselin (1995) formalized the local Moran's statistics for each region  $i$  and year  $t$  in the following way:

$$I_{it} = \left( \frac{x_{it}}{m_0} \right) \sum_j w_{ij}^* x_{jt} \quad \text{with } m_0 = \sum_i x_{it}^2 / n \quad (3)$$

with  $x_{it}$  ( $x_{jt}$ ) is the observation in region  $i$  ( $j$ ) at year  $t$  (measured as a deviation from the mean value for that year). The results from the application of LISA with  $k=10$  nearest neighbors are summarized in columns three to seven of table 2. The robustness of these results is revealed in tables 3 and 4 with  $k=15$  and 20 neighbors respectively. The significance level is based on a conditional permutation approach with 10000 random

permutations of the neighboring regions for each observation (Anselin, 1995). The pseudo-significance level is 5%. However, due to a problem of multiple statistical comparisons, since the neighborhood sets of two regions may contain common regions (Ord and Getis 1995; Anselin, 1995), we follow the methodology of Le Gallo and Ertur (2003) and present also in column 8 the number of years for which the results are significant at a 5% Bonferroni pseudo-significance level (= 5% over 10 since we use the 10 nearest-neighbors).

In columns three to seven of table 2, each cell displays the number of years the significant local Moran statistics is located in a particular Moran scatterplot quadrant. The regions revealing significant and greater spatial association of per capita GDP (HH or LL) are basically those previously detected as core (HH cluster) and peripheral (LL cluster) regions. Over the period, 97% of the local statistics that are significant are either HH- or LL-type, reflecting the global trend of positive spatial association. However, not all core/peripheral regions cluster significantly over the period. Local Moran statistics are not significant over the period for various regions in different countries (column 3 in table 2). Denmark, Greece and Portugal are the only countries without any non-significant statistics throughout the period (in Germany, Düsseldorf is the only region displaying non-significant statistics). Regions displaying positive local spatial association throughout the 11 years can be identified as follows:

- two different HH-type clusters can be identified because they are distant from each other:
  - all the German regions (but Düsseldorf), Denmark, four northern French regions (Nord-Pas-de-Calais, Lorraine, Alsace, Franche-Comté), four southern Belgian regions (Antwerpen, Luxembourg, Limburg and Vlaams-Brabant), and four southern Dutch regions (Zuid-Holland, Zeeland, Noord-Brabant and Limburg).
  - six Italian regions (Piemonte, Valle d'Aosta, Lombardia, Trentino-Alto Adige, Veneto and Friuli-Venezia Giulia).

- two different LL-type clusters can also be identified for the same reason :

- all the Portuguese regions and eleven Spanish regions (Galicia, Asturias, Cantabria, Madrid, Castilla-y-Léon, Castilla-la-Mancha, Extremadura, Comunidad Valenciana, Baléares, Andalucia and Murcia)

- all the Greek regions and four southern Italian regions (Puglia, Basilicata, Calabria, Sicilia).

All of them show positive spatial autocorrelation with a significance level  $p < 0.05$  for more than 5 years. The persistence of different clusters of high and low income is a sign of spatial heterogeneity among European regions confirming the persistence of income disparities. These results are robust when we use  $k=15$  or 20 neighbors, confirmed by the robustness analysis for LISA (suggested by Le Gallo and Ertur, 2003) displayed in tables 3 and 4. Significant negative spatial autocorrelation occurs over 10 years for the French region of Corsica (LH-type), but no more than three years elsewhere. Two interpretations can be noted from these tables. First, when we increase the number of neighbors, a region with a significant LISA remains in the same quadrant. Secondly, respectively 21.9% and 31.6% of the regions with non significant LISA for  $k=10$  become HH-type when  $k=15$  and  $k=20$ . These regions are mostly French, North-Italian, Belgian, Dutch and British, whereas the regions becoming LL-type (4.6% when  $k=15$  and 4.5% when  $k=20$ ) are mostly Spanish and Southern Italian.

<<insert tables 3 and 4 here>>

If we focus now on the column giving the significant Moran scatterplot quadrants for growth over 1989-1999, the significant HH-type correlation applies to all the Portuguese and Irish regions, the Greek regions (except Ipeiros and Sterea Ellada), only Extremadura in Spain and five British regions. Only three regions have a significant Moran statistic in Spain, which can be explained by the fact that Spain is the country where regional inequities have increased the

most over this period. The LL-growth-type regions are Italian (except Calabria and Puglia), ten French regions, mostly in the South, six German regions (Tübingen, Freiburg, Karlsruhe, Rheinhessen-Pflaz, Darmstadt and Arnsberg) and Baleares in Spain. Six regions show significant negative spatial autocorrelation: Andalucia and Galicia in Spain, Sterea Ellada in Greece are LH-type, which indicates that they failed to develop in spite of the dynamism of their neighboring regions. On the other hand, three HL-type regions (Corse in France, Gießen and Kassel in Germany) show a significantly higher dynamism than their neighbors.

<<insert table 5 here>>

Table 5 is a correlation table between the initial per capita income and the growth rate over the period. Only 27% of the results are significant for both initial per capita income and growth rate. However, it is interesting to note that 82% of these results show an inverse relationship between initial conditions and growth rates. The five Portuguese regions, nine out of thirteen Greek regions (the others do not have significant results) and Extremadura in Spain were LL-type for their initial income, but were HH-type for their growth rate over 1989-1999. Among the significant results, the conditions of  $\beta$ -convergence seem respected since the poor regions also have the highest growth rates. The Irish and Spanish regions do not appear here since the results for initial income are not significant in Ireland, and most of the results for growth are not significant in Spain. On the contrary, the regions displaying significant HH-type for the initial income and significant LL-type for growth are six German regions (Karlsruhe, Freiburg, Tübingen, Darmstadt, Arnsberg, Rheinhessen-Pflaz), three French regions (Alsace, Franche-Comté, Provence-Alpes-Cote-d'Azur), nine northern Italian regions (Piemonte, Valle d'Aosta, Liguria, Lombardia, Trentino-Alto Adige, Veneto, Friuli-Venezia Giulia, Emilio-Romagna). Three regions, Gießen and Kassel in Germany and Corse in France (but only in 1989) were HH-type for the initial income and HL-type for growth. The two German regions have therefore succeeded in growing faster than their neighbors, in

spite of a high initial level of income, like their neighbors. Three regions (Galicia and Andalucia in Spain and Sterea Ellada in Greece) are significantly LL-type for their initial income but LH-type for their growth. It means that even if these regions started with the same initial conditions as their neighbors, their neighbors performed better in terms of development.

Instead of describing the significant results for LISA statistics on regional funds presented in the last three columns of table 2, the last step of our analysis will focus directly on the correlation between structural funds (then additional funds) and regional growth presented in table 6.

<<insert table 6 here>>

Only 28% of the results are significant for both structural funds and growth. However, 78% of these results show a positive relationship between growth and structural funds. Fourteen regions characterized by significant HH-type structural funds show significant HH-type growth. These regions are nine Greek regions (see table 2), Dublin in Ireland, three Portuguese regions (Centro, Alentejo and Algarve) and Northern Ireland (UK). On the contrary, the regions with LL-type growth and LL-type structural funds are six German regions (Karlsruhe, Freiburg, Tübingen, Damrstadt, Arnsberg, Rheinhessen-Pflaz), five French regions (Alsace, Franche-Comté, Poitou-Chatentes, Limousin, Auvergne), six Italian regions (Piemonte, Valle d'Aosta, Lombardia, Trentino-Alo Adige, Veneto, Fruili Veneza Giulia) and Luxembourg (country).

The atypical patterns of growth-structural funds relationships for regions with a different development behavior than their neighbors, in spite of the fact that they all are “similarly” assisted.<sup>12</sup> For instance, Gießen and Kassel (Germany) are LL-type for structural funds, but HL-type for growth. They performed better than their neighbors, in spite of a similar low

---

<sup>12</sup> We put this word into quotation marks because the per capita levels of regional assistance may be very different, even if they belong to the same quadrant in the Moran scatterplot.

level of structural funds. Norte and Liboa e Vale do Tejo in Portugal and Scotland (UK) are also insightful since they are HH-type growth but LH-type structural funds. On the contrary, Galicia, Andalucia (Spain) and Sterea Ellada (Greece) do not grow as fast as their neighbors, even if they received “similar” structural assistance (LH growth, HH funds).

Clearly, structural funds are not the main variable driving even/uneven regional development. A closer look at the economic structure, the accessibility, the institutional aspects of each region as well as the type of projects that structural funds finance in these regions and their neighboring regions could help explain why these regions display greater/smaller development progress than their neighbors even if they receive similar amount of structural funds.

Further, the perpetuation of disparities may be attributed in part to a region’s ability to provide additional, matching funds. Again, the correlation displays that regions with low additional funds (the poor ones since they cannot afford additional investment) have a HH-type growth and inversely<sup>13</sup>. An interesting case is for the three regions that display significant LH-type for growth and LL-type for additional funds: Sterea Ellada in Greece, Andalucia and Galicia in Spain. Remember that these regions are HH-type for structural funds. Therefore, if they do not perform as well as at their neighbors in terms of development, the reason does not come from higher additional funds in neighboring regions. Once again, a closer look at the specific economic structure of these regions as well as the use of regional funds could help to clarify the presence of “atypical” linkages between growth and structural funds detected in table 6.

## 5 Conclusion

The aim of this paper has been to perform an exploratory analysis of the ability of the European Commission to reduce regional disparities through its regional policy. We have investigated relationships between the spatial distribution of per capita GDP and of regional funds of 145 European regions over 1989-1999, using an exploratory spatial data analysis. This period corresponds to the two first program periods wherein regional assistance to the poorest regions was made available. We first used Moran's  $I$  to detect the presence of positive global spatial autocorrelation in the distribution of per capita GDP to explore whether the rich (poor) regions have a propensity to be clustered close to other rich (poor) regions. Global spatial autocorrelation also characterizes the regional growth rate, structural funds and Community projects total costs. Further analysis using Moran's scatterplot reveals also the presence of positive local spatial autocorrelation for each of the previous variables.

When LISA is performed, the results confirm the significant presence and persistence over time of local spatial autocorrelation in the form of two distinct spatial clusters of high and low values of per capita income. This form of spatial heterogeneity reflects a core-periphery pattern since per capita GDP inequalities are persistent among European regions. LISA is also performed on the spatial distribution of the regional growth rate. When an exploratory investigation of the correlation between the spatial patterns of the variables is performed, a negative relationship between regional growth and initial income level is detected among the significant results, a finding that seems consistent with the hypothesis of  $\beta$ -convergence. A positive relationship between regional growth and structural funds is also identified among the significant results. It may reflect the distributional efforts of the European Commission that has devoted the most important part of its funds to help the least developed regions and therefore provides little assistance to the rich regions. However, the results also indicate that structural funds are clearly not the only variable to control for the various growth rates among

European regions. This is confirmed by the presence of “atypical” linkages between both variables in Andalusia, Galicia and Sterea Ellada. These results show that studies of European regional development should take into account the level of structural funds devoted to the objective region itself, but also to its neighboring regions. However, given the exploratory nature of our analysis, this paper calls for a thorough mutli-regional estimation of the workings of the system involved. In the absence of interregional input-output tables in Europe, this could be done, for example, using a spatial econometric estimation where spatial effects, initial conditions and the spatial distribution of both structural funds and Community projects total costs would be included in the estimation of the European regional convergence process. While this need is important for a better understanding of the impact of regional funds on cohesion, this is beyond the scope of this paper.

Note: Level of pseudo-significance  $p < 0.05$ . **Not sign.** denotes the number of years local statistics is not significant at 0.05. Maximum number of years is 11. **HH**, number of years local statistics of significant and in quadrant HH of Moran's scatterplot; **LL**, number of years local statistics of significant and in quadrant LL of Moran's scatterplot; **HL**, number of years local statistics of significant and in quadrant HL of Moran's scatterplot; **LH**, number of years local statistics of significant and in quadrant LH of Moran's scatterplot. **Bonf. 5%** indicates the number of years the statistics is significant at 5% Bonferroni pseudo-significance level. **Growth 89-99** indicates if local statistics of growth rate over 1989-1999 is significant or not, if yes, then the quadrant in Moran's scatterplot it belongs to. ns means no significance at  $p < 0.05$ . **fs/m** is total structural funds 89-99 divided by the region's mean per capita GDP over 1989-1999; **ct/m** is Community projects total costs 89-99 divided by the region's mean per capita GDP over 1989-1999; **ct/fs** is Community projects total costs divided by structural funds over 1989-1999, \* indicates that the LISA statistics is not significant at the 5% pseudo-significance level.
