#### Abstract

By using data from the latest wave of the Indonesia Life Family Survey, the present work investigates whether and to which extent child time allocation depends on the joint impact of liquidity constraints and risk attitudes. We employ a double selection model of school hours, by adding time preferences, risk attitudes and proxies of risks and shocks among the relevant regressors, and controlling for sample selection and endogeneity of liquidity constraints and school enrolment. To this aim, we exploit measures of time preferences and risk attitudes elicited from individuals' responses to hypothetical gambles and consider the past occurrence of shocks to proxy the risk profiles of the households under the assumption that households use past income volatility to predict future volatility. It will be shown that, under liquidity constraints, risk averse parents raise a precautionary demand for education as an ex-ante risk coping strategy, so to insure future consumption through higher returns from their children's work.

## 1. Introduction

The economic literature investigating the determinants of child labor can be divided in two parallel, though separated, strands: one emphasizing the role of capital market failures; the other emphasizing the importance of subsistence concerns and parental preferences.

The present work proposes an empirical framework to simultaneously account for both, by investigating whether and to which extent children's time allocation depends either on the preclusion of borrowing possibilities, and on risk attitudes and time preferences.

We deem that such an analysis provides relevant results to the existing literature which mostly ignore the possibility that time preferences, risk attitudes and the existence of borrowing constraints interplay in affecting school investments. On the one hand, the presence of borrowing constraints directly induce households to supply more child labor as a substitute for the optimal amount of borrowing. On the other hand, the preclusion of borrowing possibilities may indirectly affect school investments by influencing the likely impact of other characteristics on the same outcome. For example, it can be reasonably supposed that risk aversion affects the school investments of liquidity constrained households to a larger extent and therefore access to appropriate insurance markets discourage the use of child labor supply as a risk-coping strategy.

This paper employs a double selection model of school hours, by adding time preferences, risk attitudes and proxies of risks and shocks among the relevant regressors, and controlling for sample selection and endogeneity of borrowing constraints and school enrolment. To this aim, we exploit measures of time preferences and risk attitudes elicited from individuals' responses to hypothetical gambles and consider the past occurrence of shocks to proxy the risk profiles of the households under the assumption that households use past earnings volatility to predict future volatility.

The paper is structured as follows. Section 2 presents a brief review of the relevant literature about the impact of credit markets imperfections and parents' preferences on schooling. In section 3, we develop a simple theoretical model to investigate the likely response of child time to parents' risk and time preferences and whether this response depends on credit market conditions. Section 4 presents the dataset and, specifically, how the key variables for risk and time preferences and exogenous income shocks are constructed. Section 5 outlines the hypotheses to be empirically tested. Section 6 discusses the empirical strategy used in the proceeding of the paper to verify our model's predictions while sections 7 and 8 present the econometric regressions and results. Section 9 concludes.

## 2. Related literature

The analyses of the determinants of child time-use and the reasons why the supply of child labor significantly increases with household's poverty have typically focused on the role of capital market failures, subsistence concerns and parental preferences.

### 2.1. The role of capital market failures

The literature emphasizing the role of capital market failures on child labor and early education is extensive, both theoretically and empirically.

Baland and Robinson (2000) show that child labor is inefficient when the family is so poor that the parents do not leave bequests to their children. By adopting a two-periods model, they show that, despite parental altruism, child labor is inefficient when it is used by parents as a substitute for negative bequests (to transfer income from children to parents), or as a substitute for borrowing (to transfer income from the future to the present). Pouliot (2006) introduces uncertainty to the Baland and Robinson's model of child labor. He finds that, under non-borrowing restrictions, the set of conditions generating an inefficiently high level of child labor is determined by the presence of uncertain returns to human capital and incompleteness of insurance markets. Rajan (2001) adopts a two-periods model to study the relationship between income inequality and the incidence of child labor in presence of credit constraints. The model shows that, when individuals have different abilities, higher income inequality is associated with higher incidence of child labor. For each level of ability there is a threshold level of parental income such that households below that threshold send their children to work. Parsons and Goldin (1989) show that the sub-optimality of schooling investments is closely-related to the availability of efficient capital markets. The negative impact of credit constraints on investments in early education has been discussed also by Laitner (1997), Parsons and Goldin (1989), and Jacoby and Skoufias (1997).
There is an abundance of empirical evidence concerning the role of incomplete financial markets on educational attainment, in response to shocks. Some of these recent findings are provided - among the others - by Guarcello, Mealli e Rosati (2010), Fitzsimons (2007), Beegle, Dehejia and Gatti (2005), Dehejia and Gatti (2002), Edmonds (2002), Pörtner (2001), Ranjan (2001), Jacoby and Skoufias (1997), Jacoby (1994).

### 2.2. The role of risk attitudes and time preferences

Given the uncertainty surrounding the income stream, it is not surprising that risk attitudes and time preferences have played a key role in the theory of human capital accumulation. ${ }^{1}$ In practice, however, given the difficult job of measuring risk and time preferences, their impact on educational investments has attracted limited attention in the empirical literature and with ambiguous results. In some empirical models of human capital accumulation, a parameter of constant risk aversion has been included; ${ }^{2}$ however, such an approach does not allow variation in risk preferences across individuals to play a role in the investment decision-making process. Belzil and Hansen (2004), for example, estimate a dynamic programming model of schooling decisions where the degree of risk aversion is inferred from school decisions. In this model, individuals are assumed to be heterogeneous with respect to ability yet homogenous with respect to the degree of risk aversion.

An important exception in the literature is Shaw (1996) who jointly models investments in risky human capital and financial wealth allowing for interpersonal differences in risk preferences.
Among the others, ${ }^{3}$ these papers typically treat human capital accumulation as a standard investment process, predicting that the less risk averse individuals invest in relatively high levels of education.

Differently from the previous works, Belzil and Hansen (2004) find that a counterfactual increase in risk aversion induces a precautionary accumulation of human capital. Gould, Moav, Weinberg (2001) find similar results. They analyze the impact of human capital depreciation risks on the choice of the type of education, asserting that in periods of technological progress, risk aversion induces workers to invest in general education to avoid the risk of losing their technology-specific skills. Their findings however do not control for any possible variation in this response due to capital markets conditions and to the source of expected risks.

[^0]
### 2.3. A new perspective: linking the two approaches

While the role of risk attitudes, time preferences and capital market failures on school investments has been widely investigated especially in the theoretical literature, at our knowledge there is still no attempt to analyze their joint effect.

This paper aims to fit this gap by exploring whether the lack of insurance and capital markets exerts heterogeneous effects on school investments, according to risks attitudes and time preferences. It is commonly thought that uninsured exposure to income risks induce parents to rely on internal assets (such as income from child labor) to secure a smoothed consumption path. This paper is intended to verify whether this occurs independently on risk attitudes and time preferences. Indeed, in case of preference for precautionary wealth accumulation (elicited by a positive third derivative of the utility function), parents with an uninsured exposure to income risks (due to the preclusion of borrowing and private insurance, for example) may desire to raise a precautionary demand for education in order to safeguard future consumption through higher returns from their children's work. Instead, parents with access to capital markets can rely on borrowing or private insurance.

## 3. The model

Our model is comprised of two periods, referred to 1 and 2. At the beginning of period 1 , parents decide how to allocate their children's unit time endowment between child labor $l_{c}$ and human capital accumulation $\left(1-l_{c}\right)$, where $l_{c}$ represents the fraction of a child's unit time endowment allocated to work. ${ }^{4}$ For simplicity, we assume that parents earn income $A$, in periods 1 and 2 . We introduce uncertainty, by allowing parental income to include an absolutely continuous negative random variable $\Phi$, with $E(\Phi)=0$ and $\operatorname{var}(\Phi)=\sigma_{\Phi}^{2}$.
In period 2, each child supplies $h\left(1-l_{c}\right)$ units of labor, where $h(\cdot)$ represents the human capital production function of the following form: ${ }^{5}$

$$
\begin{equation*}
b\left(1-l_{c}\right)=\vartheta\left(1-l_{c}\right)^{\alpha} \kappa^{\beta} \tag{1}
\end{equation*}
$$

[^1]where $\alpha, \beta>0$ and $\alpha+\beta<1 ;\left(1-l_{c}\right)$ is the time spent at school, $\kappa$ represents the given amount of goods (i.e., the services from teachers, physical capital, etc.) invested in human capital, $\vartheta$ is a productivity parameter (i.e., learning ability), $\alpha$ and $\beta$ are returns elasticities.

We normalize the returns to human capital to 1 . Parents' utility function is separable in period 1 and period 2 consumption ( $c_{p}^{1}$ and $c_{p}^{2}$, respectively) and is denoted by

$$
\begin{equation*}
W_{p}\left(c_{p}^{1}, c_{p}^{2}\right)=U\left(c_{p}^{1}\right)+\frac{(1+r)}{(1+\delta)} U\left(c_{p}^{2}\right) \tag{2}
\end{equation*}
$$

where $U(\cdot)$ is twice continuously differentiable and strictly concave, $r$ is the constant net return to financial assets and $0<\delta<1$ is the discount factor with $(1+r) /(1+\delta)<1$. ${ }^{6}$

The interest in investigating the role of risk preferences on child time allocation motivates the adoption of an isoelastic utility function: $u(c)=\left(c^{1-\gamma}-1\right) /(1-\gamma)$, with $\gamma \geq 1$ as absolute coefficient of risk aversion and absolute coefficient of prudence.

Parents can transfer income between periods by saving (denoted $b<0$ ) or borrowing (denoted $b>0$ ). Capital markets are imperfect and some parents are prevented from borrowing. Borrowing restrictions are exogenously determined.

The household maximization problem can be represented as,

$$
\begin{equation*}
\max _{s, l_{c}} U\left(c_{p}^{1}\right)+\frac{(1+r)}{(1+\delta)} U\left(c_{p}^{2}\right) \tag{3}
\end{equation*}
$$

subject to

$$
\begin{align*}
& c_{p}^{1}=A+l_{c}+b \\
& c_{p}^{2}=A+h\left(1-l_{c}\right)-b+\Phi \tag{4}
\end{align*}
$$

We have the following first order conditions,
$U^{\prime}\left(A+l_{c}+b\right)=\frac{(1+r)}{(1+\delta)} E\left[U^{\prime}\left(A+h\left(1-l_{c}\right)-b+\Phi\right)\right] \quad b=b^{*}<0$

[^2]$U^{\prime}\left(A+l_{c}\right)>\frac{(1+r)}{(1+\delta)} E\left[U^{\prime}\left(A+h\left(1-l_{c}\right)+\Phi\right)\right] \quad b=0$
$U^{\prime}\left(A+l_{c}+b\right)=\frac{(1+r)}{(1+\delta)} E\left[U^{\prime}\left(A+h\left(1-l_{c}\right)-b+\Phi\right)\right] h^{\prime}\left(1-l_{c}\right)$
$b^{*}>0$ can be interpreted as the optimal amount of parental borrowing. If parents do not desire to borrow $\left(b^{*} \leq 0\right)$, then consumption always equals its optimal level; otherwise $\left(b^{*}>0\right)$, consumption may be inefficiently low if borrowing is prevented. In this case households are considered as liquidity constrained.

Using the first order conditions, the following conclusions can be established.
Proposition 1. If borrowing is interior, then the laissez-faire level of child labor is efficient, i.e. $h^{\prime}\left(1-l_{c}\right)=1$. Hence, in absence of liquidity constraints, the allocation of children's time does not depend either on goods and productivity parameters of the human capital production function or on expected income risks, even in presence of a possibly high coefficient of relative risk aversion ( $\gamma>0$ ) [Result 1].
Proposition 2. If borrowing is at corner, then $h^{\prime}\left(1-l_{c}\right)>1$ and the laissez-level of child labor is inefficiently high [Result 2]. When capital markets are imperfect and parents cannot borrow, child labor supply is used to smooth the expected marginal utilities from consumption between period 1 and period 2 . As a consequence, the marginal investment in schooling may be inefficiently low. Considering the exact functional forms for the utility and the human capital production functions, eq. (7) with $b=0$ becomes:

$$
\begin{equation*}
\frac{(1+r)}{(1+\delta)} E\left(\frac{A+h\left(1-l_{c}\right)+\Phi}{A+l_{c}}\right)^{-\gamma}=\vartheta \alpha\left(1-l_{c}\right)^{\alpha-1} \kappa^{\beta} \tag{8}
\end{equation*}
$$

We take logs in eq. (8) and use the following hypotheses on the consumption growth distribution,

$$
\begin{equation*}
\ln c_{p}^{2}-\ln c_{p}^{1}=\Delta \ln c_{p}^{2} \mid I_{t} \sim N\left(\mu, \sigma_{\Phi}^{2}\right) \text { and } \Delta \ln c_{p}^{2}-\mu=\Delta \ln c_{p}^{2}-E \Delta \ln c_{p}^{2}=\Phi \tag{9}
\end{equation*}
$$

with $\mu=\vartheta\left(1-l_{c}\right)^{\alpha} \kappa^{\beta}-l_{c}$, where first and second moments are conditioned to the set of information available at time 1 , to get: ${ }^{7}$

[^3]$\ln \alpha \vartheta \kappa^{\beta}+(\alpha-1) \ln \left(1-l_{c}\right)=\ln \frac{(1+r)}{(1+\delta)}-\gamma \mu+\frac{1}{2} \gamma^{2} \sigma_{\Phi}^{2}$
where $(\alpha-1) \ln \left(1-l_{c}\right)>0$ being $(\alpha-1)<0$ and $\ln \left(1-l_{c}\right)<0$.
The first two terms on the right-hand side of equation (10) represent the determinist component of the marginal return to human capital investments, which decreases with the number of hours spent at school and with the coefficient of absolute risk aversion $A\left(c_{p}^{1}\right)=\gamma$. The last term on the righthand side measures the volatile component of the marginal return to human capital investments, which increases with the expected variability of future income ( $\sigma_{\Phi}^{2}$ ) and with the squared of the coefficient of absolute risk aversion $\left(A\left(c_{p}^{1}\right)\right)^{2}=\gamma^{2}$. According to (10), in presence of liquidity constraints, the allocation of children's time depends on expected income risks, on the degree of time preference $(\delta>0)$ and on the coefficient of absolute risk aversion.

Rearranging (10), we get:

$$
\begin{equation*}
(\alpha-1) \ln \left(1-l_{c}\right)+\gamma \vartheta\left(1-l_{c}\right)^{\alpha} \kappa^{\beta}-\mu_{c}=\ln \frac{(1+r)}{(1+\delta)}+\frac{1}{2} \gamma^{2} \sigma_{\Phi}^{2}-\ln \alpha \vartheta \kappa^{\beta} \tag{11}
\end{equation*}
$$

Given the constancy of $\alpha, \beta, k$ and $\vartheta$, it is straightforward to notice that any increase in the righthand side of (11) implies a correspondent increase in the left-hand side of the same equation, which occurs at larger investments in early education (an increase in $\left(1-l_{t}\right)$ ). Hence, any increase of expected income risks implies an upward shift in the number of hours children spend at school. Moreover, at any increase of $\sigma_{\Phi}^{2}$, the likely impact on educational investments is larger at increasing coefficient of absolute risk aversion. Indeed, if households were not risk averse ( $\gamma=0$ ), the time allocation response to $\sigma_{\Phi}^{2}$ would be null; instead, a positive value of $\gamma$ requires a positive number of hours at school in order to restore the equilibrium. In other words, under liquidity constraints, risk averse households are characterized by a precautionary demand for education: education is thought a precautionary asset, an insurance device against expected income risks [Result 3].

In a similar vein, it can be noticed that household's impatience (defined by $\delta$ ) lowers the number of hours children spend at school [Result 4]. This last result suggests that households with a higher inter-temporal preference are more inclined to withdraw their children from schooling and to send them at work in order to feed up current consumption.

Finally, it is easy to notice that the time allocation response to expected income risks and parental preferences is lower at increasing child's ability, $\alpha$.

Hence, in presence of liquidity constraints, household's characteristics (such as risk attitudes, time preferences and subjective expectations of income risks) interact in shaping the optimal allocation of child time. Conversely, in absence of liquidity constraints, the allocation of children's time is not affected by interactions between risk preferences and expected income risks. As a consequence, we can conclude that two human capital production functions exists: one for liquidity constrained households and another for non-constrained households.

## 4. Data

We use data from the Indonesia Life Family Survey to verify our model's predictions.
The IFLS data have been largely used in the literature to study the likely effect of risks on child labor supply. This paper adds to and updates this literature by considering the most recent wave of the survey (the IFLS 4), fielded in 2007/2008.

The Indonesian Family Life Survey (IFLS) is an on-going longitudinal survey in Indonesia, containing widespread current and retrospective information about adults, children and household's assets. The sample is representative of about $83 \%$ of the Indonesian population and contains over 30,000 individuals living in 13 of the 27 provinces in the country.

The choice to use this dataset has been motivated by the extensive set of information provided. Indeed, the IFLS contains a wealth of information collected at the individual and household level, including multiple indicators of economic well-being (consumption, income, and assets); education, migration, and labor market outcomes; marriage, fertility, and contraceptive use; health status, use of health care, and health insurance; relationships among coresident and non-coresident family members; processes underlying household decision-making; transfers among family members and inter-generational mobility; and participation in community activities.

Compared to the previous rounds of the survey, IFLS4 provides a new set of information on risk preferences and discount rate. In particular, and as it will be discussed below, the discount rate will be measured from hypothetical questions on whether the respondent prefers a lower amount of money now or a higher amount in one year. Risk preference coefficients will be extrapolated from hypothetical questions of a choice between a job that guarantees a certain amount of lifetime income, and another job that gives the individual a 50-50 chance of getting a higher or lower
amount than the previous one. Finally, since the waves of the IFLS span the period from several years before the economic crisis hit Indonesia to one year prior to the crisis as well as three years after the incident, extensive research can be carried out regarding the living conditions and coping mechanisms of Indonesian households during this tumultuous time period.

Table 1 presents definitions and summary statistics of the variables used in the analysis.

## TABLE 1 AROUND HERE

The dependent variable is the number of school hours during the last week or the last week the school was in session during the school year of the survey, 2007-2008, for any child between 6 and 17 years old (SCH_HOURS). This variable does not take into account past temporary interruptions to schooling, which are one way of dealing with contemporaneous shocks. Hence, it is plausible to assume that any income shock occurred until 2006 should not directly affect the number of hours children currently spend at school but rather to indirectly bear on it, by affecting the expectations of future earnings volatility as discussed below.

### 4.1. Measuring income risks

This paper uses past occurrence of shocks and the cross-sectional coefficient of variation of households income to proxy the risk profiles of the households. ${ }^{8}$ This approach is based on the assumption that households use past income volatility to predict future volatility, which we believe is a reasonable starting point. Ideally, we should measure the uninsured portion of the unanticipated components of income variability to obtain an accurate representation of the household's exposure to risk. However, the last wave of IFLS does not contain accurate retrospective income information. To proxy the riskiness profile of income due to past macroeconomic shocks we employed a categorical variable MRISK. It runs from 0 to 2 representing the number of the following shocks the household faced between 2000 and 2006: flood, landslide, volcanic eruption, earthquake, tsunami, windstorm, forest fire, fire, civil strife.

We also include a measure of idiosyncratic risks in parents' job prospects, JRISK. It is a categorical variable from 0 to 7 , standing for the number of years the household's head experienced job termination (in the form of unemployment or inactivity) between 2000 and 2006. JRISK synthesizes

[^4]the household's head past difficulties to maintain a job, and its inclusion among the independent regressors of school hours estimates quantifies the likely impact of idiosyncratic riskiness in job prospect on educational investments.

Following Guiso et al. (1996), we consider a further measure of income risks, such as the crosssectional coefficient of variation of households income (HINCM_CV) as proxy for the degree of overall income uncertainty.

### 4.2. Measuring income shocks

Similarly to uncertainty, we included two indicators for the occurrence of contemporaneous income shocks: MSHOCK and JSHOCK. MSHOCK is a proxy for recent macroeconomic income shocks. It is a categorical variable from 0 to 3 , standing for the number of the following shocks the household has experienced since 2007: flood, landslide, volcanic eruption, earthquake, tsunami, windstorm, forest fire, fire, civil strife.

Accordingly, JSHOCK is a categorical variable from 0 to 2 , representing the number of years the household's head experienced job termination (in the form of unemployment or inactivity) since 2007. It is as a measure of recent idiosyncratic job shocks experienced by the household's head and quantifies the troubles in maintaining a job.

It might be objected that the school hours response to JRISK and MRISK may be the result of an expost risk coping strategy to past persistent job termination events. Indeed, JRISK exhibits a relevant degree of path dependence. ${ }^{9}$ Exactly due to this persistence, the variable JSHOCK embeds past persistent income shocks in household's head labor income households have not yet completely recovered from. Hence, any significant impact of JRISK on school hours is likely to measure the school hours response to any residual information embedded in JRISK which does not concern the current activity status of the household's head. Therefore, the contemporaneous introduction of both JRISK and JSHOCK among the independent regressors of school hours equation contributes to disentangle the impact of JRISK - as a proxy of the riskiness of job prospects (out of any recent shock) - from that of JSHOCK as a proxy of contemporaneous or past persistent shocks in labor income.

[^5]With respect to MRISK, $98 \%$ and $96 \%$ of households who faced shocks on agricultural activities between 2000 and 2006 reported no loss in business and non-business assets, respectively, as a consequence of those events. Similarly, only $23 \%$ of households who faced macro shocks between 2000 and 2006 declared its own house was heavily damaged by the disaster; and $89 \%$ of those households whose house was slightly or heavily damaged declared to have already rebuilt the house at the time of the survey. Hence, it is plausible to assume that the degree of shock persistence in the case of macro disaster is not significant and, as a consequence, MRISK reasonably represents a good proxy for the expected risk profile of households, even without the inclusion of MSHOCK among the regressors. Alongside MSHOCK, we introduce a further measure of income shocks caused by macroeconomic events, such as CROPLOSS. It is a dummy variable taking value 1 if the household reported at least one event of crop loss in the past 12 months, and 0 otherwise.

### 4.3. Measuring time preference and risk aversion

To measure parents' degree of risk aversion, a categorical variable RISKPREF has been created. It takes value 1 if the household head is not risk averse, value 2 if the household head is moderately risk averse (MRISKAV), and value 3 if the household head is highly risk averse (HRISKAV). Household's heads are considered as highly (moderately) risk averse if they declare to be more willing to accept a certain amount of rupias (which is lower in the case of moderately risk aversion) compared to playing a lottery in which there is a $50-50$ probability to win significantly more or significantly less than the certain amount.

## TABLE 2 AROUND HERE

In particular, the household's head is considered as highly risk averse if he/she answered 1 to at least one of the following hypothetical lotteries listed in table 2: si03, si04, si05, sil3, si14, si15. The household's head is considered as moderately risk averse if he/she answered 2 to at least one of the following hypothetical lotteries listed in table 2: SI13, si14, si15; and 1 to at least one of the following hypothetical lotteries listed in table 2: $\mathrm{sI} 03, \mathrm{si} 04, \mathrm{~s} 015$.

Parents' time preferences are captured by the dummy variable HHIMPATIENCE, taking value 1 if the household's head declares to be more focused on the well-being in the presence and the immediate future, and 0 otherwise. In particular, each household is classified as time impatient if the
household's head is more willing to accept a 1 million of rupias today, rather than waiting 1 year to get an amount which is significantly higher.

On the bases of the hypothetical lotteries shown in table 2, the household's head is considered as time impatient if he/she answered 1 to at least one of the following hypothetical lotteries listed in table 2: SI21B, SI21C, SI21D.

### 4.4. Measuring liquidity constraints

A household is defined as liquidity constrained (LIQCON) if at least one of the following conditions applies: i) the household's head and/or his/her spouse tried to borrow money from non-family members or friends over the past 12 months but the number of household reported loans is null, ii) if the household head and/or his/her spouse turned down in his/her efforts to secure a loan from non-family members or friends during the past 12 months, iii) if the household head and/or his/her spouse was not successful in securing a loan from non-family members or friends in the past 12 months, iv) nobody in the household declares to know a place where borrowing money from nonfamily members or friends.

By adopting this approach, $12.1 \%$ of all the children between 6 and 17 years old are found to belong to liquidity constrained households in 2007.

## 5. Theoretical hypotheses testing

Using the dataset discussed above, the model results outlined in paragraph 3 will be tested along the following lines.
[Hp.1] - The "Result 2", according to which, ceteris paribus, the presence of liquidity constraints decreases the time children spend at school, will be tested through the significance of a two-sample mean comparison test of the variable SCH_HOURS between liquidity constrained and nonconstrained households.
[Hp.2] - Interactions between the proxy variables for expected income risks (JRISK, MRISK, HINCM_CV) and the variables for risk attitudes discussed above (RISKPREF: MRISKAV, HRISKAV) may be used to verify whether, among liquidity constrained households, the presence of exogenous income risks positively affects the number of hours children spend at school at increasing positive degree of parents' risk aversion ("Result 3"). For example, the significance of the of the interactions
between RISKPREF and MRISK on the amount of time children spend at school will test whether there is a precautionary demand for education due to income risks from macroeconomic shocks. Similarly, interactions between the variables RISKPREF and JRISK will test whether there is a precautionary demand for education due to idiosyncratic risks in parents' job prospects. Finally, interactions between HINCM_CV and RISKPREF will test whether households' perception of overall income uncertainty positively affects child schooling at increasing parents' risk aversion for children living in liquidity constrained households. If households are not liquidity constrained, these interactions should not significantly affect the outcome variable SCH_HOURS since, according to our theoretical findings, child labor is not used as an ex-ante risk coping strategy.
[Hp.3] - A negative and significant impact of hHimpatience on schooling hours will verify the "Result 4", according to which, in presence of liquidity constraints, a positive degree of impatience exerts a downgrading effect on school hours.
[Hp.4] - To control for the possibility that the likely response of child labor to risks depends positively on the degree of household's wealth, we include two further interactions terms: WEALTHPC $\times$ MSHOCK $\times$ RISKPREF and WEALTHPC $\times$ JSHOCK $\times$ RISKPREF. WEALTHPC is the constructed index of household wealth ${ }^{10}$ in three quintile categories. The relevance of their coefficients on the school hours regression estimates allows us to investigate whether the response of school hours to the interactions between uncertainty and risk attitudes are sensible to marginal changes in household's wealth (i.e. whether the evidence of a precautionary motive for education is prevalent among wealthier households).
[Hp.5] - Finally, we also included interactions between the three measures of recent idiosyncratic and macroeconomic income shocks (JSHOCK, MSHOCK, CROPLOSS) and RISKPREF on the regression equation of school hours. Any significant difference between the coefficients of the interaction variables JSHOCK×RISKPREF (or MSHOCK×RISKPREF) and those of the interaction variables JRISK×RISKPREF (or MRISK×RISKPREF) might help to understand whether household's responses in terms of educational investments differ according to the timing of shock occurrence. In this paper, we argue that, for liquidity constrained households, expected income risks give rise to a precautionary demand for education (positive signs for the interaction variables JRISK×RISKPREF or MRISK×RISKPREF on school hours regressions). Conversely, the contemporaneous occurrence of

[^6]adverse income shocks negatively affect the amount of hours children spend at school, with child labor acting as an initial buffer against those shocks (negative signs for the interaction variables JSHOCK $\times$ RISKPREF, MSHOCK $\times$ RISKPREF or CROPLOSS $\times$ RISKPREF on school hours regressions). However, if households are not liquidity constrained, these interactions should not significantly affect the outcome variable SCH_HOURS since, according to our theoretical findings, child labor is not used as a risk coping strategy.

## 6. The Empirical Strategy

This section discusses the empirical strategy used in the proceeding of the paper to verify the hypotheses listed in the previous paragraph. Detailed materials of the econometric model are provided in the Appendix.

Researchers are usually left to compare investments in early education among liquidity constrained households and non-liquidity constrained households. However, the problem of endogeneity (Hausman 1978) of liquidity constraints arises due to the fact that households who invest less in education are more likely to be those who face credit constraints. Because the overall circumstances responsible for differing initial conditions of constrained and unconstrained households are known only to the household and not to the researcher, these cannot be directly controlled to single out the pure effect of liquidity constraints on schooling. For instance, if ability is at least partly inheritable, less able children are more likely to belong to liquidity constrained households and, ceteris paribus, to invest less in education. Then, failure to control for this correlation will yield an estimated liquidity constraints effect on schooling that is biased down. In addition, a problem of sample selection also arises due to the fact that the dependent variable (the number of weekly hours at school) is observed only for a restricted non-random sample. For example, we observe the time at school of a child living in a liquidity constrained household only if the household the child belongs to is liquidity constrained and the child is enrolled in school. Conversely, one observes the time at school of a child living in a non-liquidity constrained household only if the household the child belongs to is not liquidity constrained and the child is enrolled in school. If the samples of liquidity constrained households and of children at school were random draws from the population, a tobit regression of school hours could be fitted, by including credit status as a right-hand-side variable and pooling the entire sample. However, this approach becomes problematic if children in liquidity constrained and non-constrained households differ systematically in the expected amount of school
hours not only because of a merely intercept effect but also because of a slope effect. This occurs for example when the returns to different observable attributes vary by credit regime or if the subsample of students is non-randomly selected. ${ }^{11}$ In other words, estimating a tobit model where non-students are simply treated as zeros may be problematic, as it assumes that the decision to be enrolled in school is qualitatively the same as the decision related to the degree of enrolment in terms of the amount of time spent at school. However, there may be important differences related to these decisions. Consider for example the effect of age: the older the child is, the more likely it is that she is involved in some form of market or non-market work, thereby subtracting time to school. Secondly, children at school may differ from children not at school with respect to unobserved characteristics, such as ability. Hence, treating the decision to abstain from school as a corner solution may provide biased results due to a possible correlation of the error terms. As a consequence, studying the determinants of the amount of children's time at school needs to account for the presence of children who are not enrolled in school at all and to correct for the possible sample selection.

A common means of "correcting" for both the endogeneity and sample selection biases associated with systematic differences between groups is to impose a specific probability distribution structure on the model which explicitly incorporates the selection rule(s). That is the modeling strategy adopted here. We follow Barham and Boucher (1998) in extending the specification of Heckman $(1976,1979)$ to include two selection criteria before running the school hours regression equations: a rule for credit regime affiliation (first-stage probit) and a rule for the school enrolment decision (second-stage probit).

To account for the possible presence of sample selection biases discussed above, we choose to split up the whole sample into two subsamples: one including children living in liquidity constrained households (denoted by C ) and the other including children living in non-liquidity constrained households (denoted by U).

To proceed we estimate the probit for credit regime affiliation first for the whole sample and then generate the Inverse Mill's Ratio (IMR) term for each sub-sample (IMRU1, IMRC1). These terms will then be included in the probit equation explaining enrolment status for each subsample. The appropriate IMR terms from these equations (IMRU2, IMRC2) will then be included in the two final schooling hours equations (one for each subsample, Amemiya 1985).

[^7]
### 6.1. Identification issues

As in any model, one must be aware from where identification arises.
The identification approach adopted in this paper relies on Heckman's procedure and sample splitting. From the credit selection equation on the whole sample, the appropriate IMR terms are generated for each credit regime. Then, we opted for splitting up the sample into children living in liquidity constrained households and children living in households with access to capital markets. The IMR terms obtained in the first probit will be included in a second probit equation explaining the school enrolment status for each subsample. The appropriate IMR terms from these equations will then be included in the final SCH_HOURS equation of each credit regime.
Identification in the second-stage probit is provided by the presence of an exclusion restriction, the variable GIV_HASSIST, in the credit regime selection rule and by the nonlinearity of the IMR term obtained in the first-stage probit (Heckman, 1978; Wilde, 2000). GIV_HASSIST is a categorical variable, representing the number of times the household has provided help in the form of money, goods, services to persons outside the household (other than biological parents, siblings, children) or to other parties (for example like a foundation/organization, friends, and relatives) during the last 12 months (except gifts, souvenirs, etc.). The use of this variable as exclusion restriction is based on the assumption that parents care more about their children's wellbeing than about the wellbeing of friends or relatives outside the household. Hence, the amount of assistance received is supposed to be positively correlated with school enrolment as it represents a sets of goods and services households members do not longer need to get from child work. Instead, the amount of assistance provided to friends or other relatives is supposed not to affect school enrolment, as parents are thought to assign priorities to their children's wellbeing. Conversely, both of them should be significantly and inversely correlated with the likelihood for households to be liquidity constrained, since, ceteris paribus, it is reasonable to suppose that better off households are more likely to provide assistance to non-family members.

To assess the validity of this identification strategy, we ran an instrumental variable probit of the probability to be enrolled at school including LIQCONS among the relevant regressors and GIV_HASSIST as instrument for LIQCONS. The Wald test signals a non-rejection of the null hypothesis of exogeneity of LIQCONS in the school enrolment probit. Hence, in principle, the equation of school enrolment would be identified also in absence of any exclusion restriction. Similarly, we performed an instrumental variable regression of SCH_HOURS including LIQCONS among the relevant regressors
and GIV_HASSIST as instrument for LIQCONS. The underidentification and weak identification tests conclude in favor of the hypothesis that the model is identified and the excluded instruments are relevant.

Because the IMR terms are nonlinear functions of the variables included in the probit models, then the SCH_HOURS regression equations are identified because of this nonlinearity. Since the nonlinearity of the IMR terms arises from the assumption of normality in the probit models, we tested this normality assumption in the school enrolment selection equation for each credit regime. Lagrange multiplier tests conclude that the normality of residuals cannot be rejected for both credit regimes.

The analysis of the inter-quartile ranges of residuals helps us to evaluate whether our double selection model is fairly specified. The inter-quartile range assumes the symmetry of the distribution. Severe outliers consist of those points that are either 3 inter-quartile-ranges below the first quartile or 3 inter-quartile-ranges above the third quartile. The presence of any severe outliers should be sufficient evidence to reject normality at a $5 \%$ significance level. Mild outliers are common in samples of any size. In our estimates of school hours, we don't have any severe outliers and the distributions seem fairly symmetric. The residuals have an approximately normal distribution, thereby suggesting that our school hours estimates are well specified.

All details are available from the authors under request.

## 7. Estimation Results

This section presents and discusses regression results.
The dependent variable SCH_HOURS is the number of school hours during the last week or the last week the school was in session during the school year of the survey, 2007-2008 for any child between 6 and 17 years old.

Sample statistics indicate that this variable differs in mean and variance between liquidity constrained and non-constrained households. The mean value of SCH_HOURS is 17.8 for the sample of children living within non-liquidity constrained households and drops to 16.6 for the sample of children living within liquidity constrained households. The correspondent standard deviations are 12.3 and 12.2 , respectively.

The $t$-test for sub-samples with unequal variances shows that the mean of SCH_HOURS significantly differs between the two groups. The null hypothesis of equality between the two sample means is rejected at a $1 \%$ significance level against both the alternative hypotheses.

The same results are obtained from the Hotelling's T2 test. These findings suggest that school hours are significantly related to the credit regime, thereby confirming [Hp.1].

Results from the double selection models (outlined in section 6.1) complete the overall understanding of the effects of liquidity constraints on school investments.

### 7.1. $\quad$ Credit regime selection rule

The maximum likelihood estimation of the probability of households to be liquidity constrained is presented in Table 3.

## TABLE 3 AROUND HERE

Goodness of fit measures indicate that the estimated model fits the data reasonably well. The Wald test showed that the parameter estimates were significantly different from zero. The model correctly predicts the overall probability of households to fall into the true credit regime for $88 \%$ of the sample.

The results show that the coefficients of most of the variables hypothesized to influence the likelihood for children to belong to liquidity constrained households have the expected signs.

Among the traditional human capital and employment characteristics of the household's head and his/her spouse, a high educational attainment (measured by a level of qualification above upper secondary education) seems to significantly lower the probability for children to live in liquidity constrained households (by between $-4.3 \%$ and $-9.2 \%$ ). Among household demographic characteristics, larger numbers of household members and of children positively effect the outcome. Ceteris paribus, the probability for children to belong to liquidity constrained households is significantly larger in rural areas ( $+3.8 \%$ ).

Alongside education, household wealth seems the most relevant determinant for the credit regime affiliation. In particular, at increasing household wealth (measured by the quintiles of household wealth index) the probability for children to belong to liquidity constrained households decreases.

The household's head activity status also matters: when she is employed in a dependent job, the probability of positive liquidity constraints significantly drops. The variable chosen as exclusion restriction, GIV_HASSIST, is significantly and inversely related to the likelihood for children to live in a households with liquidity constraints.

### 7.2. School enrolment selection rule

The maximum likelihood estimations of the probability of children to be enrolled in school are presented in Table 4.

## TABLE 4 AROUND HERE

Goodness of fit measures indicate that the estimated models fit the data reasonably well. In both models, the Wald test showed that the parameter estimates were significantly different from zero. The models correctly predicts the overall probability of households to fall into the true credit regime for more than $90 \%$ of the sample.

The results show that the coefficients of most of the variables hypothesized to influence the likelihood for children to be enrolled in school have the expected signs and are substantially similar across credit regimes.

Ceteris paribus, the probability for children between 6 and 17 years old to go to school lowers with age ( $-2.9 \%$ for the constrained sample and $-1.8 \%$ for the non-constrained sample) and increases with the educational attainment of the household's head.

There is a strong evidence of persistence in child's time use: being at school during the previous school year significantly increases the likelihood to be still enrolled in school by $61 \%$ for the sample of children living in liquidity constrained households, and by $52 \%$ for the sample of children not living in liquidity constrained households. The degree of persistence in child's time use also matters: any additional year spent in education increases the likelihood of being currently at school by between $1.7 \%$ and $2.4 \%$.

The inverse Mills ratio (IMR1) of the credit regime selection rule exerts a significant effect only for the unconstrained sample, with a negative coefficient of $-7.7 \%$. This suggests the presence of unobserved variables which increase the probability of selection into the unconstrained credit regime and the probability of a lower than average score in the probability of school enrolment.

### 7.3. Regression estimates on school hours

The regression estimates on the amount of school hours for children between 6 and 17 years old are presented in Tables 4 and 5.

## TABLES 4 AND 5 AROUND HERE

We included seven model specifications for the determinants of school hours in order to investigate step by step the role of risk attitudes and time preferences on child time allocation.

The results for the sample of children within liquidity constrained households show that risk attitudes, time preferences and shocks are not individually significant. Overall, unobserved characteristics affecting the likelihood of being liquidity constrained are inversely related to school hours, suggesting that the average SCH_HOURS of children living in liquidity constrained households is lower than the average potential SCH_HOURS. When risks and shocks are jointly considered (models 5 and 6), JSHOCK and JRISK exert significantly impacts on SCH_HOURS (which are, respectively, negative and positive). The substantial difference between the impacts of JRISK and JSHOCK confirms that their contemporaneous consideration within the same regression is sufficient to capture the distinct roles they exert on SCH_HOURS. JRISK is a proxy for household's expectations of income risks and, in turn, affects the dependent variable as a potential ex-ante risk-coping strategy; JSHOCK is a proxy for household's unexpected income shocks and affects the dependent variable as a potential ex-post risk coping strategy.

In order to further investigate the appropriateness of the distinction between JRISK and JSHOCK and between MRISK and MSHOCK, we carried out a further specification by including the overall measures of parental job-related uncertainty (as the sum of JRISK and JSHOCK) and of macro uncertainty (as the sum of MRISK and MSHOCK). Regression results of model 7 suggest that it is indeed the case. The impact of the variable JRISK+JSHOCK is now not significantly different from zero, pooling the observed opposite effects of JRISK and of JSHOCK evidenced by model 6 results. Hence, the sole introduction of JRISK+JSHOCK as a compound measure of household's uncertainty in income sources may be misleading as it embeds two distinct components of income uncertainty: one referred to expected job-related risks and the other referred to unexpected job-related shocks. Differently from what found in the school enrolment equation, the number of times the household
has received help in the form of money, goods or services from persons outside the household or from other parties during the past 12 months (REC_HASSIST) is significantly and positively related to the amount of school hours.

Differently from the previous estimation results, our findings for the sample of children living in non liquidity constrained households show that, across all the specification models, path dependence in child time allocation (SCH_PREV_YEAR and YEARS_SCHOOL) and selectivity correction factors (IMRU1, IMRU2) represent the most relevant determinants of school investments. In model specification 2, time preferences and risk attitudes appear significant: household's head impatience exerts a positive effect on the dependent variable, while risk aversion induces parents to invest less in early education. Moving to models 3 to 5, it can be noticed that JRISK and JSHOCK are the only proxies for income uncertainty to be significantly related to the outcome (with a positive and negative coefficient, respectively). As in the constrained sample, regression results of model 7 suggest that the distinction between JRISK and JSHOCK is appropriate as the non significant (and almost null) impact of the variable JRISK+JSHOCK pools the significant opposite effects of JRISK and JSHOCK evidenced by models 5 and 6 . Hence, again, the sole introduction of JRISK+JSHOCK as a compound measure of household's uncertainty in income sources may be misleading as it embeds two distinct components of income uncertainty: one referred to expected job-related risks and the other referred to unexpected job-related shocks.

To verify model's hypotheses [Hp.2] and [Hp.5], we add interaction terms between our measures of macro and idiosyncratic risks and shocks to model 6 specification. Results are presented in Table 6.

## TABLE 6 AROUND HERE

Goodness of fit measures indicate that the estimated models fit the data reasonably well: the Rsquared statistics for the constrained and unconstrained sample are 0.29 and 0.20 respectively. The significance of the coefficients of correlation between the selection equations and the school investment function (IMR1 and IMR2) indicates that sample selections effectively occur. The regression estimate on school hours for children living in liquidity constrained households shows that, after controlling for the sample selection and endogeneity issues (through the introduction of the inverse Mills ratios, IMR1 and IMR2, among the regressors), demographic characteristics are no longer highly significant compared to measures of income uncertainty, risk attitudes and time preferences.

In absence of risks and shocks, household's head risk aversion reduces the number of school hours (as shown by the negative coefficients of HRISKAV and MRISKAV).

When parents are not risk averse, any macroeconomic shock affecting land crops increases the predicted number of school hours by 4 (that is, 25.968-21.533). This effect decreases by over 1 hour when parents are risk averse (that is, $-12.931+11.707$ ). This result is apparently odd. However, it can be reasonably thought that, after adverse events on agricultural business, less time and efforts in harvest activities is required. Moreover, in absence of risk aversion, job related risks and shocks (JRISK, JSHOCK) exert no significant impact, while a one point increase in the uncertainty of household income (HINCM_CV) reduces the predicted number of weekly school hours by 22.

The picture relevantly changes for risk averse households. First of all, job-related shocks (JSHOCK) turn out to significantly lower school hours for children whose household's head is risk averse. Hence, our [H.5] is verified and child labor acts as an initial buffer against those shocks. Moreover, when parents are risk averse, job-related risks (JRISK) and overall income uncertainty (HINCM_CV) significantly increase the number of hours children spend at school. An inverse-Ushaped relationship can be observed between the dependent variable and the degree of household's head risk aversion. Hence, [Hp.2] is verified especially for children whose household's head is characterized by a moderate degree of risk aversion.
The significance of the coefficient of the interactions between the variables RISKPREF and JRISK (or HINCM_CV) on school investments confirms that uncertainty in job prospects or overall income positively affect child schooling at increasing degree of parents' risk aversion for children living in liquidity constrained households. This result verifies [Hp.2], by suggesting the presence of a precautionary demand for education from income risks.

Household's head impatience does not seem to significantly affect school investments (thereby not verifying [Hp.3] predictions). Moreover, interactions between wealth, risk aversion and income uncertainty show that the school hours response to the interactions between income uncertainty and risk attitudes is sensible to marginal changes in household wealth and the precautionary demand for education is prevalent among wealthier households (thereby, confirming [Нр.4]).

The regression results on school hours for children living in non-liquidity constrained households differ substantially from those obtained for liquidity constrained households. After controlling for sample selection and endogeneity issues (through the significant impacts of the inverse Mills ratios, IMRU1 and IMRU2, among the regressors), child's individual and household characteristics not related to risk preferences remain the sole relevant determinants of the number of school hours.

Indeed, contrarily to the constrained sample, our proxies for path dependence in child's time use represent the most relevant determinants of school investments. Being at school during the previous school year as well as any additional year spent in education in the past significantly increase the current number of school hours. Interactions between our measures of risks and risk attitudes are not significantly related to the dependent variable, suggesting that there is no evidence of a precautionary demand for education arisen from risk aversion. This result confirms our model's prediction according to which a precautionary demand for education typically arises as a consequence of liquidity constraints and parents' risk aversion [Hp.2]. Similarly, interactions between our measures of shocks and risk attitudes do not exert any significant role, thereby confirming that child labor is used as an ex-post risk coping strategy by risk averse households only when borrowing possibilities are precluded ([Hp.5]).

Ceteris paribus, macro risks and shocks are not significant determinants of school investments. Instead, in absence of risk aversion, the occurrence of adverse idiosyncratic income shocks (JSHOCK) and uncertainty in job prospects (JRISK) seem to significantly affect the number of school hours (with negative and positive coefficients, respectively). Finally, time preference - measured by the degree of household's head time impatience - exert a positive impact on school investments by increasing the number of school hours.

### 7.4. Oaxaca decomposition

In this section, we employ the Neuman-Oaxaca decomposition (2002) to decompose the effect of credit regime on the number of school hours into fourth terms. The first one represents differences attributable to explanatory variables (explained component); the second term represents behavioral differences (unexplained component); the third and fourth terms can be thought of as the differences due to, respectively, observed and unobserved self-selection into credit regime and school enrolment. Details of the econometric specification can be found in Appendix.

Results from Oaxaca's decomposition are reported in table 7.

## TABLE 7 AROUND HERE

In this application, gap in endowments and coefficients account for the great bulk of the gap in outcomes. The first ones are mostly driven by the between-samples differences in the selectivity
correction factors. In particular, the between sample differences due to observed self-selection into the credit regime (school enrolment) is significantly negative (positive) suggesting that for the sample of children living in liquidity constrained households there is a significantly higher (lower) correlation between unobserved variables of the school enrolment (credit regime) selection rule and those of the school hours regression estimates. Gap in coefficients are mostly due to betweengroups differences in the returns to past investments in education (SCH_PREV_YEAR) and to the interactions between risk attitudes and risk measures.

As support of our previous findings and model predictions, the between-groups differences in the coefficients of the variables MRISKAV $\times$ JRISK, HRISKAV $\times$ JRISK and MRISKAV $\times$ HINCM_CV, HRISKAVXHINCM_CV are significantly negative. This result confirms that job-related risks and overall income uncertainty increase school investments of risk averse parents who are liquidity constrained to a larger extent. This between-groups gap is more pronounced at increasing degree of risk aversion.

The significant positive difference in the coefficients of MRISKAV $\times$ JSHOCK and HRISKAV $\times$ JSHOCK between the two subsamples suggests that the occurrence of adverse idiosyncratic income shocks seems to exert a larger negative effect on the school hours of the disadvantaged sample.

Overall, these results are coherent with our previous findings that the phenomenon of a precautionary demand for education is more relevant among liquidity constrained households. At the same time, the reduction in school investments as an ex-post risk coping strategy is predominantly used by risk averse parents who are liquidity constrained.

## 8. Conclusions

Using the Indonesia Life Family Survey dataset, this paper has shown that the determinants of child time allocation decisions significantly differ according to households' borrowing possibilities.

Though this evidence has been widely explored in the literature, this paper adds that the presence of liquidity constraints affects the joint impact of risk attitudes, income risks and shocks on schooling investments. When households are liquidity constrained, the weekly amount of hours children spend at school is found to be positively related to the interactions between risk attitudes and expected income risks.

This result suggests that a precautionary demand for education typically arises as a consequence of both liquidity constraints and risk aversion. When borrowing is precluded, risk averse parents are
found to invest in schooling as a substitute for the optimal amount of precautionary savings so to insure future consumption through higher returns from their children's work. At the same time, our results point out that the lack of market insurance mechanisms against the contemporaneous realizations of adverse income shocks induces risk averse parents to underinvest in schooling and to increase the time children spend at work as an ex-post risk coping strategy.

No precautionary demand for education has been found in the face of expected macroeconomic risks, suggesting that the prospect of community-level risks is sufficient to trigger no ex-ante and ex-post risk coping strategy based on child time allocation.

Our results are supported by Belzil and Hansen (2004) and Gould, Moav, Weinberg (2001) who find that a counterfactual increase in risk aversion increases educational attainment as a safeguard strategy. Their findings however do not control for any possible variation in this response due to capital markets conditions and to the source of expected risks.

The role of riskiness in human capital investments deserves further research.

## Tables in the text

Table 1: Variable definitions

| Variable | DESCRIPTION |
| :---: | :---: |
| Child and Household's Demographic Characteristics |  |
| SCH_HOURS | Number of hours any child between 6 and 17 years old the child was at school during the last week (or the last week the school was in session) within the school year, 2007-2008. |
| AT_SCHOOL | Dummy variable equal to 1 if any child between 6 and 17 years old is enrolled at school and 0 otherwise |
| SCH_PREV_YEAR | Dummy variable equal to 1 if any child between 6 and 17 years old was enrolled at school during the year prior to the survey and 0 otherwise |
| YEARS_SCHOOL | Number of years at school |
| CHEDUC | Highest level of education attended by any child between 6 and 17 years old. It takes value 0 for "no education" (reference), 1 for "elementary school" (ELEMENTARY), 2 for "junior high educational level" (JUNIOR_HIGH). |
| GRADE | Categorical variable taking value from 0 to 7 , standing for the class completed at the highest level of education. |
| AGE | Age in years of the child any child between 6 and 17 years old was enrolled at school prior to the survey |
| MALE | Dummy variable equal to 1 if any child between 6 and 17 years old is male and 0 otherwise |
| NCHILD | Number of children below 18 years old in the household |
| HSIZE | Number of household's members |
| PROVINCE | Categorical variable for the province of residence |
| RURAL | Dummy variable taking value 1 if the area of household's residence is rural and 0 if it is urban |

## Time and Risk Preferences Characteristics

| HHIMPATIENCE | Dummy variable proxy for the degree of time preference, taking value 1 if the household's head <br> declared to be more focused on the well-being in the presence and the immediate future, and 0 <br> otherwise. In particular, households are classified as time impatience if the household's head is <br> more willing to accept a 1 million of rupias today, rather than waiting 1 or 5 years to get an <br> amount which is significantly higher. |
| :--- | :--- |
| RISKPREF | Categorical variable for the degree of household's head risk aversion. It takes value 1 if the <br> household's head is not risk averse, value 2 if the household's head is moderately risk averse <br> (mRISKAV), and value 3 if the household's head is highly risk averse (HRISKAV). |
| Compound dummy variable which takes value 2 if RISKPREF is larger than 1 and 1 otherwise. |  |

|  | experienced job termination since 2007. |
| :---: | :---: |
| HINCM_CV | Coefficient of income variation across households |
| Household's Wealth |  |
| LIQCONS | Dummy variable equal to 1 if the household is liquidity constrained and 0 otherwise. Any household is classified as liquidity constrained if at least one of the following conditions applies: i) the household's head and/or his/her spouse tried to borrow money from non-family members or friends over the past 12 months but the number of household's reported loans is null, or ii) if the household's head and/or his/her spouse turned down in his/her efforts to secure a loan from non-family members or friends during the past 12 months, or iii) if the household's head and/or his/her spouse was not successful in securing a loan from non-family members or friends in the past 12 months, or iv) nobody in the household declare to know a place where borrowing money from non-family members or friends. |
| WEALTHINDEX | Continuous variable, proxy for the household's wealth. |
| WEALTHPC | Categorical variable, constructed by taking 3 quintile categories of the variable WEALTHINDEX. |
| Activity and Employment Status of Household's Head and Spouse |  |
| HHEDUC | Categorical variables for the educational attainment of household's head, taking values 0 for "no education" (reference), 1 for "elementary education" (HHEDUC1), 2 for "secondary or tertiary education" (HHEDUC2), and 3 for "other type of education" (es. Religious, HHEDUC3). |
| SPEDUC | Categorical variables for the educational attainment of the spouse of household's head, taking values 0 for "no education" (SPEDUC0), 1 for "elementary education" (SPEDUC1), 2 for "secondary, tertiary or religious education" (SPEDUC2). |
| HHACT, SPACT | Categorical variables for the activity status of household's head and his/her spouse, respectively, taking values 0 for "non-employed" (reference, HHNOTEMPLOYED, SPNOTEMPLOYED), 1 for "dependent employment" (HHDEPENDENT, SPDEPENDENT), 2 for "selfemployment" (HHSELFEMPLOYED, SPSELFEMPLOYED), and 3 for "casual work" (HHCASUALWORK, SPCASUALWORK). |
| ADEMPL | Number of adult household's members who are employed |
| Transfers |  |
| REC_HASSIST | Number of times the household has received help in the form of money, goods, services from persons outside the household (other than biological parents, siblings, children) or from other parties (for example like a foundation/organization, friends, and relatives) during the last 12 months (except gifts, souvenirs, etc.). |
| GIV_HASSIST | Number of times the household has provided help in the form of money, goods, services to persons outside the household (other than biological parents, siblings, children) or to other parties (for example like a foundation/organization, friends, and relatives) during the last 12 months (except gifts, souvenirs, etc.). |

Table 2: The hypothetical lottery for measuring risk and time preferences

| SIO1. | Suppose you are offered two ways to earn some money. <br> With option 1, you are guaranteed Rp 800 thousand per month. <br> With option 2, you have an equal chance of ither the same income, Rp 800 thousand per month, or, if you are lucky, Rp 1.6 million. per month, which is more. <br> Which option will you choose? | 1. Rp 800 thousand per month <br> 2. Rp 1.6 million or Rp 800 thousand per month $\rightarrow$ SIO3 <br> 8. DON'T KNOW |
| :---: | :---: | :---: |
| SI02. | Are you sure? In option 2 you will get at least $R p 800$ thousand per month and you may get Rp 1.6 million per month. In option 1 you will always get $\operatorname{Rp} 800$ thousand per month. | 1. Still picks option $1 \rightarrow$ SI11 <br> 2. Switches to option 2 <br> 8. DON'T KNOW |
| SI03. | Now, in option 2 you have an equal chance of receiving either Rp. 1.6 million per month or Rp. 400 thousand per month, depending on how lucky you are. <br> Option 1 guarantees you an income of Rp 800 thousand per month. <br> Which option will you choose? | 1. Rp 800 thousand <br> 2. Rp 1.6 million or Rp 400 thousand $\rightarrow$ SIO5 <br> 8. DON'T KNOW |
| SI04. | Now, in option 2 you have an equal chance of receiving either Rp 1.6 million per month or $\operatorname{Rp} 600$ thousand per month, depending on how lucky you are. <br> Option 1 guarantees you an income of Rp 800 thousand per month. <br> Which option will you choose? | 1. Rp 800 thousand <br> 2. Rp 1.6 million or $\operatorname{Rp} 600$ thousand <br> 8. DON'T KNOW $\rightarrow \mathrm{S} \mid 11$ |
| SI05. | Now, in option 2 you have an equal chance of receiving either Rp 1.6 million per month or Rp 200 thousand per month, depending on how lucky you are. <br> Option 1 guarantees you an income of Rp 800 thousand per month. <br> Which option will you choose? | 1. Rp 800 thousand <br> 2. Rp 1.6 million or Rp 200 thousand <br> 8. DON'T KNOW $\rightarrow \mathbf{S} \mid 11$ |

| SI11. | Suppose you are offered two ways to earn income. <br> With option 1, you are guaranteed an income of Rp 4 million per month. <br> With option 2, you have an equal chance of earning either the same income, Rp 4 million per month, or, if you are unlucky, Rp 2 million per month, which is less. <br> Which option will you choose? | 1. Rp 4 million $\rightarrow$ SI13 <br> 2. Rp 4 million or Rp 2 million <br> 8. DON'T KNOW |
| :---: | :---: | :---: |
| SI12. | Are you sure? In option 1you will always get Rp 4 million per month but in option 2 you may get $\operatorname{Rp} 4$ million per month but you may get only Rp 2 million per month.. | 1. Still picks option $1 \boldsymbol{\rightarrow} \mathbf{S I 2 1}$ <br> 2. Switches to option 2 <br> 8. DON'T KNOW |
| Sl13. | Now, in option 2 you have an equal chance of receiving either Rp 12 million per month or nothing, depending on how lucky you are. <br> Option 1 guarantees you an income of Rp 4 million per month. <br> Which option will you choose? | 1. Rp 4 million <br> 2. Rp 12 million or $\mathrm{RpO} \rightarrow \mathrm{Sl} 15$ <br> 8. DON'T KNOW |
| SI14. | Now, in option 2 you have an equal chance of receiving either Rp 8 million per month or Rp 2 million per month, depending on how lucky you are. <br> Option 1 guarantees you an income of Rp 4 million per month. <br> Which option will you choose? | 1. Rp 4 million <br> 2. Rp 8 million or Rp 2 million <br> 8. DON'T KNOW $\rightarrow \mathrm{Sl} \mid 21$ |
| Sl15. | Now, in option 2 you have an equal chance of receiving either Rp 16 million per month or having to pay out Rp 2 million per month depending on how lucky you are. <br> Option 1 guarantees you an income of Rp 4 million per month. <br> Which option will you choose? | 1. Rp 4 million <br> 2. Rp 16 million or -Rp 2 million <br> 8. DON'T KNOW $\rightarrow \mathrm{Sl} 21$ |

SI21. You have won the lottery. You can choose between being paid
A. 1. Rp 1 million today Which do you choose?
B. 1. Rp 1 million today o Which do you choose?
C. 1. Rp 1 million today
or
2. Rp 6 million in 1 year Which do you choose?
D. 1. Rp 1 million today or
2. Rp 2 million in 1 year Which do you choose?
E. Are you sure you prefer the same amount in the future although you get the same amount if you do not wait?

## Annex A.2. The econometric model

The model is specified as follows:
$y_{1 i}^{*}=\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}+u_{1 i} ; \quad$ credit regime affiliation rule
$y_{2 i}^{*}=\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2}+u_{2 i} ; \quad$ school enrolment selection rule
$y_{3 i}=\mathbf{x}_{3 i}^{\prime} \boldsymbol{\beta}_{3}+\sigma_{3} u_{3 i} ; \quad$ hours at school

Let our dependent variable, namely the number of hours the $i$-th child spent at school during the last week or the last week the school was in session, be identified by $y_{3 i}$. The response $y_{i}$ of the $i$ th individual from a random sample $N=\{1, \ldots, n\}$ is assumed to depend on a $K \times 1$ vector of explanatory variables (including the constant term), $\mathbf{x}_{3 i}$, with $\boldsymbol{\beta}$ representing the related $K \times 1$ vector of parameters to be estimated. $\sigma_{3}$ is an unknown scale parameter, and the $u_{m i}$ 's (with $m$ from 1 to 3 ) are the unobserved terms with zero means and the following correlation matrix:
$\Sigma=\left[\begin{array}{ccc}1 & \rho_{12} & \rho_{13} \\ \rho_{12} & 1 & \rho_{23} \\ \rho_{13} & \rho_{23} & 1\end{array}\right]$

The selection variables, $y_{1 i}^{*}$ and $y_{2 i}^{*}$, representing the likelihoods for a child to belong to a liquidity constrained household and to be enrolled in school respectively, are not observed. Only their signs are observed, i.e. whether or not a child belongs to a liquidity constrained household and whether or not she is enrolled in school. Thus, the variances of the unobserved terms in the selection equations cannot be estimated and are set to one. The binary variables $D_{1}$ and $D_{2}$ are the observed outcomes of the selection rules and allow classification of the sample following:

$$
\begin{align*}
& D_{1}= \begin{cases}1 & \text { if } y_{1}^{*}>0 \\
0 & \text { if } y_{1}^{*} \leq 0\end{cases}  \tag{A4}\\
& D_{2}=\left\{\begin{array}{lll}
1 & \text { if } y_{2}^{*}>0 \\
0 & \text { if } y_{2}^{*} \leq 0
\end{array}\right. \tag{A5}
\end{align*}
$$

As a result of the two selection rules, four possible outcomes can occur: 1. $\left(D_{1}=1, D_{2}=1\right)$, living in a liquidity constrained household and being enrolled in school; 2. $\left(D_{1}=1, D_{2}=0\right)$, living in a liquidity constrained household and not being enrolled in school; 3. $\left(D_{1}=0, D_{2}=1\right)$, not living in a liquidity constrained household and being enrolled in school; 4. $\left(D_{1}=0, D_{2}=0\right)$, not living in a liquidity constrained household and not being enrolled in school.

To account for the possible presence of sample selection biases (discussed above), we choose to split up the whole sample into two sub-sample: one including children living in liquidity constrained households (denoted by C) and the other including children living in non-liquidity constrained households (denoted by U).

To proceed we estimate the probit for credit regime affiliation first for the whole sample and then generate the Inverse Mill's Ratio (IMR) term for each sub-sample. These terms will then be included in the probit equation explaining enrolment status for each sub-sample. The appropriate IMR terms from these equations would then be included in the two final schooling hours equations for each subsample (Amemiya 1985). Hence, formally, for each subsample, we would end up with only three observed (out of four) outcomes. For the liquidity constrained sample: 1. $\left(D_{1}=1, D_{2}=1\right)$, living in a liquidity constrained household and being enrolled in school; 2. $\left(D_{1}=1, D_{2}=0\right)$, living in a liquidity constrained household and not being enrolled in school; 3. $\left(D_{1}=0\right)$, not living in a liquidity constrained household. For the liquidity unconstrained sample: $1\left(D_{1}=0, D_{2}=1\right)$, not living in a liquidity constrained household and being enrolled in school; 2. $\left(D_{1}=0, D_{2}=0\right)$, not
living in a liquidity constrained household and not being enrolled in school; 3. $\left(D_{1}=1\right)$, living in a liquidity constrained household.

With this structure, the regression function for the equation of interest for each subsample is:
$E\left(y_{3 i} \mid \mathbf{x}_{3 i}, D_{1}, D_{2}\right)=\mathbf{x}_{3 i}^{\prime} \boldsymbol{\beta} \boldsymbol{\beta}_{3}+\sigma_{3} E\left(u_{3 i} \mid \mathbf{x}_{3 i}, D_{1}, D_{2}\right)$

If $E\left(u_{3 i} \mid \mathbf{x}_{3 i}, D_{1}, D_{2}\right) \neq 0$, then a linear regression of $y_{3 i}$ on $\mathbf{x}_{3 i}$ will result in biased parameter estimates. In order to generate unbiased estimates of the elements of $\boldsymbol{\beta}_{3}$, additional information regarding the conditional distribution of the unobserved term, $u_{3 i}$, is required. The additional structure imposed here is the form of the joint distribution of the three unobserved terms. Assume $\left(u_{1 i}, u_{2 i} u_{3 i}\right) \sim N(0, \Sigma)$, independent of the observation of the covariates. For a same individual, however, the unobserved terms may be correlated.

For the liquidity constrained subsample, school hours are observed only when $y_{1 i}^{*}>0$ and $y_{2 i}^{*}>0$. Then, for this subsample, the conditional expectation of $y_{3 i}$ is:

$$
\begin{equation*}
E\left(y_{3 i}^{c} \mid \mathbf{x}_{3 i}^{c}, D_{1}, D_{2}\right)=\left(\mathbf{x}_{3 i}^{c}\right)^{\prime} \boldsymbol{\beta}_{3}^{c}+\sigma_{3}^{c} E\left(u_{3 i}^{c} \mid u_{1 i}>-\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}, u_{2 i}>-\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2}\right) \tag{A7}
\end{equation*}
$$

The multivariate normal structure allows the derivation of an expression for the conditional expectation of the disturbance, $u_{3 i}$ :
$E\left(u_{3 i}^{c} \mid u_{1 i}>-\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}, u_{2 i}>-\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2}\right)=\rho_{13}^{c} \lambda_{1}^{c}+\rho_{23}^{c} \lambda_{2}^{c}$
where the two $\lambda^{c}$ terms are the analogues to the selection inverse Mill's ratio. With these results, the conditional expectation in (A7) becomes:

$$
\begin{equation*}
E\left(y_{3 i}^{c} \mid \mathbf{x}_{3 i}^{c}, D_{1}, D_{2}\right)=\left(\mathbf{x}_{3 i}^{c}\right)^{\prime} \boldsymbol{\beta}_{3}^{c}+\theta_{1}^{c} \lambda_{1}^{c}+\theta_{2}^{c} \lambda_{2}^{c} \tag{A9}
\end{equation*}
$$

where $\theta_{1}^{c}=\sigma_{3}^{c} \rho_{13}^{c}$, and, $\theta_{2}^{c}=\sigma_{3}^{c} \rho_{23}^{c}$.
Similarly, for the liquidity unconstrained subsample, school hours are observed only when $y_{1 i}^{*} \leq 0$ and $y_{2 i}^{*}>0$. Then, for this subsample, the conditional expectation of $y_{3 i}$ is:
$E\left(y_{3 i}^{u} \mid \mathbf{x}_{3 i}^{u}, D_{1}, D_{2}\right)=\left(\mathbf{x}_{3 i}^{u}\right)^{\prime} \boldsymbol{\beta}_{3}^{u}+\sigma_{3}^{u} E\left(u_{3 i}^{u} \mid u_{1 i}>\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}, u_{2 i}>-\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2}\right)$

The multivariate normal structure allows the derivation of an expression for the conditional expectation of the disturbance, $u_{3 i}$ :
$E\left(u_{3 i}^{u} \mid u_{1 i}>\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}, u_{2 i}>-\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2}\right)=-\rho_{13}^{u} \lambda_{1}^{u}+\rho_{23}^{u} \lambda_{2}^{u}$
where the two $\lambda^{u}$ terms are the analogues to the selection inverse Mill's ratio, with $\lambda_{2}^{u}=\varphi\left(\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2}\right) / \Phi\left(\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2}\right)$, and $\lambda_{1}^{u}=\varphi\left(\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}\right) / 1-\Phi\left(\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}\right)$. With these results, the conditional expectation in (19) becomes:
$E\left(y_{3 i}^{u} \mid \mathbf{x}_{3 i}^{u}, D_{1}, D_{2}\right)=\left(\mathbf{x}_{3 i}^{u}\right)^{\prime} \boldsymbol{\beta}_{3}^{u}+\theta_{1}^{u} \lambda_{1}^{u}+\theta_{2}^{c} \lambda_{2}^{u}$
where $\theta_{1}^{u}=-\sigma_{3}^{u} \rho_{13}^{u}$, and, $\theta_{2}^{u}=\sigma_{3}^{u} \rho_{23}^{u}$.
The estimation is conducted in two steps. First, data on the outcomes of the two selecting rules are used to obtain the likelihood function for the bivariate probit. Letting $G(\cdot)$ denote the standard normal cumulative distribution functions, this likelihood function is:

$$
L=\prod_{\substack{D_{D}=0 \\ D_{2}=1}} F\left(-\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}, \mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2} ;-\rho_{12}\right) \cdot \prod_{\substack{D_{1}=1 \\ D_{2}=1}} F\left(\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1}, \mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2} ; \rho_{12}\right) \cdot \prod_{\substack{D_{1}=0 \\ D_{2}=0}} F\left(-\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1},-\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2} ; \rho_{12}\right) \cdot \prod_{\substack{D_{1}=1 \\ D_{2}=0}} F\left(\mathbf{x}_{1 i}^{\prime} \boldsymbol{\beta}_{1},-\mathbf{x}_{2 i}^{\prime} \boldsymbol{\beta}_{2} ;-\rho_{12}\right)
$$

The first term of the likelihood function corresponds to children living in non-liquidity constrained households who are enrolled in school; the second term to children living in liquidity constrained households who are enrolled in school; the third term to children living in non-liquidity constrained households who are not enrolled in school; the last term to children living in liquidity constrained households who are not enrolled in school. Maximum likelihood estimation of (A13) yields consistent estimates of $\hat{\boldsymbol{\beta}}_{1}, \hat{\boldsymbol{\beta}}_{2}, \hat{\rho}_{12}$.
These parameter estimates are used to construct $\hat{\lambda}_{1}$ and $\hat{\lambda}_{2}$ for each child, either living in liquidity constrained households and not living in liquidity constrained households. These can be inserted into eqs. (A9) and (A12) to yield the selection corrected school hours equations:
$E\left(y_{3 i}^{u} \mid \mathbf{x}_{3 i}^{u}, D_{1}, D_{2}\right)=\left(\mathbf{x}_{3 i}^{u}\right)^{\prime} \boldsymbol{\beta}_{3}^{u}+\theta_{1}^{u} \lambda_{1}^{u}+\theta_{2}^{u} \lambda_{2}^{u}+\sigma_{3}^{u} v_{3}^{u} ; E\left(v_{3}^{u} \mid D_{1}=0, D_{2}=1\right)=0$

$$
\begin{equation*}
E\left(y_{3 i}^{c} \mid \mathbf{x}_{3 i}^{c}, D_{1}, D_{2}\right)=\left(\mathbf{x}_{3 i}^{c}\right)^{\prime} \boldsymbol{\beta}_{3}^{c}+\theta_{1}^{c} \lambda_{1}^{c}+\theta_{2}^{c} \lambda_{2}^{c}+\sigma_{3}^{c} v_{3}^{c} ; \quad E\left(v_{3}^{c} \mid D_{1}=1, D_{2}=1\right)=0 \tag{A15}
\end{equation*}
$$

Eqs. (A14) and (A15) is fit by ordinary least squares regression of $y_{3 i}$ on $\mathbf{x}_{3 i}$ and the constructed variables $\hat{\lambda}_{1}$ and $\hat{\lambda}_{2}$ for those children who are both living in liquidity constrained and non-liquidity constrained households. Finally, estimates of the correlation coefficients $\rho_{12}$ and $\rho_{13}$ are obtained by solving the equations for $\theta_{1}$ and $\theta_{2}$ given in eqs. (A9) and (A12).

## Annex A.3. Oaxaca Decomposition

Once the dependent variable and the model parameters are consistently estimated, the effect of credit regime on the number of hours at school can be decomposed into several components. In particular, three terms can be identified (Neuman and Oaxaca, 2002) such that:

$$
\begin{aligned}
E\left(\bar{y}_{3}^{\prime \prime} \mid \overline{\mathbf{x}}_{3}^{\prime \prime}, D_{1}, D_{2}\right)-E\left(\bar{y}_{3}^{c} \mid \overline{\mathbf{x}}_{3}^{c}, D_{1}, D_{2}\right) & =\left\{\left(\overline{\mathbf{x}}_{3}^{\prime \prime}\right)^{\prime} \hat{\boldsymbol{\beta}}_{3}^{\prime \prime}+\hat{\boldsymbol{\theta}}_{1}^{\prime \prime} \hat{\boldsymbol{\lambda}}_{1}^{\prime \prime}+\hat{\boldsymbol{\theta}}_{2}^{\prime \prime} \hat{\lambda}_{2}^{\prime \prime}\right\}-\left\{\left(\overline{\mathbf{x}}_{3}^{c}\right)^{\prime} \hat{\boldsymbol{\beta}}_{3}^{c}+\hat{\boldsymbol{\theta}}_{1}^{c} \hat{\boldsymbol{\lambda}}_{1}^{c}+\hat{\boldsymbol{\theta}}_{2}^{c} \hat{\boldsymbol{\lambda}}_{2}^{c}\right\} \\
& =\left\{\left(\overline{\mathbf{x}}_{3}^{\prime \prime}-\overline{\mathbf{x}}_{3}^{c}\right)^{\prime} \hat{\boldsymbol{\beta}}_{3}^{c}\right\}+\left\{\left(\overline{\mathbf{x}}_{3}^{\prime \prime}\right)^{\prime}\left(\hat{\boldsymbol{\beta}}_{3}^{\prime \prime}-\hat{\boldsymbol{\beta}}_{3}^{c}\right)\right\}+ \\
& +\left\{\left(\hat{\lambda}_{1}^{u}-\hat{\boldsymbol{\lambda}}_{1}^{c}\right) \hat{\boldsymbol{\theta}}_{1}^{c}\right\}+\left\{\left(\hat{\lambda}_{1}^{\prime \prime}\right)\left(\hat{\boldsymbol{\theta}}_{1}^{\prime \prime}-\hat{\boldsymbol{\theta}}_{1}^{c}\right)\right\}+ \\
& +\left\{\left(\hat{\lambda}_{2}^{\prime \prime}-\hat{\lambda}_{2}^{c}\right) \hat{\boldsymbol{\theta}}_{2}^{c}\right\}+\left\{\left(\hat{\lambda}_{2}^{\prime \prime}\right)\left(\hat{\boldsymbol{\theta}}_{2}^{\prime \prime}-\hat{\boldsymbol{\theta}}_{2}^{c}\right)\right\}
\end{aligned}
$$

where $\bar{y}_{3}^{u}=\left(1 / N_{u}\right) \sum_{i=1}^{N_{u}} y_{3 i}^{u}, \bar{y}_{3}^{c}=\left(1 / N_{c}\right) \sum_{i=1}^{N_{c}} y_{3 i}^{c}$ are the predicted means of the number of hours children living in liquidity unconstrained and constrained households spent at school, respectively; $\overline{\mathbf{x}}_{3}^{u}=\left(1 / N_{u}\right) \sum_{i=1}^{N_{u}} \mathbf{x}_{3 i}^{u}, \overline{\mathbf{x}}_{3}^{c}=\left(1 / N_{c}\right) \sum_{i=1}^{N_{c}} \mathbf{x}_{3 i}^{c}$ are the predicted means of the vectors of characteristics for children living in liquidity unconstrained and constrained households, respectively; $N_{u}$ and $N_{c}$ are the size of children within the liquidity unconstrained and constrained households, respectively. The first term in equation (A16) corresponds to the differences between the number of hours spent at school by children in liquidity constrained and unconstrained households attributable to explanatory variables (explained component); the second term in equation (A16) represents behavioral differences between children in liquidity constrained and unconstrained households (unexplained component); the third and fourth terms can be thought of as the differences due to, respectively, observed and unobserved self-selection into credit regime; the last two terms can be thought of as the differences due to, respectively, observed and unobserved self-selection in school enrolment.

[^0]:    ${ }^{1}$ See, for example, Johnson (1978), Levhari and Weiss (1974), Gibbons and Murphy (1992), Shaw (1996) and PalaciosHuerta (2003).
    ${ }^{2}$ Such studies include Brown and Rosen (1987), Moore (1995) and Murphy and Topel (1987).
    ${ }^{3}$ Brown and Taylor (2005), Brunello (2002), Guiso and Paiella (2008), Belzil and Leonardi (2007) and Barsky et al. (1997)

[^1]:    ${ }^{4}$ In the literature there is a tendency to narrow the discussion and analysis of the determinants of children's activities to two non-leisure activities - market labor and schooling. There are a number of reasons why there has been a focus in the empirical literature on children market labor and schooling. First, both are important outcome variables that policymakers like to target. Second, it embeds the evidence that not only work "outside" home (i.e that for wage) should to be considered as "child labor". In developing countries the time children do not spend at school is largely dedicated to work at home or in the family enterprise which can be as hard as work outside.
    ${ }^{5}$ See, Trostel (2004), Ben-Porath (1967).

[^2]:    ${ }^{6}$ As in Carroll (2001), I assume that consumers are impatient, in the sense that if there were no uncertainty or liquidity constraints, they would choose to spend more than current income. For many people, particularly those close to subsistence in low developed countries, this assumption seems to be a natural one.

[^3]:    ${ }^{7}$ If a random variable X is distributed with a lognormal probability distribution function, then: $\ln E(X)=E \ln (X)+1 / 2 * \operatorname{var}(\ln (X))$.

[^4]:    ${ }^{8}$ See, among the others, Fitzsimons (2007) and Guiso et al. (1996).

[^5]:    ${ }^{9}$ On average, across the whole period 2000-2008, the probability of the household's head to not be employed in $t$, after having experienced a job termination in $t-1$ is over $50 \%$.

[^6]:    ${ }^{10}$ The Wealth Index is a composite measure of the cumulative living standard of a household, calculated using easy-tocollect data on a household's ownership of selected assets, such as televisions and bicycles, materials used for housing construction, and types of water access, sanitation facilities, jewelry and savings. Generated with a statistical procedure known as principal components analysis, the Wealth Index places individual households on a continuous scale of relative wealth.

[^7]:    ${ }^{11}$ This is indeed the case in many developing and under-developed countries where school enrolment rates are very low.
