Comments are Welcome

Draft: June 11, 2011

Abstract: In this paper we study the impact of AGOA and CBTPA preferences on the African and Caribbean Basin beneficiaries respectively. Our methodology consists of modelling the selection in exporting that occurs and to account for the zero trade occurring at the HS 6 digit level of disaggregation used in the paper. The AGOA impact has in the literature been found to be driven mainly by apparel and textiles and oil and energy related products. We however, do find a strong impact of the AGOA and CBTPA preferences for the beneficiary countries.

Key Words: Trade preference regimes, African Growth and Opportunity Act (AGOA), Caribbean Basin Initiative (CBI), Africa, Latin America and Caribbean, international trade, Generalised System of Preferences (GSP)

JEL Classification: F10, F13

¹I acknowledge the valuable input of my supervisor Michael Gasiorek. I am also indebted to ZhenKun Wang, Javier Lopez Gonzalez, Maximiliano Mendez Parra, faculty and colleagues in Sussex for discussions on various aspects of the paper as well as participants at the economics Dphil conference in Sussex and development seminar at Nottingham for insightful comments. As usual all remaining errors are entirely mine.

1 Introduction and Background

There has been much debate in the literature about the impact of the USA's preferences for developing countries. These studies include the impact of the African Growth and Opportunity Act (AGOA) (for example, Brenton and Hoppe, 2006, Brenton and Ikezuki, 2004, Collier and Venables, 2007, Frazer and Biesebroeck, 2007, Frazer and Van Biesebroeck, 2010, Gibbon, 2003, Mattoo et al., 2003, Páez et al., 2010, Tadesse and Fayissa, 2008) and studies on the North American Free Trade Agreement (NAFTA), Caribbean Basin Initiative (CBI) and Dominican Republic–Central America Free Trade Area (CAFTA-DR) (Ames, 1993, Haar, 1990, Hornbeck, 2010, Hutchinson and Schumacher, 1994, Ozden and Sharma, 2006, Yeboah et al., 2009). However, to date Collier and Venables (2007), Di Rubbo and Canali (2008) and Nilsson (2005) prove to be the main comparative approaches in the literature estimating the impact of AGOA on beneficiaries while controlling for the EU's preferences. This paper intends to follow in this tradition, however, the analysis is done controlling for the exports of the developing countries to the rest of the world. Nonetheless, the studies on the impact of the CBI focus on the effects on the CBI of NAFTA and CAFTA-DR agreements. We however, also expect similar effects to be experienced by the Caribbean Basin¹ countries as a result of the implementation of AGOA.

Frazer and Van Biesebroeck (2010) argue that the nonuniform preferences provided by AGOA and its selective choice of countries from within the continent satisfy the requirement for analysing the policy impact impact of AGOA. CBI was also unilaterally applied to selected Caribbean and Latin American Countries². This variation in countries selected and products covered is employed in the analysis to study the impact of the AGOA and CBI/CBTPA preferences on selected products at the 6 digit level of trade (that is, HS chapters 1, 2, 25, 26 and 50-63). Besides, Agostino et al. (2007) also notes that in the absence of these preference agreements the average level of trade becomes the counterfactual hence, adopting their idea—the introduction of the CBI and AGOA would lead to a departure from the normal level of trade. This departure from the normal level of trade can thus be interpreted as the effect of the policy.

In this paper, we (1) estimate the impact of the USA's preferences on exports of developing countries given their exports to the rest of the world (focussing on the AGOA, CBI and GSP preferences), (2) compare the impact at various levels of disaggregated trade (3) compare AGOA to the CBTPA preferences noting any significant differences (4) determine which products have been the export drivers while comparing the importance of apparel in the exports of the preference beneficiaries and (5) show that the results are robust to the choice of econometric technique and not sensitive to controls included in the regressions. In doing this, we contribute to the existing empirical literature on USA preferences by controlling for the world exports of the developing countries. Secondly, we add to the few existing empirical work on the CBTPA preferences. In addition, we also find support for the importance of apparel and textiles in AGOA (and CBTPA) exports as has been underscored by for example Collier and Venables (2007) and Frazer and Van Biesebroeck (2010). The non apparel and textile products in our sample have not been important exports for these beneficiaries but has however, been exported more beneficially under the GSP. Finally, we show that with large N panels the random effects estimator is inconsistent and inefficient. However, the Heckman two step procedure, fixed and Mundlak corrected random effects estimators provide similar estimates.

The rest of the paper is organised as follows. Section 2 provides a brief review of the empirical literature and some initial exploration of the data on preferential imports. Section 3 presents the data and methodology. Section 4 presents econometric modelling issues that need to be addressed and section 5 is a discussion of the results. The conclusion is provided in the final Section.

¹Caribbean and Central American Countries: Anguilla, Antigua and Barbuda, Aruba, Bahamas The, Barbados, Belize, British Virgin Islands, Cayman Islands, Costa Rica, Dominica, Dominican Republic, El Salvador, Grenada, Guatemala, Guyana, Haiti, Honduras, Jamaica, Montserrat, Netherlands Antilles, Nicaragua, Panama, St. Kitts and Nevis, St. Lucia, St. Vincent and the Grenadines, Suriname, Trinidad and Tobago, and Turks and Caicos Islands

²The introduction of preferences in textiles and apparel within the CBTPA category of the CBI is used to model this variation in preferences for Caribbean Basin countries

2 Review of the Empirical Literature

The AGOA and CBI preferences have undergone several amendments since their inception in 2000 (started in 2001) and 1983 respectively. We provide a summary of these important revisions in the AGOA and CBI preferences below. For the AGOA preferences the following revisions are noteworthy³:

- AGOA I - extended GSP product eligibility (4650 products); certain limitations (eg. *competitive needs legislation*) removed; inclusion of 1835 products not covered in the GSP as duty free products.
- AGOA II - (2002) further relaxation of rules of origin in apparel and selected textile articles (eg. towels & blankets, etc); knit-to-shape apparel included; rules of origin relaxed to include yarn; Botswana and Namibia given LDC status; volume cap limit doubled
- AGOA III - extended AGOA to 2015 and apparel provisions to 2007, ethnic printed fabrics added; use of foreign collars and cuffs in domestic garments allowed
- AGOA IV - (2006) Access given to LDC AGOA countries for HS 50 - 63; new rules of origin allowing inputs to be sourced from the AGOA LDC group. Third country fabric extended to 2012; increase in volume cap on garments.
- AGOA V - (Nov. 2009) single implementation of rules of origin; harmonisation and expansion of USA preferences and extension of trade benefits currently available.

The CBI has also undergone several phases and these include⁴ :

- Launched in 1983 as the Caribbean Basin and Economic Recovery Act (CBERA)
- 1984 - 20 countries received benefits (Includes El Salvador, Guatemala and Honduras. Nicaragua in 1990).
- 1990 - CBERA made permanent and amended.
 - 20 % tariff reduction on certain leather products
 - Duty free treatment for products using 100% inputs from the US
- 1991 - 94 tariff categories added or expanded
- 1992 - 28 tariff categories added or expanded.
- 2000 - US Caribbean Basin Trade Partnership Act enacted.
 - Added apparel exports
 - This expires in 2010 (or if an FTA of the Americas comes into force)
- 2002 - CBERA amended
- 2006 - CAFTA-DR benefits begin for Dominican Republic, Honduras, Guatemala, El Salvador and Nicaragua. Costa Rica joins in 2009.
- The CBTPA has however, been extended for the remaining countries beyond 2010.

2.1 AGOA and Sub Saharan Africa

Tadesse and Fayissa (2008) use HS-2 digit disaggregated data to analyse the impact of AGOA on exports of eligible countries to the US. In doing this they adopt a gravity model and they also separate the AGOA impact into intensive and extensive margins⁵. In addition to the standard gravity variables they include the stock of immigrant population (per country) in the US, dummies for landlocked, AGOA eligibility, English language, an index of economic openness, years elapsed under AGOA, lagged imports and time and country effects. Using a tobit estimation technique they carry out regressions for each HS-2 digit product (that is chapters 00 - 99) and decompose the coefficient of the AGOA dummy into extensive and intensive margin effects.

Generally, the gravity coefficients had the expected signs—distance (-0.5) and economic size (0.495) for HS 03 products (that is fish and crustaceans). Moreover, US population and income levels had no significant impact on AGOA imports in several of the HS-2 categories. AGOA had approximately a 64% increase in HS 03 imports although it was insignificant. The lag of the dependent variable (0.65) was significant in most of their regressions. They reported both positive and negative immigrant stocks in several cases. The extensive and intensive margin effects reported by them for HS 01 products were 0.085 and 0.51 respectively and significant. In relation to the decomposition, only a few products recorded significant values for both effects—much less than the 24 significant extensive margin effects across products.

Collier and Venables (2007) estimate the impact of trade preferences on exports of developing countries to the USA relative to the EU. Their focus however, is on the impact of AGOA on exports of African countries. Their total sample was 110 developing and middle income countries resulting from selecting countries with mean apparel exports of US\$ 100,000 and above. However, the main regressions are estimated for a sub sample of 86 countries whose apparel exports were US\$ 1 million and above during 1991 - 2005. The coefficients for AGOAA (AGOAA apparel) in their first three regressions were significant and varied from 2.00 to 2.21. The coefficients signify the strong impact of AGOA in increasing exports to the US relative to the EU in apparel products. The actual impact on exports to the US relative to the EU is given by the exponents of 2.00 and 2.21 which are 7.39 and 9.12 times the exports to the EU respectively. The result signifies an increase in AGOA country exports to the USA relative to the EU by a multiple of 7.39 and 9.12 respectively.

On the contrary, EBANC (Cotonou ineligible countries receiving EBA preferences) and EBA were not significant and had the wrong positive relationship with the dependent variable. Three subsequent regressions with 110 countries correct the sign for the EBA dummies and produces a marginal increase in the AGOAA coefficient. A quadruple difference in difference method to sort out the effects of having between country characteristics vary over time is also used. In the two regressions carried out with this method, the AGOAA effect recorded significant values (2.65 and 1.98 respectively). The first regression excluded the AGOA and EBANC terms. They therefore confirm that, AGOA had a large impact on its beneficiaries.

Nilsson (2005) and Di Rubbo and Canali (2008) who instead employ a gravity model do not find such strong results for AGOA in their sample. It must however, be noted that these studies did not use the same product groups and level of aggregation. Nilsson (2005) explored the effects on total exports while Di Rubbo and Canali focussed on agri-products. Collier and Venables on the other hand, limited their analysis to apparel. In summary, Nilsson (2005) and Di Rubbo and Canali (2008) did not find significant trade creating effects for AGOA. EU trade policy was found to be more trade creating compared to AGOA.

Nilsson (2005) in a study of EU and USA trade policy for 158 developing countries apply a standard gravity model in estimating the trade effects of their trade policies. Their results confirm a stronger trade

⁵They use the terms import initiation - creating new imports (extensive margin) and import intensification - the volume effect on US imports (intensive margin).

creating effect of EU policy compared to the USA trade policy. However, one drawback is that, the study did not account for the zero exports in the model estimated ⁶. This is presented as a censoring problem in the econometrics literature and can create significant biases in coefficient estimates thus making them unreliable for inference (Cameron and Trivedi, 2005, Greene, 2003, Jensen et al., 2002, Wooldridge, 2002).

However, Nilsson's (2005) cross section estimation using the 2001 - 2003 annual average exports reduce the censoring problem. The coefficients of both sets of regressions are similar; however, the t-statistics estimated in the 2001 - 2003 panel are twice the cross-section estimates indicating the potential bias of ignoring the censoring of the dependent variable in his model. The reported trade creation values for the cross-section regression ⁷ include EU imports-35.6%; low income countries-50.3%; lower middle income countries-22.9% and upper middle income countries-46.2%. The percentages indicate the amount of trade generated by EU trade policy compared to USA policy. Thus the 50.3% reported for low income countries imply that EU policy created 50.3% more exports compared to USA policy for low income countries. All but lower middle income countries had significant coefficients in the cross-section regression. The coefficients for the panel regression are not discussed in this section due to the potential bias in the coefficients identified above.

Di Rubbo and Canali (2008) in a study of 102 developing countries for the period 1996 - 2005 for agricultural products (food and fibre products) use a similar methodology to that of Nilsson (2005). They find EU trade policy to be more effective at creating trade than USA policy. They report gross trade creation coefficients of 75.9%, 62.2%, 90.4% and 69.1% for low income, lower-middle income, upper-middle income countries and EU imports respectively for the period 1996 - 2000. Higher percentages are recorded for the period 2000 - 2005 of 80.8%, 63.1%, 91.4% and 73% for low income, lower-middle income, upper-middle income countries and EU imports respectively. A similar interpretation to Nilsson's can be given to Di Rubbo and Canali—however, EU policy generates more exports of agri-products compared to the USA. They find the trade variation to be significant for the lower income group. Compared to Nilsson (2005) the trade creation effects are stronger for the upper-middle income countries rather than the low-income countries. We note that, these effects are confined to the agri-food sector not total exports as was the case in Nilsson. Also, the reported coefficients of Nilsson above, are for his cross-section regression and therefore exclude the time variation provided by Di Rubbo and Canali (2008).

In similar fashion, a recent paper by Frazer and Van Biesebroeck (2010) estimates the impact of AGOA at the HS 8 - digit level using standard difference-in-differences and triple difference-in-differences – controlling for baseline levels of imports, country and product specific import trends after the adoption of AGOA. They find an increase of 42% of imports on average as a result of the AGOA preference. However, they estimate the causal impact of AGOA to be lower at 28%. On the contrary, concentrating on only non-oil imports they find the increase to be 6.6%.

In summarising, Collier and Venables (2007), Frazer and Van Biesebroeck (2010), Gibbon (2003), Páez et al. (2010) generally find apparel and textiles as well as oil and energy products to be the main drivers of the gains by AGOA beneficiaries. We do observe this also in our analysis and it is further discussed in Section 5. Gibbon (2003) and Páez et al. (2010) discuss the proliferation of firms in the textile industry and the enormous impact on employment in that sector for Lesotho and other African countries. This according to them is not limited to apparel but also to oil and energy related exports where the example provided is the increase in investments in Nigeria's energy sector. Nonetheless, for Lesotho in spite of the record investments an impediment in having further investments was the constraints on land available (Gibbon, 2003). Had these constraints not existed a much stronger impact of AGOA might have ensued.

⁶Nilsson (2005) in Section 4, the last paragraph of the gravity model sub-section makes reference to the zero exports—"No particular attempt is made to deal with the zero-or missing value observations in the trade data" The countries with zero or missing trade data can be found in footnote 32.

⁷It is converted from actual EU imports from developing countries normalized by the transformed dummy coefficient of the relevant dummy for EU imports, and various income groupings.

In an extended survey of previous empirical studies, Mold (2005) links the mild impact of AGOA to (1) the limited benefits and exclusion of sensitive products from the AGOA list, (2) the initial 8-year life span of AGOA with the subsequent extension in 2004 (of AGOA) to 2015 has not encouraged long-term investments for investors who have been given a short horizon to work with, (3) the fear that preferential access and new trade agreements under discussion if offered to the Middle East and Central America would dampen any benefits offered by AGOA and (4) Arbitrary use of AGOA ROOs in certain products. An example offered by Mold is the near-exclusion of Kenya due to its inability to meet ROOs in textiles. Mold (2005) brings to the fore the impact of the AGOA conditions on freedom of policy making and the uncertainty created by the periodic (annual) review of AGOA beneficiaries.

2.2 CBI and Caribbean Basin Countries

The CBERA preferences were less effective than the CBTPA preferences (Hornbeck, 2010) and this shows in the jump we observe in Figure (3(a)) in Appendix I. However, this is explained by Hutchinson and Schumacher (1994) to be as a result of (a) over-reliance on the market mechanism, (b) the exclusion of important Caribbean Basin products such as textile and apparel as well as tourism products hindered the reaping of its potential benefits, (c) the re-imposition and tightening of US sugar quotas and (d) the falling world prices of petroleum and petroleum products. This has led many authors to conclude that CBERA preferences failed to achieve their mandate of increasing economic growth in the region (for example, Ames, 1993, Hornbeck, 2010, Hutchinson and Schumacher, 1994). Nonetheless, the CBTPA preferences which had a large impact on the recipients also met with a decline as a result of the introduction of the CAFTA-DR (this is observed as the declining trend for our selected Caribbean countries in Figure (3(a))).

Hornbeck (2010) argues that CBI beneficiaries have suffered from erosion of their preferences as a result of the increasing move towards the adoption of free trade agreements (FTA) by the USA. NAFTA after its adoption, curtailed the trade advantage of the CBI countries over Mexico—thereby giving Mexico some advantages in apparel and other products Mexico was more competitive at producing than the Caribbean Basin countries (Hornbeck, 2010, Hutchinson and Schumacher, 1994). Hutchinson and Schumacher (1994) in calculating the revealed comparative advantage (RCA) of Mexico and the Caribbean countries in their top 30 export products did find the Caribbean countries to be competitive in 20 out of their top 30 industries and expected this to provide some buffer against NAFTA. The adoption of the CAFTA-DR has in particular adversely affected the remaining Caribbean countries within the CBI and again reduced their trade advantage in apparel and textiles and non-primary commodities (Hornbeck, 2010). The main reason provided by Hornbeck (2010) is due to the cumulation rules in apparel production among NAFTA, CAFTA-DR and Haiti which leave the remaining countries under the CBI with limited ability to adapt to the new competition from these regions. The percent of apparel imports in total US imports of apparel is even lower—this fell from 13.6% in 2005 to 1% in 2008 (Hornbeck, 2010). Hornbeck (2010) attributes this to the CAFTA-DR — CAFTA-DR countries excluding Costa Rica accounted for 90% of total apparel imports of all the Caribbean Basin countries (Hornbeck, 2010) and this accounts for the vast shortfall.

Hornbeck (2010) shows that only 7.5% of total imports from CBI recipient countries were eligible for preferential tariffs after excluding CAFTA-DR and energy exporting countries. This is what might be driving our negative coefficients discussed in section 4 of this paper. In addition, Hornbeck (2010) finds that the following additional factors contributed to the diminishing preferences (a) CAFTA-DR countries produced most of the apparel and textile products (b) the remaining CBI countries are not competitive in the apparel sector and have been unable to take advantage of the preferences and (c) The removal of the multifibre agreement (MFA) on textiles has furthered heightened their situation. It must however, be added that some of this might also be due to AGOA countries such as Lesotho and Kenya (and other smaller AGOA recipients) gaining a foothold in the US market.

2.3 Trends in Imports to the USA from Selected AGOA and CBI beneficiaries

The variation in the exports under the various programmes are shown in the graphs at the end of the paper in Appendix I. Figure (2) shows the relationship between the preferential exports and mean aggregate exports (1997-1999) to the USA for GSP and AGOA. Figure (3) on the other hand, shows the trends in the share of preferential exports in aggregate preferences and total exports to the USA respectively. For the GSP preference South Africa is the main outlier while Nigeria is the outlier for AGOA exports. Excluding these two countries in Figures (2(c)) and (2(d)) for those with exports greater than the mean total exports for the period 1997-1999 (\$35.37 million) improves the fit and the line becomes steeper (Angola now becomes the outlier with exports close to \$1 billion) to the USA.

There is no clear indication of the relationship for countries below the mean, however, rescaling the the graph would show a very steep line of fit as in (2(c)) for these countries. In Figure (3), the selected CBI countries within Latin America in (3(b)) do not show much difference between their shares. On the contrary, a clear jump in the share of exports for the selected AGOA countries in (3(c)) is noticed in 2001 (countries begin to use their AGOA preferences). Similarly, noticeable differences exist in (3(a)) with the prominent case being the large jump in 2005 for Barbados but which gradually falls over time.

Figures (4) and (5) show the mean imports by applied and MFN tariffs for selected African and Caribbean Basin countries at the 6 digit level. Figures (6) and (7) show the maximum imports into the USA within each category. Ghana and Barbados are observed to export under each category. However, their mean imports into the USA are far below US\$1 million and that of the remaining countries (with the exception of Angola that has mean imports into USA below US\$ 20000). Kenya, Costa Rica and Jamaica have higher means, however, these are concentrated in two dominant categories—apparel and textiles, and salt/ore, slag and Ash exports. For the selected AGOA beneficiaries, their mean imports into the USA are dominated by free imports. The same can be said of Barbados and Jamaica. Although Ghana had low mean imports into the USA of apparel, the maximum imports into the USA from Ghana are concentrated in apparel and the imports are above US\$ 6 million. For the remaining countries the pattern in the mean category is maintained.

Finally, Figure (8) shows the competitiveness of selected AGOA and CBI beneficiaries in four sectors, animals/meat, apparel, salt/ores and textiles. For both panels of the graph, the mean competitiveness prior to the adoption of AGOA (1996 - 2000) and post AGOA (2001 - 2009) are compared. In Panel (a), apart from South Africa the remaining countries—Ghana, Kenya and Nigeria show increased competitiveness in textiles in the post-AGOA period. South Africa on the other hand, has increased its competitiveness in salt/ores. This is similarly shown for selected CBI countries using the pre- and post-AGOA periods for comparative purposes. The selected CBI countries in Panel (b) show a decline in their competitiveness in the apparel and textiles sector post-AGOA. However, Honduras and Jamaica have seen an increase in their competitiveness within the salt/ore sector while Costa Rica has experienced a marginal improvement in the animals/meat sector.

3 Data and Methods

Data for the analysis is obtained from the World Integrated System⁸ (WITS) which queries data from UN Comtrade for export (and import) data and UN TRAINS for the tariff data. Gross domestic product data is obtained from The World Bank's World Development Indicators⁹ (WDI) and gravity type variables (*viz.*, landlocked, area, latitude, number of cities, official language, etc) are obtained from the CEPII distances database¹⁰. In addition, our political variables (military and religion) are obtained from the Database of

⁸<http://wits.worldbank.org/wits/>

⁹<http://data.worldbank.org/>

¹⁰Centre d'Etudes Prospectives et d'Informations Internationales: <http://www.cepii.fr/anglaisgraph/bdd/distances.htm>

Political Institutions¹¹ (DPI) and democracy time series dataset¹². Finally, the preferential dummies are constructed based on information sourced from the WITS preferential database and USITC¹³. The remaining variables constructed (*viz.*, RCA and market size) are based on the variables obtained from the sources above. Table (1) provides further information on the variables used as well as summary statistics.

There are 166 countries and 981 different products at the 6 digit level in the dataset. The products comprise of 808 apparel and textile and 173 non apparel and textile products at the 6-digits level. Fewer products are however, exported by several of the countries. For example, for the African countries fewer than 400 products are exported in any given year. Of these products there are some products that are not exported in all years. In Table (1), the probability of exporting a particular 6-digit product in our sample is 0.342, the average number of free lines per 6-digit category is 0.444, the average weighted MFN tariff is 9.03% and the average applied tariff is 8.09%. The probability of exporting under the GSP, AGOA, CAFTA-DR and CBTPA are 0.008, 0.004, 0.01 and 0.007 respectively. The tariff margins are constructed based on information provided at the 6-digit level on the MFN and applied tariff provided by WITS. In cases where missing values are encountered we checked the preferential status of the country and replaced the missing values with the average estimate based on the region, preference group and product. Exports not provided by UN Comtrade were assumed to be zero. This holds since for developing countries we use mirror exports (that is, the USA and World import values from these countries) in place of the actual export values. By doing this, we are able to observe whether they actually exported those products. Nonetheless, the mirror export values are better recorded than the export values from the developing countries (Piermartini and Teh, 2005).

Finally, it is acknowledged that the tariff margin variable might be measured with some error given the paucity of tariff data available on UN TRAINS. We do, however, believe that this would not seriously affect our estimates. Besides, the tariff margin is not used in all regressions as we allow the country-product fixed effects to capture the tariff margin. Nonetheless, the product dummies also play the same role as the tariff margin variables in modelling preferences in gravity models (see for example, Cipollina and Salvatici, 2010).

The basic idea of our econometric formulation for investigating trade preferences at the macro level is adopted from Collier and Venables's (2007) paper. They estimate the impact of the USA's AGOA and EU trade preferences (given by dummies) on the log of exports from developing countries to the USA relative to the EU-15 countries. They control for market size and market demand shocks. We depart from Collier and Venables (2007) by looking at disaggregated 6 digit HS chapters 1, 2, 25, 26 and 50-63¹⁴ and instead use the ratio of imports from developing countries to the USA relative to imports from developing countries to the rest of the world (see equation 4). Additional controls included here are the ratio of USA to World revealed comparative advantage in each product exported¹⁵, lagged values of applied preferential and MFN tariffs (or preference margins) at the 6-digit product level and lagged political controls such as democracy and political stability. In addition, imports under the GSP is controlled for by interacting our GSP dummy with the CBI and AGOA dummies.

At the 6 digit level of disaggregation, zero exports would be observed for some countries hence the Heckman two-stage panel estimator is more appropriate in modelling Equation (5). This is needed to correct for selectivity bias in the decision to export a particular HS 6 digit product in the case of the Heckman selection. Essentially, there is self-selection in the exports of products at highly disaggregated levels,

¹⁴1–Live animals; 2–Meat and edible meat offal; 25–Salt, sulphur; earth & stone; plastering, etc; 26–Ores, slag and ash; 50–60–Textiles; and 61–63–Textile articles (apparel and clothing).

¹⁵This is used here to control for products that the US is more competitive at producing. Essentially, products in which the US is more competitive in than the world would tend to be absorbed by the world from developing countries and vice versa.

whereby countries do not randomly choose to export a particular product. Our panel approach to estimation allows us to include fixed effects (exporter and product fixed effects) and time effects to control for some of the unobserved characteristics and market shocks respectively. The principal model is the Heckman selection — the Poisson pseudo maximum likelihood estimator (PPMLE), panel fixed effects, and Mundlak corrected random effects models are included for comparative purposes.

Equation (1) and (2) below model exports from country i (partner) to j (USA) and rest of the world as a function of exporter nation characteristics (E), USA and World characteristics - captured by market size (M), between country characteristics (d) and an error term (μ). The total imports into the USA relative to the World of product p from all countries is the proxy for market size—which additionally controls for market demand shocks in these importing regions. The between country characteristics (d) includes fixed elements—for example distance and constant trade preferences over time as well as time varying country-pair specific trade preferences (Collier and Venables, 2007, 1338-9). We proxy these using exporter and product fixed effects for the constant parts and dummies for trade preferences for the time varying parts. Equation (3) is then the ratio of the first two equations—this substitutes out the exporter characteristics leaving us with an estimable equation in the form of Equation (5). Equation (4) is our selection equation and the *Inverse Mills Ratio* calculated from (4) is incorporated into (5) to complete the Heckman two-step procedure.

The PPMLE is estimated using Equation (3) in its multiplicative form. The Poisson regression log linearises this equation and thus our results would be similar to the log linearised model in Equation (5) (for example, Herrera, 2010, Silva and Tenreyro, 2003). Our argument is that a country given a preference would then decide which products to produce. In this decision, rules of origin, cummulation rules, preference margins, competitiveness and other factors determine whether the country exports to the USA. In modelling the second stage we do not believe that, the preference margin then plays a significant role since this is captured in the product exported under the preference. Hence our exclusion restriction includes the preference margin and this is discussed further in the next section.

$$X_{ip,j} = E_i(t) * M_j(t) * d_{ip,j}(t) * \mu_{ip,j}(t) \quad (1)$$

$$X_{ip,w} = E_i(t) * M_w(t) * d_{ip,w}(t) * \mu_{ip,w}(t) \quad (2)$$

$$x_{ipt} = M_t * d_{ipt} * \mu_{ipt} \quad (3)$$

$$exports_{ipt} = \alpha + \beta' TP_{it} + \gamma_1 lat + \gamma_2 RCA_{ipt}^{i,w} + \gamma_3 Mil_{ipt-1} + \gamma_4 tariff\ margin_{ipt-1} + \Gamma' Z^a + \eta_{ip} + \eta_t + \mu_{ipt} \quad (4)$$

$$exports_{ipt} = \begin{cases} 1 & \text{if } positive\ exports \\ 0 & \text{otherwise} \end{cases}$$

$$\ln x_{ipt} = a + \alpha' TP_{ipt} + \gamma_1 MSize_{pt} + \gamma_2 RCA_{ipt-1}^{i,w} + \hat{\lambda}_{ipt} + \delta' Z^b + \eta_{ip} + \eta_t + \epsilon_{ipt}. \quad (5)$$

Where: $x_{ipt} = \frac{X_{ip,j}}{X_{ip,w}}$; $M_t = \frac{M_j}{M_w}$; $d_{ipt} = \frac{d_{ip,j}}{d_{ip,w}}$

i , p , and t subscripts refer to country, product and time respectively, j refers the USA while w refers to rest of the world, “a” in Equation (5) is the constant of the regression. The log of the dependent variable is taken as $\ln(1 + X)$. Tariffs and political variables are lagged in order to avoid introducing any simultaneity or endogeneity into our model.

X_{ij}	is Imports from partner i
E_i	is exporter nation characteristics
M_j	is importer characteristics
d_{ij}	is between country characteristics - given by trade preferences offered by j to i
$\mu_{ipt}; \epsilon_{ipt}$	is an error term
TP_{it}	is trade preferences offered by the USA. It takes the value 1 from the year in which a country first receives the preference and 0 before ¹⁶ . Includes, GSP, AGOA and CBI beneficiaries
TP_{ipt}	is trade preferences offered by the USA. It takes the value 1 for a product exported under a preference and 0 otherwise ¹⁷ . Includes, GSP, AGOA and CBTPA beneficiaries for each product
$MSize_{pt}$	is market size the ratio of total imports of our selected commodities into j excluding country i .
$tariff\ margin_{ipt}$	calculated as $\frac{MFN\ tariff - Applied\ HS\ tariff}{MFN\ tariff}$ for each country, year and product.
Mil	is Military - 1 if chief executive is a serving military officer
$\hat{\lambda}_{ipt}$	Is the inverse Mills ratio from the first stage regression, calculated as: $\frac{\phi(\cdot)}{\Phi(\cdot)}$, where $\phi(\cdot)$ is the standard normal probability density function and $\Phi(\cdot)$ is the standard normal density function of the Equation (4) when $E(exports = 1 covariates)$.
η_t	Time effects
η_{ip}	exporter and product fixed effects in the fixed effects regression. Is the random effects in the panel random effect models
Z^a	vector of control variables – latitude, natural log of area, number of cities, Number of Free lines, dummies for Africa, Latin America & Caribbean, landlocked Christians, Muslims, English and Spanish speaking countries
Z^b	vector of control variables – latitude, natural log of area, number of cities, dummies for landlocked, Africa, Latin America & Caribbean, NAFTA, CAFTA, English and Spanish speaking countries
RCA	Based on Balassa (1967) ¹⁸ and Gasiorek et al (2009) the revealed comparative advantage (RCA) is calculated as: $RCA_{ipt}^{i,w} = \left(\frac{X_{p,i}^w}{\sum_p X_{p,i}^w} \right) \div \left(\frac{X_{p,w}^w}{\sum_p X_{p,w}^w} \right)$ where: $X_{p,i}^w$ is exports of product p from country i to the World and $\sum_p X_{p,i}^w$ is total exports from country i to World, $X_{p,w}^w$ and $\sum_p X_{p,w}^w$ are the world exports of product p and total exports respectively

4 Econometric Modelling Issues

We attempt various econometric techniques *viz.*, the Heckman selection and the Poisson models. These are then compared to traditional estimates from the fixed effects and random effects models based on positive export flows. We employ the fixed effects regressions in most of our estimations as this approach allows for the existence of a correlation between the fixed effects and the regressors (Baltagi, 2001, Greene, 2003, Wooldridge, 2002). Secondly, the fixed effects approach minimises the omitted variable problem as the fixed effects capture variables omitted from the model leaving the coefficients unbiased to a large extent. A problem with the fixed effects is the inability to estimate time invariant variables. However, the time invariant variables can be recovered from a regression of the variables on the extracted fixed effects. The time invariant variables are not pivotal to our analysis so this is pursued only in a couple of regressions for comparison purposes—that is to compare the coefficients to those of the random effects, which allows for time invariant variables.

Unlike the fixed effects, the random effects approach does not allow for a correlation between the random effects and the explanatory variables. The model assumes this correlation to be zero. Hence, in

¹⁶Definition allows preferences to overlap for each country. Thus a country can be an AGOA and a GSP beneficiary. To control for these overlaps we include interaction terms for those cases where countries have two or more preferences

¹⁷Previous footnote applies here also

¹⁸Balassa, Bela 1967, Studies in Trade Liberalization, John Hopkins Press, Baltimore: Maryland

the presence of a correlation, the random effects model becomes inconsistent and inefficient. Additionally, Mundlak (1978) argues that the random effects model in the presence of the correlation is misspecified. Mundlak (1978) argues that the random effects model is biased when there is a correlation between the random effects and the explanatory variables. To overcome this, Mundlak (1978) suggests adding the mean of the explanatory variables as additional regressors in the random effects model. Thus in our case the η_{ip} in Equation (4) and (5) (when estimated by random effects can be assumed to be capturing the random effects) can be specified as:

$$\eta_{ip} = \varphi' \bar{X}_{ip} + \vartheta_{ip} \quad (6)$$

where:

$$\vartheta_{ip} \sim N(0, \sigma_{\vartheta}^2), \quad \bar{X}_{ip} = \frac{\sum_{t=1}^T X_{ipt}}{T} \quad \text{and } X \text{ is the vector of explanatory variables in Equation (4) or (5)}$$

This is pursued for all the random effects models presented in the results section. The *Hausman test* allows a choice to be made between the fixed effects and the random effects models. In addition, the *Breusch and Pagan test* provides a way of testing whether the random effects are significant. In Table (2) we report the *Breusch and Pagan test* and these are significant for all random effects models estimated (with and without Mundlak's correction). The *Hausman test* is not pursued since we employ the fixed effects model to capture country and product specific effects that are not captured by the variables included in our model. The fixed effects are significantly different from zero in all estimations as provided in the table's footnotes.

We now turn to specific econometric modelling issues found in the trade literature that requires our attention in this paper—as well as revisit some of the issues raised in the preceding paragraphs. The *Heckman selection* and *Poisson pseudo maximum likelihood (PPMLE)* have become dominant techniques in empirical trade studies (for example, Helpman et al., 2007, Herrera, 2010, Silva and Tenreyro, 2003, 2006, 2009, Silva et al., 2010). Given the presence of zeros in the trade data and the large literature on selection into exporting we pursue the Heckman selection as one of our models. In light of the zeros we also pursue the PPMLE. The Heckman selection is motivated by the desire to model the self-selection into export markets (for example, Agostino et al., 2007, Cardamone, 2007).

It was earlier mentioned that, mirror exports are used to help reduce the missing or unrecorded exports of developing countries. The missing data problem is not entirely resolved as this is symptomatic of highly disaggregated trade data. However, we are reassured of the reliability of the import data since import data tend to be more accurately recorded compared to export data (for example, Piermartini and Teh, 2005). This is the case since tariffs have to be applied to imports at the border. Thus, in our case, imports into the USA would be more reliable since the USA has to decide which imports are allowed in duty free, under the various preferences, MFN or at normal tariff rates—this makes them more reliable. One can safely conclude that most of the remaining missing or unrecorded values in the dataset represent countries not exporting that particular product. This essentially motivates the Heckman's two stage panel estimator to control for self-selection into export markets and thus reduce the problem of selection bias that arises.

Import data includes cost insurance and freight charges. This is absent in export data that is reported free on board (Piermartini and Teh, 2005). In addition, this creates an estimation problem due to the correlation between imports and the error term as a result of transport costs (Piermartini and Teh, 2005). We do not expect this to pose any problems since we take the log ratio of mirror exports from developing countries to the rest of the world as the dependent variable. The use of this ratio cancels the transport costs and some constant characteristics of the exporters from the model.

An issue prevalent in pursuing Heckman's selection model is finding appropriate exclusion restrictions. The use of appropriate exclusion restrictions reduces the bias in standard errors calculated at the second

stage and allows the model to be identified (Bushway et al., 2007). Nonetheless, the use of a probit in the first stage without the necessary exclusion restrictions holds as the non linear nature of the probit model provides identification (Zabel, 1992). In circumstances where both the first stage and the second stage are non linear (or linear if the first stage is based on a linear probability model) then the exclusion restrictions are important in identifying the second stage (Zabel, 1992). More importantly, failure to find adequate exclusion restrictions implies that the second stage cannot be identified in this case and estimates of the second stage would be inconsistent and inefficient (Zabel, 1992). To overcome these issues we adopt Jensen et al.'s (2002) approach of estimating a Mundlak corrected random effects probit model in the first stage and a fixed effects model in the second stage. This reduces the problem of having omitted variables in the first stage as well as mis-specifying the model. The challenge in carrying out the first stage probit model in our case is getting the model to converge—especially for the disaggregated product regressions. If faced with this problem we can safely adopt a linear fixed effects or a Mundlak corrected linear random effects estimator for the first stage. This, then requires us to include valid restrictions in our first stage to aid the identification of our second stage regressions.

Helpman et al. (2007) adopted religion as their exclusion restriction in modelling firm heterogeneity within the gravity framework. However, this has been criticised by some authors (for example, Silva and Tenreyro, 2009) who do not find a link between religion and the probability of exporting. We instead use the tariff margin, military and preference dummies created at the country level (not product level and irrespective of whether the country uses the preference). Our argument is that, a country given a preference would then decide which products to export. This decision would be influenced by rules of origin, cumulation rules, preference margins and competitiveness at the product level as well as other factors that determine whether the country exports to the USA (*viz.*, autocracy, number of free lines, landlocked among others). In the second stage we do not believe that the tariff margin plays a significant role since this is captured by the product dummies (defined at the preference level and indicate products that were processed under the preferences) exported under the preference or the fixed effects.

The PPMLE has been shown to provide consistent results for gravity models and in our case it would also yield consistent estimates. The *zero inflated poisson (ZIP)* model can be an alternative to the PPMLE since it models excess zeros through a logit and hence solves any headaches with selection¹⁹. However, this is not pursued due to estimation problems encountered—due to the large number of parameters (mainly the fixed effects) the model is unable to converge. Another model within the *pseudo maximum likelihood* family, the *negative binomial regression (NBREG)* is also a useful alternative in the presence of over-dispersion in the dependent variable. However, the NBREG is sensitive to the scaling of the dependent variable and is restrictive. It does not do well in the presence of excess zeros, thus it is not pursued here. Bosquet and Boulhol (2010) show that the NBREG PMLE is not consistent and is sensitive to the scale of the dependent variable—thus not good for modelling trade flows. On the contrary, the PPMLE is consistent as long as the conditional mean function is correctly specified (Cameron and Trivedi, 1998). As a result the PPMLE can be applied to data generating processes for the dependent variable in cases where it is not poisson distributed (*ibid.*).

Finally, Piermartini and Teh (2005) argue that GDP is unreliable in estimations using disaggregated data and that the right controls in such cases is output data for the exporting industry or sectoral-country specific effects. In this paper, product-country effects are included in all fixed effects estimations and an additional variable, the revealed comparative advantage for each country is included to capture its competitiveness at the product level. This hopefully, solves the problem and reduces any omitted variables problem from not controlling explicitly for sectoral output.

¹⁹Thanks to Barry Reilly for pointing this out

5 Results and Discussion

The results in this section focus on the HS-6 digit level of disaggregation. All regressions apart from the regression of time invariant characteristics on the fixed effects in Table (4), include country-product and time fixed effects. All regressions with the exception of the random effects probit and the Poisson PMLE fixed effects estimates report robust standard errors clustered around the country-product groups. Table (2) reports three different estimators—the fixed, Mundlak corrected random effects and the ordinary panel random effects estimators. Table (3) reports the Heckman two-step estimator and the Poisson PMLE. This allows a comparison of the various estimators and also to show any indication of bias in our chosen Heckman model. Table (4) presents the time invariant variables regressed on the extracted fixed effects reported in the first four columns of Table (2) and the Heckman second stage estimations in Table (3). Finally, Table (5) allows us to check the sensitivity of our estimates to the exclusion of OECD and European countries as well as China and Hong Kong from our regressions. In Appendix II, more results are presented showing estimates of other levels of disaggregation (HS2 and HS4)—to show whether our estimates are sensitive to the level of disaggregation. Additionally, the tables in the appendix also compare estimates of non apparel and textiles to those of apparel and textiles to confirm whether the USA preferences are being driven by apparel and textiles.

We next discuss the results in the main paper. Columns (1) - (4) of Table (2) reports estimates from the fixed effects regression. The difference between columns (1) and (2) is the inclusion of the military variable in column (2). Columns (3) and (4) augment Columns (1) and (2) respectively with the interaction of AGOA and CBTPA preferences with year dummies respectively. The base year for AGOA is 2001 and that for the CBTPA is 2000. Columns (5) - (8) reports the Mundlak corrected random effects—these follow the same pattern as columns (1) - (4). The main difference is the incorporation of time invariant variables. Thus in column (6) and (8) dummies for Christians and Muslims (base category is other religions) are included in addition to military. The inclusion of military and the religious dummies in these models allows us to test whether they can be omitted from the model and used as valid exclusion restrictions for the Heckman two-step estimator. We can reject the alternate hypothesis that the military coefficient is different from zero at the 5% level of significance in columns (2), (4), (6) and (8)—thereby indicating that it is not correlated with the dependent variable in the second stage. We cannot do the same for the religious dummies which are significantly different from zero at the 0.1% level and thus correlated with our dependent variable. Hence, if used in the Heckman first stage as an exclusion restriction, the residuals might be correlated with the second stage error. The Muslim dummy is however, not significant at conventional levels in columns (4) and (8) of Table (4) when regressed on the fixed effects. The final two columns of Table (2) reports the ordinary random effects estimator.

The AGOA, CBTPA and GSP preferences are significant in all eight columns of Table (2). Our controls CAFTA-DR, the lag of each country's RCA and market size of the USA are also significant in all columns. The interaction of GSP and AGOA is not significant in any of the columns of the table. The interaction of CBTPA and GSP is however, significant in our random effects type models. With the exception of the English speaking dummy all other time invariant controls included in the random effects type models are significantly different from zero. NAFTA has a coefficient of 1.7 in the Mundlak corrected random effects models indicating that NAFTA increases exports to the USA relative to the world by 447.39% compared to non NAFTA countries. Similarly, Latin American and Caribbean countries on average and holding all things constant significantly increase exports to the USA relative to the world. These are expected given the close proximity of NAFTA countries and to a large extent the Latin American and Caribbean countries to the USA. On the contrary, on average and holding all else constant, African exports to the USA are significantly lower relative to the rest of the world in the Mundlak regressions but positive in columns (9) and (10). In summarising, Table (2) indicates that AGOA and GSP preferences increase exports to the USA

relative to the rest of the world holding all else constant. While CAFTA-DR decreases exports to the USA relative to the world.

For the CBTPA preferences, a positive coefficient is achieved only after controlling for annual variations in preferences through the inclusion of preferences and time interactions. In the case of AGOA, controlling for the annual variation in the preferences makes no difference to the sign or significance of the estimated coefficient. Also, the interaction of time and preferences is significantly lower in 2008 and 2009 compared to the base years of AGOA (2001) and CBTPA (2000). An indication of the harm caused to exports of developing countries and the ability of the USA to absorb additional imports from the world as a result of the financial crisis of that period. In spite of this, the AGOA and CBTPA preferences on average and holding all things constant have been able to increase exports of developing countries to the USA relative to their exports to the rest of the world.

Turning our attention to the next table (Table (3)) we find qualitatively similar results. AGOA is positive and significant in both the Heckman model and the Poisson PMLE. Similarly, the CBTPA preferences are only positive when the annual variation to the preference is controlled for. On the contrary, the GSP becomes negative in the Poisson models. They are however, significant in all models in which they appear within the table. In both tables the annual variation of the AGOA preferences indicates that the first few year of AGOA saw a rapid rise in exports to the USA relative to the rest of the world compared to the base year of 2001. Columns (1) and (4) report the first stage results for our Heckman model. All variables with the exception of the number of free lines have a significant impact on the probability of exporting to the USA. Apart from countries that qualify for the CBI, all the remaining preferences, that is, GSP and AGOA eligible countries significantly lower the probability of exporting to the USA. A country's competitiveness (RCA) in a product and the tariff margin significantly increases their probability of exporting to the USA. This is in line with our earlier assertion in the preceding section that, the larger the margin between the MFN tariff and the applied tariff (in this case the preferential tariff) the more likely a country would try to exploit the gains from exporting that particular product. Nonetheless to exploit these advantages a country with a competitive advantage in production is more likely to benefit from the higher tariff margins by increasing its exports.

In column (4), latitude, English and Spanish speaking as well as land area significantly increase the probability of exporting to the USA holding all else constant. The remaining variables, number of cities, landlocked, Christianity and Muslim dummies (compared to the other religions) reduce the probability of exporting to the USA. The negative coefficients for the Muslim and Christian dummies might largely be due to the Chinese effect. However, for the Muslim dummy the composition of the exports of Muslim countries is also playing a role here. The military coefficient significantly lowers the probability of exporting to the USA. This is evidenced in the fact that, the USA normally imposes trade sanctions on countries it believes to be undemocratic or ruled by military leaders. The significance of military and the religious dummies indicate that they must be included in the first stage regression. They are thus highly correlated with the probability of exporting to the USA. In addition, all exclusion restrictions are jointly significantly different from zero. The case for military is however, much stronger than the religious dummies. The main difference between the two first stage regressions is that column (1) is based on a fixed effects regression, while column (4) is a Mundlak corrected random effects estimator—modified from that proposed by Jensen et al. (2002). Column (4) allows additional exclusion restrictions in the form of the religious dummies as well as additional controls provided by the time invariant variables.

In the second stage, we include the time and preference interactions in the immediate column after each first stage regression. The second column after the first stage estimates (columns (3) and (6)) exclude these interactions. The time-preference interactions only make a difference for the CBTPA in this table as previously shown in Table (2). The last two columns report the coefficients for the Poisson PMLE model. The coefficients for the Poisson model in most cases are larger than the previous models discussed.

However, the Poisson model's standard errors are lowest among all the models reported above. In most cases it is less than half the standard error of the other models—thus indicating that it provides the lowest variance among the estimators presented in this section. The standard errors of the Heckman model are quite similar to those of the fixed effects model in Table (2). This in turn indicates that our exclusion restrictions are reasonable. The Heckman second stage standard errors reported in Table (3) have not been corrected as has been suggested by for example Wooldridge (2002). The similar standard errors reported by both model types reduces the pressure of correcting the second stage errors reported and also leads us to believe that the standard errors are unbiased. This result can be attributed to the large sample dimension of our data and given that our estimators have large N and small T sample properties we can overlook the correction at this stage.

Given these comparisons, all models presented with the exception of the ordinary random effects estimator are consistent to a large extent. The ordinary random effects model however, has presented us with relatively larger coefficients—at times twice the estimated coefficients in the other models. This points to its inconsistency and inefficiency, hence the other models perform better in reducing this bias. An argument which we do not find tenable here is whether the model is misspecified and that the random effects model is inappropriate. It does not seem so, since the Mundlak corrected random effects attenuates the bias of the ordinary random effects. The explanation could be the presence of a correlation between the random effects and some explanatory variables. Thus the inclusion of the averages of the explanatory variables as suggested by Mundlak (1978) has greatly reduced the misspecification and problems created by the assumption of no correlation. Nevertheless, the ρ reported by the random effects type models is significantly different from zero indicating that the random effects model is preferred to a pooled OLS regression. In addition, the Breusch and Pagan LM tests of random effects indicate the presence of the random effects and these are significantly different from zero. Finally, the goodness of fit measures of the Mundlak corrected random effects are larger than those of the ordinary random and fixed effects models. As a result, the Mundlak random effects model provides a better fit and is the more appropriate model to present.

Table (4) shows the median and OLS regression of the time invariant variables on the fixed effects. Apart from the NAFTA coefficient the median regressions report lower coefficients compared to the OLS regression. In almost all cases there are no sign reversals. Comparing the coefficients to that of the Mundlak corrected random effects model, it is observed that Spanish speaking, English speaking and African dummies are now positive in the fixed effects models. The NAFTA coefficient is smaller than that reported in Table (2). The first eight columns of Table (4) correspond to the first four columns of Table (2). The remaining four columns correspond to the Heckman second stage regression in Table (3). To sum up, the remaining coefficients have the same sign as the random effects models but are marginally larger in most cases.

The final table reports results for a sub-sample of countries. In columns (1), (3) and (4) we exclude OECD and European countries from our sample leaving us with 119 countries. In columns (2), (5) and (6) China and Hong Kong are also excluded in addition to the countries excluded earlier. The results are qualitatively similar to the ones reported earlier. The only difference is in the first stage regression, the GSP eligible country dummy is now positive.

In order to make the comparison across the models we summarise the coefficients and the exponentiated coefficients of the dummies of the models in Figure (1). The minimum and maximum coefficients are reported for each model and for the AGOA, GSP, CBTPA and CAFTA-DR preferences. The noticeable difference is the ordinary random effects and the Poisson model coefficients. The remaining models have quite similar coefficients. The graph on the right side (panel b) reports the exponentiated coefficients of the non Poisson models. We do this since our dependent variable is in logs and the explanatory variable is a dummy. We thus report the percentage impact of the preferences. The analysis above points towards the tendency of the USA preferences in increasing the exports of its preference beneficiaries relative to

their exports to the rest of the world. Various attempts at testing the robustness and sensitivity of the estimates also lend support to the conclusion above. Thus, the maximum impact of AGOA, GSP, and CBTPA is 57.8%, 13.4%, and 48.4% respectively ignoring the results from the ordinary random effects model. Similarly, the minimum impact is 38.3%, 11.5% and -48.8% respectively. The CAFTA-DR impact is negative in all models—the magnitude of the impact is 40.3% in absolute terms. On the whole, these are much smaller than Collier and Venables (2007) but quite close to Frazer and Van Biesebroeck (2010). A comparison in this case is quite difficult since Collier and Venables (2007) uses more aggregated data while Frazer and Van Biesebroeck (2010) uses data at the HS-8 level but for all products.

We now briefly discuss the results presented in Appendix II. The results presented here include HS-2 and HS-4 digit results. The HS-6 results are repeated in the tables for comparative purposes. In Table (7), the impact of a country's previous competitiveness has a larger effect at the 6-digit level compared to the more aggregated 2- and 4-digit levels. Market size of the USA relative to the world becomes negative at the other levels of disaggregation and also becomes insignificant (except at the 2-digit level where it is marginally significant at 10%). the positive sign recorded for the 6-digit level of disaggregation is significant at the 0.1% but the effect is small. The negative coefficient for the 2- and 4-digit levels probably indicates that at higher levels of aggregation the rest of the world tends to provide a larger market relative to the USA. The AGOA preferences are negative and insignificant in the 4-digit columns. They are however, significant in the 2-digit regressions in columns (2) and (5). The coefficients are larger accounting for the aggregated nature of the data. The GSP dummy is insignificant in both the 2-digit and 4-digit regressions—this might be due to the fact that countries are graduated or de-graduated in products at the 6-digit level and not at higher levels of aggregation. On the contrary, the CBTPA dummy is negative and significant in the 4-digit regressions but insignificant in the 2-digit regressions.

The next two tables present results from looking at non apparel and textile and apparel and textile products separately. Table (8) reports the fixed effects estimates while Table (9) reports the Mundlak corrected random effects estimates. Both tables show quite similar results. The AGOA coefficient is significant and positive in both tables at the 6-digit level for non apparel products. However, in Table (8) significance is at the 10% level and the coefficients of 0.017 and 0.036 (in Table (9) yield relatively small impacts of 1.71% and 3.71% respectively. This significance was obtained after including the time-preference interactions. The inclusion of the time-preference interactions also led to the exclusion of the CBTPA coefficients. The exclusion of the time-preference dummies leads to a negative coefficient for AGOA in the 6-digit level regressions. This compared to the apparel impact is relatively small in size. The inability to estimate a coefficient for the CBTPA preference does not allow us to make any comments about the impact of the preference. The 2- and 4-digit results are insignificant for the GSP and AGOA preferences. The evidence thus far points to AGOA being more favourable to apparel and textile products. In Table (9) all three regressions for the apparel and textile products yield coefficients for all three preferences. At the 6-digit level AGOA, CBTPA and GSP product dummies do lead to higher exports to the USA relative to the rest of the world and are significant. At the 2-digit level the signs became negative for the GSP and CBTPA preferences but remain positive and larger for AGOA. The 4-digit level estimates of AGOA are no longer significant. The estimates for CBTPA and GSP are significant and negative. These results so far show that care must be taken in choosing a level of disaggregation when analysing trade data. The 2-digit and 6-digit levels of disaggregation tend to provide coefficients with the same sign compared to the 4-digit level coefficients. In addition, the apparel and textile products seem to be the driving force behind the performance of the AGOA and CBTPA preferences in our regressions.

Tables (10) and (11) carry out the Heckman selection and Poisson PMLE regressions respectively. The results are qualitatively similar to those reported in Table (7). Table (12) summarises the impact of the preferences across all five tables. The large impact of AGOA at the 2-digit level is the most noticeable feature of the table. This large impact might be due to problems present in the regressions as result of

the aggregation of the 6-digit trade data. However, the remaining preferences do not present such outliers in the impact of the preferences. The final set of tables, Tables (13) and (14) present the results from carrying out estimations on selected countries. Table (13) reports the Mundlak corrected random effects estimates while Table (14) does same for the Heckman second stage results. Among the AGOA countries (Ghana, Kenya, Nigeria and South Africa) Kenya posts a significant and positive coefficient. The remaining three countries report insignificant coefficients. In terms of the CBTPA dummy, Guatemala and Honduras report positive and significant coefficients in both tables. Costa Rica and Jamaica on the other hand, post insignificant coefficient estimates. For these countries with insignificant estimates a much closer look at the data and re-estimating the regressions to control for country specific shocks and controls might provide better estimates of the impact. However, at the moment given our general model which is applied to the individual countries, they seem not to have significantly increased their exports to the USA relative to the rest of the world. Nigeria and South Africa might not show the significance due to the composition of their exports and the fact that they do not benefit from the special textile preferences provided by the USA. Our choice of products for South Africa are mostly exported under the GSP hence we observe a significant coefficient for the GSP preference. On the contrary, for Ghana as shown in Figure (3(c)) the share of AGOA exports in exports to the USA has declined over time since the initial jump in 2001.

We have presented results of various models to show the impact of USA's preferences on developing countries. In doing this, we have controlled for the exports of these countries to the rest of the world to isolate the impact of the preferences. The results after various robustness and sensitivity checks point to a positive impact of AGOA and the CBTPA preferences of the USA on the exports of its beneficiaries to the USA. Nonetheless, the USAs GSP preference is also increasing exports to the USA relative to the rest of the world. Most of these results pointing to a positive impact can be attributed to the ability of the USA to absorb imports from the world given its huge demand and consumption of its citizens. We do not however, attribute causation to these results but would like to point out that these are the relative impacts given our model and data.

Table 1: Variable definitions and summary statistics

Variable Name	Variable Description	Source	HS6-Mean	HS4-Mean	HS2-Mean	Time invariant (at HS6)-Mean
Probability of exporting	Dependent variable for 1st stage of Heckman. 1 if country exports to the USA	UN Comtrade	0.342	0.282	0.16	
US/World Import ratio (logs)	Dependent variable for all other regressions	UN Comtrade	0.323	0.293	0.202

Observations			1047124	292598	37567	12177

(a) The means above are for the sample of positive trade. There are cases where a country exports to the rest of the world but not to the USA hence the probability of exporting is less than 100%. After incorporating the zero trade scenarios the sample size for HS6, HS4 and HS2 becomes 2279844, 501984 and 41832 respectively. The probability of exporting then becomes 0.157, 0.107 and 0.145 for HS6, HS4 and HS2 respectively. (b) The preferential country dummies, religious dummies, military, regional and language dummies have marginally higher means for the larger sample. However, the preferential product dummies and constructed trade variables have marginally lower means for the larger sample

Standard errors in parentheses. † $p < 0.1$, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. (a) Dependent variable is the log of (imports into the US/into rest of world) (b) Estimation is done at 6 digits on positive flows (c) F-test of exclusion restrictions: $F(3,162845)=45.34$ and Chi-squared test $\chi^2(5) = 3150.25$ for columns (1) and (4) respectively. Column 1 uses fixed effects and the exclusion restriction does not include religion. Column 4 has religion (christian and muslim) as additional exclusion restrictions. The F-test (Chi-squared test) is a joint significance test of military, number of free lines, tariff margin and religion dummies (where applicable) (d) robust standard errors used (except the Poisson case)

Robust Standard errors in parentheses (excluding median regressions). $+$ $p < 0.1$, $*$ $p < 0.05$, $**$ $p < 0.01$, $***$ $p < 0.001$. (a) Dependent variable is the estimated fixed effects from the panel regression. (b) Estimation is done at 6 digits on positive flows. (c) Pseudo R^2 is Calculated as $1 - \frac{\text{minimised sum of absolute deviations}}{\text{raw sum of absolute deviations}}$ for median regressions. (d) FE1 and Heck1 are based on the fixed effects extracting from the models in the previous table with similar column headings.

Exponentiated coefficients calculated as $(\exp^{\beta} - 1) \times 100$

Figure 1: Summary of coefficients and impact of preference dummies

6 Conclusion

In this paper we have attempted to estimate the impact of the USA's AGOA and CBTPA preferences on its beneficiary countries. Adopting Collier and Venables (2007) methodology and making the required changes to fit their methodology within our framework. We find a strong impact of the AGOA and CBTPA preferences. However, the CBTPA preferences is sensitive to the exclusion of the interaction of the preferences and time. AGOA on the other hand is not and is robust to the exclusion of the agoa preference-time interaction as well as the exclusion of some variables. HS-6 and HS-2 levels of disaggregation tend to provide consistent estimates with the same signs and significance. The HS-4 disaggregation on the other hand, tends to be sensitive and the signs switch around a lot. However, at higher levels of aggregation (HS-2) the explanatory variables tend to be correlated with each other, especially the preference-time interactions and the CBTPA preferences. Also, with the non apparel and textile regression, correlation among the variables is higher and the concentration of exports in this cluster is less.

Using the ordinary random effects model leads to inconsistent estimates which in several cases are twice the estimates of the fixed effects, Mundlak corrected random effects and Heckman selection models. The Poisson PMLE estimates are also larger but they report much smaller standard errors affirming its popularity in the current trade literature as an applied model of choice. The inclusion of preference-time interactions

increases the impact of the preferences. The increase is smaller in the other non Poisson models—but quite larger—more than twice for the Poisson model. The Mundlak corrected random effects and fixed effects estimates are quite similar to the Heckman model indicating that these models are good alternatives to the Heckman model. An implication, is that non exporting is distributed randomly in our dataset. Thus, the estimates not controlling for selection bias are not as severely biased as expected.

Studies based solely on the ordinary random effects model as shown by our analysis tend to overestimate the impact of preferences. Increasing the sample size and allowing N to increase infinitely does not resolve this inconsistency. However, the differences between the fixed effects, Mundlak corrected random effects and Heckman selection models are not so different in very large samples. This holds because our sample is relatively large and with fixed T—thus consistency holds for increasing N. Thus for fixed T but large N the differences in estimates are quite small as the benefits of the large sample tends to lead us towards the true parameters. In smaller N samples however, care needs to be taken in choosing the appropriate estimator to obtain consistent estimates.

In concluding, we note that further work needs to be done in identifying the causal impact of the preferences. Extensions to this paper to overcome the present short-coming includes exploring causality within a matching framework. Matching allows the countries to be compared, such that, countries that are similar before receiving the preferences are matched—to limit the differences in their exports to the USA to the preference received. As at now, the impacts can be considered as *intention to treat* (ITT) as described in the evaluation literature and not *average treatment effects* (ATE). Finally, a potential question for further research is whether the move by the EU towards *Economic Partnership Agreements* (EPAs) at the end of 2007 has transferred advantages enjoyed by the *European Union-African Caribbean and Pacific* (EU - ACP) beneficiaries to their current status in the American market.

Standard errors in parentheses. † $p < 0.1$, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. Robust standard errors used for all non linear models. Dependent variable for 1st stage regressions is the probability of exporting to the USA. For the 2nd stage this is the log of (imports into the US/mo test of world). Columns (1), (3), & (6) use the linear probability model (LPM) for the 1st stage. Columns (2), (4), (5), & (7) are based on the panel probit random effects model. The second half of the table is augmented with the Mundlak averages and the LPM are based on the random effects model. Estimation in the second stage is done digits on positive flows. The error of the panel probit is decomposed into $\varepsilon_{it} = u_i + v_{it}$, where u_i is the random effect component and v_{it} is the iid error. When $\rho = 0$, then the pooled effects probit is no longer different from the panel probit. † indicates variable dropped in estimation, ‡ indicates not applicable.
