ABSTRACT

Purpose: The primary purpose of this investigation was to determine if age is associated with blood markers of inflammation (C-reactive protein [CRP]) and fibrinolysis (fibrinogen, tissue plasminogen activator [t-PA], and plasminogen activator inhibitor – 1 [PAI-1]), independent of body fat and physical activity levels.

Methods: A total of 40 healthy males and 42 healthy females ranging in age from 21 to 89 years participated in this cross-sectional study. Blood levels of CRP, fibrinogen, t-PA, and PAI -1 were measured and compared with age, clinical characteristics, physical activity levels, and body composition. Body composition was assessed with dual-energy x-ray absorptiometry and physical activity was assessed with a StepWatch Activity Monitor.

Results: Age was not associated with concentrations of CRP ($r = -0.073$, $p = 0.519$). CRP was significantly correlated ($p < 0.05$) to HDL levels ($r = -0.255$), BMI ($r = 0.304$), percent body fat ($r = 0.221$) and trunk fat mass ($r = 0.234$). Of these, BMI was the only significant predictor ($r^2 = 0.095$, $p = 0.002$) of CRP levels. Age was not correlated with fibrinogen ($r = 0.206$, $p = 0.065$), or PAI-1 ($r = 0.084$, $p = 0.454$), but was initially correlated with t-PA ($r = 0.228$, $p = 0.042$). The markers of fibrinolysis were correlated ($p < 0.05$) with blood pressure, HDL, triglycerides, percent body fat, body fat mass, percent trunk fat, and trunk fat mass. However, none of these variables or age were independent predictors of

blood concentrations of fibrinogen ($r^2 = 0.237$, $p = 0.226$), t-PA ($r^2 = 0.079$, $p = 0.636$), or PAI – 1 ($r^2 = 0.137$, $p = 0.333$).

Conclusions: The primary finding of the current study is that age is not independently associated with blood concentrations of CRP, fibrinogen, tPA or PAI-1. However, it was observed that inflammation and fibrinolysis were associated with blood pressure, cholesterol levels, and measures of body fatness. These associations provide a possible explanation for the discrepancy between our findings and those of previous studies which did not control for such factors.

CHAPTER ONE

INTRODUCTION

Cardiovascular disease (CVD) has been and remains the leading cause of death in the United States over the last century, claiming nearly 700,000 lives annually in the United States (U.S.) (6). Over 27 million of the 71.3 million known cases of cardiovascular disease are found in adults 65 years of age or older (147), which is a reflection of the increased risk for CVD associated with aging (5,22,130). Over the last decade, evidence suggests that chronic, low-grade inflammation is an underlying component in the initial development and progression of atherosclerosis and an independent risk factor of cardiovascular disease (43,114,130). C-reactive protein (CRP), a hepatocyte-derived acute-phase protein (21,22), is the most commonly studied marker of inflammation, and is clearly related to the incidence of atherosclerosis and acute coronary syndrome (12,97,101,111,130). CRP initiates production of inflammatory cytokines such as tumor necrosis factor - alpha [TNF-α] and interleukin-6 [IL-6] (48,95) and mediates monocyte and macrophage infiltration into endothelial tissue (79). Consequently, CRP is considered to be the "golden marker" for chronic, low-grade inflammation (97).

Fibrinogen is another acute-phase protein that is often considered to be a marker of inflammation (11), but is actually a determinant of blood viscosity and an important factor in the formation of a blood clot (thrombosis) in the blood vessel (41,42). Fibrinolysis is a natural defense against development of thrombosis (45,131) and is closely linked to inflammation. Tissue plasminogen activator (t-PA) has a major role in activating the fibrinolytic system and initiating the release of plasmin, which is responsible for fibrin clot degradation (135). However, fibrinolytic activity is impaired by plasminogen activator inhibitor-1 (PAI-1), the most important inhibitor of plasma fibrinolytic activity (126). Thus, fibrinogen, t-PA, and PAI-1 are perceived as independent risk markers and prognostic indicators of cardiovascular disease (11,111,126,135).

Inflammation (6,21,22,69,130) and fibrinolysis (1,36,135) are suggested mechanistic links between cardiovascular disease (CVD) and aging (24). However, previous examinations of age-related changes in inflammation and fibrinolysis often included questionable "healthy" populations (48) that presented with confounding conditions such as hypertension (27), hypercholesterolemia (51), diabetes (37), metabolic syndrome (4,28), and smoking (37). Unfavorable changes related to inflammation and fibrinolysis are also associated with obesity, defined as a body mass index [BMI] of greater than 30.0 kg/m^2 (40), and physical inactivity (69,135). Whole body adiposity and visceral adiposity, in particular, are suspected regulators of CRP, coagulation, and fibrinolysis (149,150), and are

associated with an increase in inflammation and a decrease in fibrinolysis (34). Conversely, inflammation and fibrinolysis are improved with frequent bouts of physical activity by means of producing a subsequent decrease in blood concentrations of CRP, fibrinogen, and PAI-1, and an increase in blood concentration of t-PA (69,72,79).

Since body composition and physical activity levels change with age (24), these factors must be considered when examining the independent role of age on inflammation and fibrinolysis. Because of the inclusion of subjects with both conditions, previous epidemiologic studies have been inconclusive in identifying causative factors of age-related elevations of inflammatory and fibrinolytic markers. Therefore, the primary aim of this study was to determine if age was related to increased blood levels of inflammatory and fibrinolytic markers, independent of body composition and physical activity status.

Purposes of the Study

The purpose of this study was to determine whether:

1. Age is related to blood concentrations of CRP, fibrinogen, t-PA, and PAI-1.
2. Whole body and trunk fat mass are related to blood levels of CRP, fibrinogen, t-PA, and PAI-1.
3. Ambulatory physical activity is related to blood levels of CRP, fibrinogen, t-PA, and PAI-1.
4. The affect of age persists after controlling for ambulatory physical activity and fatness.

Research Questions

Research questions for this study include:

1. Are the concentrations of CRP, fibrinogen, t-PA, and PAI-1 in the blood related to age?
2. Is there a relationship between whole body and trunk fat mass and the concentration of CRP, fibrinogen, t-PA, and PAI-1 in the blood?
3. Is there a relationship between the amount of ambulatory physical activity and the concentration of CRP, fibrinogen, t-PA, and PAI-1 in the blood?

4. Are the concentration of CRP, fibrinogen, t-PA, and PAI-1 in the blood related to age independent of whole body fatness, abdominal fatness, and ambulatory physical activity?

Research Hypotheses

Research hypotheses for this study include:

1. The concentration of CRP, fibrinogen, t-PA, and PAI-1 will change with increasing age.
2. Whole body and abdominal adiposity will be positively related to blood concentrations of the CRP, fibrinogen, and PAI-1 and negatively related to blood concentrations of t-PA.
3. Ambulatory physical activity levels will be negatively related to blood concentrations of CRP, fibrinogen, and PAI-1 and positively related to blood concentrations of t-PA.
4. After adjusting for whole body fat mass and ambulatory physical activity, blood levels of CRP, fibrinogen, t-PA, and PAI-1 will not be related to age.

Significance of the study:

Providing evidence that aging is linked with inflammation and fibrinolysis is of high importance, as it may provide an explanation of the causes of age-related disease. There are several reports that increasing age is associated with

unfavorable changes in inflammation (5,21,22,69,130) and fibrinolysis (34,36). Inflammation and fibrinolysis have also been associated with many clinical conditions (27,100,125,150), as well as with levels of body fat (39,49,132,150) and physical activity (103,145). The increasing prevalence of clinical conditions and unfavorable changes in body composition (i.e., decreased skeletal muscle mass and increased total body fat) occurring with age (55,98) could explain previous reports of age-related changes in inflammatory and fibrinolytic activity. Thus, controlling for these confounding factors, as was done in this investigation, helps clarify that levels of inflammation and fibrinolysis are unrelated to age and, further, underscore the importance of maintaining higher levels of physical activity and lower levels of body fat mass to protect cardiovascular health.

Delimitations

Delimitations for this study included:

1. Participants were community dwelling males and females between the ages of 18 – 80 years of age.
2. Adults with physical disabilities that limited ambulatory movement were excluded from the study.
3. The participation criteria for this study were strict to exclude confounding conditions of inflammation and fibrinolysis (i.e., existing diseases,

cardiovascular risk factors, bone or joint disorders, respiratory disease, chronic or acute infections, etc).

4. Pregnant women were not allowed to participate.
5. All subjects were from the greater Oklahoma City, OK metropolitan area.

Limitations

Limitations for this study included:

1. This study used a cross-sectional design; therefore, causal relationships can not be determined.
2. The participants in this study were volunteers and, thus, potentially were not representative of the general population.
3. The StepActivity Monitor is not waterproof; therefore, water activities could not be assessed.
4. The StepActivity Monitor was worn on the ankle; therefore, upper body activity could not be quantified independent of overall body movement.
5. The dietary intake of our subjects was not monitored.

Assumptions

Assumptions for this study included that subjects:

1. Wore the Step Activity Monitor correctly throughout the entire time between visits.
2. Were in a fasted state for the blood draw and for the body composition assessment.
3. Honestly reported their medical history, age, and race.

Operational Definitions

Inflammation - a condition of a chronic, low-grade response instead of the classical form used to describe an acute bout of redness and swelling resulting from injury or infection, and is often referred to as "microinflammation" (130).

Fibrinolysis - a cascade of enzymatic reactions designed to breakdown fibrin clot formation; our body's natural defense against thrombosis (45).

Atherosclerosis - a build-up of fatty substances, cholesterol, calcium or fibrin on the inner walls of large and medium-sized arteries (114).

Hypertension - a blood pressure that is consistently higher than normal (systolic pressure ≥ 140 mmHg and a diastolic pressure ≥ 90mmHg) (125).

Hypercholesterolemia - Above normal serum levels of total cholesterol (> 200 mg/dL) (46).

Dyslipidemia - blood levels of low-density lipoproteins, high-density lipoproteins, and triglycerides that are outside of the "normal" ranges; (LDL ≥190 mg/dL; HDL < 40 mg/dL for males and < 50 mg/dL for females; Triglycerides ≥ 200 mg/dL) (46).

Abdominal obesity - a classification for a waist circumference greater than 102 centimeters in males and greater than 88 centimeters in females (46).

Body-mass index (BMI) - an index used to assess weight relative to height, and is calculated by dividing body weight in kilograms by the square of the height in meters (BMI = kg/m^2) (46).

Obesity - defined as BMI ≥ 30.0 kg/m^2 denoting an excessive accumulation of fat on the body (40).

Physical activity - any bodily movement produced by skeletal muscles resulting in energy expenditure (46).

Percent body fat (%BF) – the relative percentage of total body weight that is fat-mass, derived by dividing fat mass by total body mass and multiplied by 100 (34).

Metabolic Syndrome – a condition defined as having at least three of five risk factors such as abdominal obesity (waist circumference ≥ 102 cm or 40 inches in males, ≥ 88 cm or 36 inches in females), dyslipidemia (Triglycerides ≥ 150 mg/dL; high-density lipoprotein cholesterol < 40 mg/dL in males and < 50 mg/dL in females), raised blood pressure (systolic pressure ≥ 130 mmHg and a diastolic of ≥ 85 mmHg), and insulin resistance (fasting glucose ≥ 110 mg/dL) (46).

CHAPTER TWO

REVIEW OF LITERATURE

Introduction

Cardiovascular disease has been and remains the leading cause of death in the United States over the last century and is responsible for nearly 700,000 deaths in the U.S. a year (6). The most recent data show that there are approximately 71.3 million known cases of all cardiovascular diseases in the United States (147), with direct medical costs tallying approximately $41.2 billion (141). The predicted overall health care expenditures related to cardiovascular disease in 2006 is $403.1 billion, which underscores the prevalence and socioeconomic impact on our society (147).

Epidemiological data shows that more than 70 percent of all cardiovascular disease cases are related to atherosclerosis (141), a build-up of fatty substances, cholesterol, calcium or fibrin on the inner walls of large and medium-sized arteries. In clinical practice, the term atherosclerosis is often used interchangeably with cardiovascular disease. Several clinical conditions have been recognized as traditional risk factors for cardiovascular disease including hypertension (51), hypercholesterolemia (27), diabetes (37), obesity (defined as a body mass index [BMI] of greater than 30.0 kg/m^2) (64), physical inactivity (96) and cigarette smoking (26). Additionally, aging is recognized as an independent risk factor for cardiovascular disease (5,21,22,69,130). Still, numerous elderly patients present

with cardiovascular disease even though no co-existing risk factors (25) exist, implying that another mechanism could facilitate the development of atherosclerosis.

Chronic-low grade inflammation is now suggested as an important underlying component in the initial pathology of vascular disease, as it precipitates the breakdown of the inner walls of blood vessels (43,114,130). The fibrinolytic system is closely linked to inflammation and is directly involved in coagulation processes (45). Both of these processes have been associated with the development and risks of atherosclerosis (9,21). Is this a mechanistic link between age and cardiovascular disease? This chapter will further review the relations among age, inflammation, and fibrinolysis, as well as other influences on these processes.

Vascular Inflammation

Over the last decade, evidence has been presented that suggest inflammation is an important underlying component in the initial development and progression of atherosclerosis (43,114,130). Traditionally, inflammation has been defined as a local response to cellular injury that is marked by capillary dilatation, leukocyte infiltration, redness, heat, and pain, serving as a mechanism initiating the elimination of noxious agents and damaged tissue. Inflammation has since been considered to be a composite of many different activities brought into action in response to an environmental challenge, not a single process (130). Thus, in this context, the word inflammation implies a condition of a chronic, low-grade response instead of the

classical form used to describe an acute bout of redness and swelling resulting from injury or infection, and is often referred to as "microinflammation." (130)

Recent research has illustrated the inflammatory component in the pathology of cardiovascular disease, as well as identified conditions that induce chronic, low-grade inflammation (97). There also is a systemic response that accompanies inflammation and is known as the acute-phase response. This response stimulates the production of many hepatocyte-derived acute-phase proteins (22). The most popular, C-reactive protein (CRP), is considered to be the "golden marker" for chronic, low-grade inflammation (97).

The production and activation of CRP by hepatocytes has long been considered to be solely a response to elevated levels of inflammatory cytokines such as tumor necrosis factor- alpha and interleukin-6 (79,97), but more recently has been shown to play a role in promoting inflammatory processes (48,95). Specifically, this acute phase protein has been localized in atherosclerotic plaques and has demonstrated an increased expression in atherosclerotic arterial tissue (24,79), which led to speculation of a pro-inflammatory role of CRP.

Circulating CRP has demonstrated detrimental affects on endothelial cells by increasing adhesion molecule expression on the cell surface (79), impairing vasoreactivity by decreasing endothelial nitric oxide expression (18), and up-regulating the expression of angiotensin receptors in vascular smooth muscle (86). CRP is also known to facilitate monocyte and macrophage infiltration into endothelial tissue (79). Collectively, these actions are trademark characteristics of

inflammation that, ultimately, result in an unresponsive vessel (i.e., diminished arterial elasticity or reduced vascular reactivity), a classical feature of early atherosclerotic development (137). Furthermore, it has been shown that individuals in the highest quartile of CRP levels have a relative risk of future cardiovascular related events that is three times greater than those in the lowest quartile (112). This potentially explains the well-documented correlations between CRP and incidence of atherosclerosis or acute coronary syndrome (12,97,101,111,130), and further supports the identification of CRP as an independent risk factor for cardiovascular disease.

Inflammation and Aging

Aging has consistently been associated with increases in inflammation (8,9,23,44,68,115). Illustrating a link between the two processes is of high importance, as it may provide an explanation of the causes, or reflections, of age-related disease. Such findings would validate the use of these blood markers as an indicator of disease in clinical practice. Previous studies have shed light on this relation, but the design of these examinations (i.e., failure to control for confounding physical characteristics) leaves the relation between age and inflammation unclear.

The case of age-related changes in acute inflammatory responses has been well illustrated with *in vitro* studies using human endotoxin challenge models. For instance, Krabbe et al. (2001) used a human endotoxin challenge model, in which a wall constituent of *Escherichia coli,* a gram-negative batcteria, was injected

intravenously to induce an inflammatory state (68) to identify age-related differences in inflammatory response. While older individuals showed quicker and more prolonged inflammatory responses than younger individuals, there was no difference in peak inflammation status between the two groups. In 1999, Bruunsgaard et al. used the same type of *in vitro* stimulation in a large, population-based study (23). After the endotoxin infusion, the 80 year old adults showed a greater decrease in inflammatory response, represented by tumor necrosis factor – alpha (TNF-α), interleukin-1Beta (IL-1β), and interleukin-6 (IL-6) than the 18 to 30 year old adults. Further observation showed that the older females, while having lower inflammatory responses than the young males, did not show any difference from the young females. These findings actually suggest that there is a decline in age-related inflammatory cytokine production and that estrogen produces a suppressive effect on inflammation (23).

In earlier studies, increased age has been associated with higher levels of inflammatory cytokines than in younger adults (19,110). Specifically, one study (19) showed that the concentrations of TNF-α and IL-1β were significantly increased in older subjects. Ironically, the levels of monocytes were unchanged, which suggests that immune responses can actually be enhanced with age. The same increase in IL-1β production with age was shown by Riancho et al. (1994); however, no age-related changes occurred in TNF-α production (110).

The conflicting results found in the acute inflammatory response investigations are sustained when examining the chronic elevations of circulating

markers of inflammation in aging populations. Many studies conclude that aging is associated with increased plasma levels of CRP, TNF-α, and IL-6 (9,22,23). However, there are studies that do not support these findings (115).

In 1996, Ballou et al. studied a group of older and younger adults who were apparently healthy (9). While this study carefully excluded individuals with disorders that could affect CRP levels, they failed to take into account blood pressure, cholesterol levels (or pertaining medications), physical activity levels, or body composition. Their findings showed that elderly people had a significantly higher level of CRP (median = 3.0 μg/ml) than a younger group of people (median = 0.9 μg/ml, $p < 0.003$) (9). Within the older group (n = 131), ranging 65-94 years in age, there was no significant correlation between age and CRP levels or other acute-phase proteins (i.e., serum-amyloid A) (9). These findings weakened the claim that age is associated with inflammation.

In another cross-sectional study with a larger sample (n = 1327), Ferrucci et al. found that inflammation increased with age (48). To date, this is one of the largest age ranges (20 to 102 years) examined. CRP and IL-6 were significantly higher in the age group 65 years of age and older in both males and females even after adjusting for the existing clinical conditions. These conditions included: presence of hypertension, history of coronary artery disease or stroke, chronic heart failure, diabetes, cancer, and smokers. However, the sample also included subjects of varying body size and physical activity status. The failure to control for such

variances precluded the researchers from confidently concluding that there were age-association changes in inflammatory status.

Changes in circulating inflammatory marker levels have also been examined in large population based studies (8,44,115). In the Framingham Heart study, 711 elderly individuals did show higher production of IL-6 and IL-1 receptor antagonists as compared to a younger control group. However, no differences in circulating TNF-α and IL-1β were found between the two age groups. Unfortunately, the control group only had 21 subjects, which could have biased the conclusions. Another study examined subjects enrolled in the SENIEUR protocol, which attempted to separate the influence of morbidity and frailty from the physiologic process of aging (44). A secondary analysis found that adults from 69 to 80 years of age had higher plasma levels of TNF and IL-6 compared to young controls (22).

The studies showing a positive relation between age and inflammation support the notion that low-grade inflammatory activity in older individuals is independent of co-existing medical disorders. However, we have yet to clearly define the existence of a primary, age-associated dysregulation of inflammatory cytokine production. The findings from some of these studies could have been explained by residual confounding factors due to the high prevalence of inflammatory, non-cardiovascular conditions in the older populations. Furthermore, there may be age-cohort effects on the levels of inflammatory markers that could not be detected in these cross-sectional studies. Future research focusing on the changes

in inflammation occurring with advancing age is necessary to better define this relation.

Inflammation and Obesity

Obesity has long been associated with an increased risk of developing numerous diseases, such as hypertension, dyslipidemia, diabetes, and atherosclerosis (60,145). Several recent studies have also shown an associated between obesity and generalized, low-grade inflammation (29,86). More recently, research shows that adipocytes can produce CRP, TNF-α and IL-6, which explains the association between obesity and inflammatory activity (34,68,132). A previous report claims that 25 to 30% of circulating IL-6 may be derived from fat (87). Thus, the age-associated increase in body fat, especially abdominal adiposity, (55,98) may be an important source for increased circulating levels of inflammatory markers in the older populations (63). The remainder of this section will highlight several studies addressing the link between obesity and inflammation.

The primary basis of the suggested causal role obesity has on inflammation is supported by many studies showing an increase in circulating inflammatory markers in obesity (39,49,132,150). For example, Yudkin et al. (1999) found a close relationship of circulating CRP, TNF-α, and IL-6 concentrations with anthropometric measures of obesity in healthy subjects (150). However, participants were not excluded for smoking, hypertension, or hyperlipidemia, and the sample consisted largely of overweight individuals. Specifically, this study compared measures of

body composition to levels of CRP, TNF-α, and IL-6 in 107 individuals from 40 to 75 years of age. The initial analysis showed that all markers of inflammation were significantly related to BMI and waist-to-hip ratio. When divided into groups of "low CRP" (<1.35 μg/mL) and "high CRP" (≥ 1.35 μg/mL), the high CRP group unsurprisingly presented significantly higher values of BMI and waist-to-hip ratio. This provided an important early observation to stimulate further investigation into the link between adiposity and inflammation.

In another study, markers of inflammation were compared in an obese group of pre-menopausal women (n = 56) and a group of age-matched, normal weight controls (n = 40) (151). In the initial baseline assessments, all subjects were sedentary with no history of participating in weight-loss related diet programs in the previous six months. The obese group demonstrated significantly higher levels of TNF-α, IL-6, and adhesion molecules (ICAM-1 and VCAM-1). Additionally, the concentrations of TNF-α and IL-6 significantly correlated to anthropometric measures of "visceral" obesity, represented by waist-to-hip ratio measures ($r = 0.55$ and $r = 0.45$, respectively). After a baseline visit, the entire obese group participated in a 12 month multidisciplinary program of weight reduction, which included diet, exercise, and behavioral counseling. All of the women lost at least 10% of their original weight (9.8 ± 1.5 Kg) and, in turn, reduced the circulating blood levels of TNF-α and IL-6 ($p < 0.01$) from baseline to post-intervention. Regardless of a causal origin, this study clearly shows that obesity is related to increases in level of markers of inflammation. While it is also possible that an improved diet regimen or exercise

could be, at least partially, responsible for the results of this study, there is a strong suggestion that weight loss could be a safe method of reducing inflammatory activity.

Piche et al. (2005) studied the association of obesity and fat distribution on inflammation in a group of 112 post-menopausal women (100). This sample was "healthy," defined as not being clinically treated for heart disease, diabetes, endocrine disorders, or additional cardiovascular risk factors. However, the sample still included (and statistically adjusted for) individuals that had a history of smoking, hypertension, and dyslipidemia. CRP concentrations were significantly correlated with BMI ($r = 0.60$) and waist circumference ($r = 0.61$). Additionally, IL-6 levels were related to BMI ($r = 0.49$) and waist circumference ($r = 0.56$), while TNF-α levels were not. A more in-depth examination of visceral adiposity, using computed tomography, showed that visceral adiposity was also correlated with CRP ($r = 0.55$) and IL-6 ($r = 0.49$). As a side note, the total sample was separated into three groups: "low CRP concentration" (< 1.0 mg/L), "normal CRP concentration" (1.0 – 3.0 mg/L), and "high CRP concentration" (>3.0 mg/L). There were no group differences in age ($p > 0.05$), but all of the body composition measures were significantly different among the groups of differing CRP concentrations. Once again, this study found elevated levels of inflammatory activity in those who were obese, while also establishing the importance of the site of fat distribution (i.e., visceral adiposity) on mediating inflammation.

Another study examined BMI, waist circumference and CRP concentrations in a population of persons older than 65 years of age (n = 1,270) (121). As expected in a sample of older people this size, there were a number of individuals who presented with clinical conditions including heart disease, chronic heart failure, history of stroke, and diabetes. In general, the individuals presenting with global obesity (defined as a BMI $\geq$ 30.0 kg/m^2) demonstrated higher levels of CRP concentrations than the non-obese individuals. The subjects considered to have central obesity, defined as being in the upper sex-specific tertile of waist circumference (121), had an even higher concentration of CRP than subjects classified as non-obese or obese without central distribution of fat. The group of subjects presenting with global and central obesity yielded the highest CRP concentrations, suggesting an additive affect of the two conditions on inflammation.

In further examination, Schrager et al. (2007) found that individuals with global obesity had higher concentrations of TNF-α than those with central adiposity (121). The highest concentrations of TNF- α were found, however, in the group presenting with both, global and central obesity. In contrast, IL-6 concentrations were highest in the central obesity group, while those with the lowest concentrations of IL-6 were in the global obesity group. The presence of global and central obesity did, however, appear to have an additive affect on cytokine concentration that was similar to that shown with CRP. Even with the slight conflict in results between inflammation and fat distribution, this study continues to claim that overall obesity is related to inflammation.

Overall, the studies showing a link between obesity and inflammation are consistent, regardless of other potentially confounding clinical conditions. With further evidence that adipose tissue secretes several inflammatory proteins activity (34,68), it is probable that excessive amounts of fat are a major source of inflammation in many populations (132). This body of research suggests that the changes in body composition that normally occur with age (i.e., decreased skeletal muscle mass and increased total body fat) (55,98) could explain some of the aforementioned associations between age and inflammation. In any case, the inflammatory response stemming from increasing whole body and, even more specific, abdominal adiposity has justified the classification of obesity as an independent risk factor of cardiovascular disease.

Inflammation and Physical Activity

Increasing physical activity level is accepted as a means to decrease risk of many health problems, especially cardiovascular disease (72,140). Additionally, it is well documented that increasing amounts of physical activity can result in a decrease in the amount of adipose tissue (55,98). Because of the common connection between physical inactivity and inflammation as risk factors for cardiovascular disease, it is a logical next step for research to examine the influence of physical activity level on inflammatory activity.

Generally, studies show that more frequent bouts of activity lower blood levels of inflammatory and fibrinolytic markers (96,135). For instance, one study

showed that individuals with higher levels of interview based, self-reported physical activity had lower concentrations of CRP and IL-6 (109). Specifically, this study examined community-dwelling subjects enrolled in the MacArthur study. When the group was divided into tertiles by amounts of activity, the most active tertile had concentrations of CRP and IL-6 that were about 30% lower than the other two-thirds of the sample. Furthermore, individuals incorporating higher amounts of house or yard work activities had an additional protective effect beyond that of recreational activity on CRP levels, but not IL-6 levels. These findings are greater than a previous report of the group in the top quartile of physical activity the Cardiovascular Health Study, a large population based study, presented with up to 19% lower concentrations of CRP (57).

Another cross-sectional study examined the association between physical activity and markers of inflammation in a cohort of the Health, Aging and Body Composition Study (n = 3,075) (30). Again, the sample was split into three groups based upon amounts of activity: No Activity (0 minutes of exercise per week), Low Activity (between 0 and 180 minutes of exercise per week), and High Activity (≥ 180 minutes of exercise per week). The concentrations of CRP, IL-6 and TNF-α were the lowest in the high activity group. It should be noted that BMI and the prevalence of hypertension, cerebrovascular disease, peripheral vascular disease, respiratory disease and diabetes mellitus were also significantly lower in this sample. Significance in inflammatory marker concentration remained after adjusting for all clinical conditions, but the concentrations of CRP and TNF-α were no longer

significantly different between activity groups after adjusting for body composition measures. Although there may be an additive affect, these data suggest that body composition may have a greater influence on inflammatory status than physical activity.

In an examination between leisure time physical activity and markers of chronic inflammation, Verdaet et al. (2004) found conflicting results with the previously discussed studies (138). This cross-sectional study found that CRP levels were not associated with leisure time physical activity in a cohort of the BELSTRESS study. It should be noted that any affect of activity might have been lost due to the fact that the sample included many subjects that smoked, were diabetic, or had other co-existing conditions. Leisure time activity was, however, negatively associated with BMI, waist to hip ratio, and the lipid profile. This suggests that these conditions may have more of an influence on inflammatory activity than the level of leisure time activity. This study also suggests that the intensity of the activity (or exercise) may have a determining role on inflammation.

A study by Pischon et al. in 2003 shed light on this particular question. A group of 859 people was separated into five groups depending on activity status (102). This study extends previous findings that CRP and other markers of inflammation are lower in men and women that are more active. As expected, the groups with higher activity (in both men and women) showed an inverse relation between CRP, IL-6, and TNF-α. Specific to CRP, the blood concentrations linearly declined through each quintile of activity level, which may suggest a dose response

exists on the protective effect of activity on inflammation. Furthermore, the groups of greater activity also demonstrated lower BMIs and a lower prevalence of smoking. Adjusting for these factors weakened the association between activity levels and inflammation. Again, this implies that the beneficial association between physical activity and inflammation is partially due to less body fat in subjects with higher levels of physical activity.

Overall, there is a general notion that physical activity and exercise is inversely related to chronic levels of inflammatory markers (30,57,102,105). There is a re-occurring observation among all of these studies that allege the link between physical activity and inflammation may be mediated by the paralleling changes in body composition. Regardless, these preliminary claims further evidence that increasing physical activity can decrease cardiovascular disease risk. Continued research in this area, which is gaining in popularity, will provide the necessary clarity to define the relation between physical activity and inflammation.

Inflammation and other clinical conditions

Numerous clinical conditions (or co-morbidities) are showing an instigative role for inflammation. While it is traditional and logical to associate inflammation with acute infections, many investigators are linking low-grade inflammation with an increased prevalence of chronic, asymptomatic infections (22,107). Interestingly, aging is associated with an increased prevalence of many of the same types of infections, such as dental infections (85), urinary tract infections (2), and bacterial

infections (59,85). This is a growing concern because bacterial infections can spread from the respiratory tract throughout the body via circulating monocytes (113) and, in turn, induce systemic immune responses by stimulating inflammatory cytokine production (i.e., TNF-α, IL-1β, and IL-6) (108,113).

Similarly, a rise in inflammatory markers or fibrinolytic activity can be caused by other existing clinical conditions or diseases. Diabetes (37,90) and components of metabolic syndrome (4,28) are shown to elevate inflammatory activity. Additionally, individuals presenting with known cardiovascular disease (22), especially atherosclerosis (97), and pulmonary disease (123) consistently have higher levels of inflammatory markers than those who are disease free.

Hypertension, which has a higher prevalence in older adults, also has been linked to chronic, low-grade inflammation (22). Typically, isolated hypertension is defined as a systolic blood pressure ≥ 140 mmHg and a diastolic blood pressure ≥ 90 mmHg (6^{th} Report). Yudkin et al. (1999) and Piche, et al. (2005) both found systolic and diastolic blood pressure levels were significantly related to markers of inflammation (CRP, IL-6, TNF-α) (100,150). Piche also found that individuals in the top two tertiles of CRP concentrations had significantly higher systolic and diastolic pressures (100). While these associations are becoming more popular, it is unclear if increased inflammatory activity is a product of sustained high blood pressure, or if it instigates hypertension. Evidence that angiotension II, a potent vasoconstrictor, causes monocytes activation would support the idea of an inflammatory response to elevated blood pressure (99,120).

Another common clinical condition that is associated with higher levels of circulating inflammatory markers is hyperlipidemia (27,51). In a study by Piche et al. (2005), triglycerides levels were positively related ($p < 0.05$) to levels of CRP ($r = 0.33$) and IL-6 ($r = 0.32$) (100). As expected, HDL levels were inversely related to the same markers of inflammation, demonstrating that higher HDL levels are associated with decreased inflammatory activity (100). These findings parallel previous cross-sectional observations linking lipid profiles to inflammation (84,111,150).

Furthermore, lifestyle characteristics, such as cigarette smoking and alcohol intake (139), have been linked to inflammation (27). In an early study, smokers had higher circulating levels of IL-6 compared to their non-smoking counterparts (122) Another adjusted analysis showed that CRP and IL-6 (as well as levels of adhesion molecules) were independently related to smoking status, which would suggest that smoking lead to increases in inflammatory activity (13).

There are a couple of additional biological factors that are speculated to influence inflammatory activity in humans. For instance, in 1996, Ballou et al. found that black people had slightly higher CRP levels than whites (7.0 vs. 3.0 μg/ml, $p = 0.019$) (9). More so, Native Americans have been shown to have higher levels of inflammatory markers than other ethnic groups (84,92). However, these investigations also note that there is a high prevalence of diabetes and metabolic syndrome, which could have additive effects on CRP levels. The genetic role of regulating inflammation has recently gained attention in research. Previous studies

have failed to directly link polymorphisms to inflammatory activity (35,142). There are known gene polymorphisms, however, that are related to several diseases, including insulin resistance, Alzheimer's disease, and arthritis, which could assuredly increase inflammatory activity (22,31,33).

The chronic inflammation resulting from these conditions can explain a mechanistic link between the traditional risk factors and atherosclerotic development. Furthermore, the associations between clinical conditions and inflammatory, while significant, may only explain a small part of the low-grade inflammatory activity (22,23). Regardless, excluding subjects presenting with these characteristics can remove any confounding influence on inflammation in future research studies.

Fibrinolysis

Fibrinolysis is a cascade of enzymatic reactions, bringing together plasminogen and its activators (tissue plasminogen activator, and is designed to breakdown fibrin clot formation (45,150). Specifically, tissue plasminogen activator (t-PA) has a major role in activating the fibrinolytic system and initiating the release of plasmin, the protein responsible for lysing fibrin clots (135). The essential balance in plasma is largely between t-PA and the inhibitor, plasminogen activator inhibitor - 1 (PAI-1) (88). PAI-1 is the most important inhibitor of plasma fibrinolysis (126). An increase of plasma t-PA and PAI-1 are both indicative of an increase in fibrinolytic activity (126,135) and can result in a pro-thrombotic state. When PAI-1

concentrations reach a level four or five times greater than the activators, haemostatic conditions favor fibrin clot formation (i.e., hypofibrinolysis) (88).

Fibrinogen, another acute-phase protein, is often considered as a marker of inflammation (11). However, fibrinogen is more of a determinant of blood viscosity, an important factor in blood clot formation (41,42). In addition to serum concentrations of CRP, fibrinogen is not only associated with the risk of developing cardiovascular disease, but is also indicative of the severity of existing disease (107,111). Therefore, fibrinogen is perceived as another independent marker of cardiovascular disease risk as well as a prognostic indicator (11).

Clot formation is an essential protector from bleeding, but persistent conditions can ultimately lead to thrombosis. The fibrinolytic system is our body's natural defense against thrombosis. Thrombosis exacerbates the risk of a catastrophic acute coronary episode in the presence atherosclerotic plaques, especially if the plaques rupture. The increase in fibrinolytic activity is capable of independently predicting catastrophic cardiovascular disease related events (52). Thus, t-PA and PAI-1 are recently being considered additional, independent risk markers of cardiovascular disease.

The role of fibrinolysis in the early development of atherosclerosis is a rather new idea. It is suggested that excessive amounts or fragments of fibrin can be deposited in the vessel wall, contributing to the progression of atherosclerotic lesions. Specifically, recent clinical evidence suggests that low fibrinolytic activity is a determinant of major CHD events in young and middle-aged men (82).

Furthermore, high PAI-1 activity combined with a low plasminogen activator capacity were risk factors for re-infarction in young, male survivors of myocardial infarction (62). Another study, also carried out in persons with severe CHD, found that tissue plasminogen activator antigen, but not plasminogen activator inhibitor activity, was predictive of total mortality during a 7 year follow-up. Thus, there is still a need for clarification of the determinants of coagulation and fibrinolytic activity.

Fibrinolysis and Aging

Age-related changes in coagulation and fibrinolytic factors are speculated to be contributors to the increase in risk of thrombotic events in older adults (61,67). Increases in fibrinogen and other coagulation factors, without a proportional increase in anticoagulant factors, likely contribute to this risk (61). Over the past couple of decades, a positive correlation between age and the occurrence of thrombosis has been presented (36,148). Hashimoto et al. presented some of the first evidence of a relationship between age and fibrinolytic activities; namely levels of tissue plasminogen activator (t-PA) antigen, plasminogen activator inhibitor (PA inhibitor) activity, and plasminogen activator activity (PA activity). A dramatic increase in both t-PA antigen and the plaminogen activator inhibitors was shown in persons with increasing age, while t-PA activity decreased with age.

DeSouza et al. (1998) also examined the age differences in coagulations and fibrinolytic factors in pre- and post-menopausal women, as well as identifying the

impact of habitual exercise on these hemostatic factors in the two age groups (36). To do so, they set up four groups: (1) pre-menopausal sedentary, (2) pre-menopausal active, (3) post-menopausal sedentary, and (4) post-menopausal active. They measured resting levels of plasma fibrinogen, tissue-type plasminogen activator (t-PA) antigen and activity, and plasminogen activator inhibitor-1 (PAI-1) activity as indicators of coagulation and fibrinolytic factors. The post-menopausal had significantly higher ($p < 0.05$) levels of fibrinogen, t-PA antigen, and PAI-1 lower t-PA activity than the pre-menopausal women, indicating that fibrinolysis is impaired with age. Furthermore, the active post-menopausal women demonstrated lower ($p < 0.01$) plasma fibrinogen, t-PA antigen, and PAI-1 activity and higher ($p < 0.01$) t-PA activity levels than the sedentary post-menopausal women (36). Even more importantly, the fibrinolytic profile of Post-PA did not differ from that of the active premenopausal women. This suggests that the adverse age-associated differences, however great they may be, in plasma fibrinogen concentrations and the endogenous fibrinolytic system in sedentary healthy women are either attenuated or absent in highly physically active women.

Changes in the endothelium, including early development of atherosclerotic plaques, have been proposed as potential contributors to the increase in thrombotic cardiovascular disease found in the elderly (148). The capacity of the vascular endothelium locally to release t-PA is critical for effective endogenous fibrinolysis. Using both cross-sectional and intervention approaches, Smith et al determined the influence of ageing and regular aerobic exercise on the net release of t-PA across the

human forearm in vivo (127). They studied the endothelial release rates of t-PA in 62 healthy men aged 22-35 or 50-75 years of age who were either sedentary or endurance exercise-trained. Similar to DeSouza's findings (36), net endothelial t-PA release was significantly blunted (approximately 35% less, $p < 0.05$) with age in the sedentary men, while no age-related declines in net release of t-PA antigen were found in the endurance-trained men. Again, these results illustrate that endothelial t-PA release declines with age in sedentary men, but the decline could be prevented, or even reversed with regular aerobic exercise. Perhaps the tendency of decreased PA activity with increasing age may be related to the high incidence of thrombosis in older persons. The influence of physical activity and exercise on fibrinolysis will be later discussed in this chapter.

In 2005, Yamamoto et al. examined if gene expression of PAI-1, as the principal inhibitor of fibrinolysis, varied across increasing age (148). The expression of PAI-1 is not only elevated in the elderly but also significantly induced in a variety of pathologies associated with the process of aging, such as obesity, insulin resistance, and vascular sclerosis. Furthermore, the gene expression of PAI-1 was found to be positively regulated by several cytokines and hormones. These included tumor necrosis factor-alpha, a marker of systemic inflammation, and angiotensin II, a mediator of vasoconstriction. This raises suspicion that impaired fibrinolysis may result from an inflammatory interaction (148). Additionally, it could explain the heightened risk for thrombotic cardiovascular disease in obesity with aging, as adipose is a known source of inflammatory cytokines. None the less, future studies

on the genetic regulators of aging-associated PAI-1 induction will be necessary to define the basis for cardiovascular aging in relation to thrombosis.

Overall, these studies show that increasing age is consistently associated with a decrease in fibrinolytic activity (36,61,148). While this could be a primary affect of aging, the data showing that increasing physical activity levels negate this affect and introduce new factors that dilute the clarity of this relation (36,127). Is this an age effect? Or is this more of a result of age-related declines in physical activity patterns? Other conditions that can affect fibrinolysis, and coincidentally change with age, will be discussed in the following sections. But regardless of why or how, further studies will be warranted to define the mechanisms for thrombosis in the elderly as the population ages.

Fibrinolysis and Obesity

Obesity has repeatedly been shown to be associated with PAI-1, the major fibrinolysis inhibitor (78,81,134). PAI-1 is directly correlated with BMI (133) and waist-to-hip ratios, indicating an influence from abdominal fat (134). More specifically, adipocytes have recently been shown to produce and mediators of fibrinolysis (126), which explains the link between high levels of fibrinolytic markers with excessive adiposity (i.e., high percent body fat) (34).

In a two-part study, a group of investigators examined a group of 66 sedentary adults, which included 28 normal-weight, 22 overweight, and 16 obese adults (136). In the first, cross-sectional observation, the amount of t-PA antigen

released from endothelial was significantly lower ($p < 0.05$) in the overweight and obese adults, compared to their normal weight peers. In a bivariate analysis, the total amount of t-PA antigen release was inversely related ($p < 0.05$) to body mass ($r = -0.47$), percent fat ($r = -0.29$), BMI ($r = -0.36$), and waist circumference ($r = -0.28$). The impaired endothelial t-PA release found in overweight individuals further support the notion that impaired fibrinolysis is a consequence of obesity, with specific emphasis on abdominal adiposity.

Mavri et al. (1999) enrolled 52 obese, pre-menopausal women in a 10-12 week body weight reductions program, with 19 age-matched lean women as a control group (78). PAI-1 concentrations were measured at the time of entry, one week after the start of the program, at time of program completion, and five months after program completion. At the start of the program, PAI-1 activity concentrations were positively correlated with BMI ($r = 0.35$), waist-to-hip ratio ($r = 0.30$), and an equation derived percent body fat ($r = 0.43$). At the end of the program, women reduced their body weight by 17% and their percent body fat by 13%, while PAI-1 activity had decreased by 74%. However, five months after program ended, 16 women regained over 25% of their original body weight. As a result, PAI-1 activity levels significantly increased, paralleling the increase in BMI. Thus, this study suggests that the elevated PAI-1 levels seen in obesity are closely linked to the amount of adipose tissue stored (78).

For three months, 55 subjects participated in a weight loss program using meal replacements or a structured eating plan (29). At the end of the study, mean

weight loss was 6.3 ± 3.7 kg with no differences between diet groups. As a whole, PAI-1 concentration significantly decreased from baseline to after weight loss (70.84 ± 30.91 ng/ml vs. 55.55 ± 31.64 ng/ml, respectively, $p < 0.001$). Furthermore, t-PA levels dropped by 7% ($p < 0.05$) from baseline. As a side note, individuals presenting with CRP concentrations higher than 10 mg/L at baseline showed significant reductions after the three month diet intervention (3.65 ± 2.15 mg /L vs. 3.01 ± 2.19 mg/L, $p < 0.01$). This supports the previous findings showing that weight loss intervention leads to a reduction in fibrinolytic activity (78).

Bouchard et al examined if there were polymorphism variations the PAI-1 gene related to body fat and abdominal fat mass (20). In women, BMI and body fat mass was associated with the PAI-1-675 4G/5G, while abdominal visceral fat mass was related to the same polymorphism and the c43G>A variant within the exon 1. Furthermore, carriers of the -675 5G and the 43A allele had nearly 50% more visceral fat (assessed by computed tomography) compared to the -675 4G allele. None of these associations were found in the men. These findings support previous claims that PAI-1 polymorphisms may be associated with BMI (65). However, this is the first study to observe an association between the PAI-1-675 polymorphisms and measures of whole body and abdominal fat mass. This implies that the association between PAI-1 activity and fat distribution may be influenced by more than lifestyle characteristics, particularly in women.

There is overwhelming evidence showing that obesity is associated with impaired fibrinolysis (78,81,134). With specific emphasis on abdominal adiposity,

these studies provide a mechanism that bridges obesity with cardiovascular disease (136). As previously mentioned, the changes in body composition occurring with age (i.e., decreased skeletal muscle mass and increased total body fat) (55,98) could possibly explain prior observations of a relation between age and fibrinolysis. At any rate, the rationale for classifying obesity as an independent risk factor for cardiovascular disease continues to grow with this evidence that decrease in fibrinolytic activity decreases with increasing whole body and, even more specific, abdominal adiposity.

Fibrinolysis and Physical Activity

Over the last few decades, it has become quite clear that regular aerobic exercise is associated with a reduction in cardiovascular events in overweight and obese adults, independent of weight changes (14,136). As a contributing mechanism, the affects of physical conditioning on fibrinolysis were examined more closely (7,32,47). By comparing 60 healthy men in three physical fitness categories (sedentary, joggers, and marathoners), Ferguson et al. discovered that fibrinolytic activity increased with exercise early on (47). More recently, physical activity is consistently understood to be inversely correlated with blood levels of fibrinolytic markers (96,135), a suggested protective mechanism of physical activity against cardiovascular disease. The general notion is that more frequent bouts of activity can lower blood levels of fibrinolytic activity.

Acute fibrinolytic responses to exercise are also being examined and are of high clinical relevance, as numerous catastrophic events occur from an occlusive thrombus (58). With previous evidence of an increased potential for blood coagulation during physical exertion (7,32), there is an urgency to learn if a body can counter by increasing fibrinolytic activity (144,145). Womack et al. examined the acute changes in fibrinolytic activity occurring with exercise (146). Specifically, 15 healthy males performed three different cycle ergometer tests: (1) a VO_{2max} and lactate threshold test, (2) a one hour exercise session over lactate threshold, and (3) a one hour exercise session below lactate threshold. t-PA activity was significantly higher immediately following the exercise above lactate threshold, but not in the exercise below the lactate threshold. The concentrations of t-PA antigens were significantly higher immediately following both exercise conditions, but were still significantly higher in the exercise session above lactate threshold. PAI-1 activity significantly decreased during both exercise conditions; however, the decrease occurring in the exercise below lactate threshold only occurred when post-exercise values were corrected for plasma volume changes. All marker concentrations, except t-PA antigen levels in the above lactate threshold exercise, returned to baseline within the one hour post measurement. Overall, this study demonstrates that intensity is a more important determinant on acute fibrinolytic responses to exercise, showing that exercising below the lactate threshold elevates t-PA antigen levels but not t-PA activity (146). Thus, a higher intensity exercise can heighten fibrinolytic activity.

In a previously discussed study, Van Guilder et al. enrolled 17 overweight or obese individuals (11 males, 6 females) of the total 66 initially examined subjects in a three month, home based aerobic exercise training program (136). During their participation, subjects were asked to exercise 5-7 days per week, 40-50 minutes a day, at 60-75% of their maximum heart rate. After the training program was completed, there were no changes observed in basal release rates of t-PA or PAI-1 antigens. However, t-PA release rates were markedly increased after bradykinin infusions, increasing net t-PA antigen amount by nearly 55%. This evidences that there is, indeed, an improved capacity of the endothelium to release t-PA in overweight and obese adults. Because these changes occurred without a paralleled shift in body size or composition, there is a much stronger notion that aerobic activity may have a primary modulatory effect on endothelial fibrinolytic regulation (136).

Another report showed that leisure-time physical activity was not an independent predictor of fibrinogen (138). In a sample of 892 male subjects, leisure-time physical activity (LTPA) was related to a number of cardiovascular risk factors, such as BMI ($p = 0.01$), waist to hip ratio ($p < 0.001$), and HDL levels ($p = 0.003$). Unadjusted means across the four categories of LTPA ("No LTPA," "Low LTPA," "Moderate LTPA," and "High LTPA") showed a significant inverse relationship with CRP ($p = 0.02$) and fibrinogen ($p = 0.02$). However, in a multivariate analysis adjusting for BMI, smoking status, presence of diabetes, and alcohol consumption, these relationships were no longer significant ($p > 0.05$). This indicates that there is

no independent association between LTPA and markers of inflammation or fibrinolysis and further strengthens the previously discussed claims that intensity has a greater influence than duration (146).

Exercise interventions have also been shown to have beneficial effects in clinical populations, especially those with cardiovascular disease (91,100). Killewich et al. (2004), studied 21 patients with peripheral arterial disease (PAD) (70). After completing a six month training program of treadmill exercise three times a week, fibrinolytic activity significantly improved, expressed as a 23% reduction in PAI-1 activity and a 28% increase in t-PA activity. No changes were noted in a control group of 20 age-matched men presenting with claudication. Additionally, it was noted that the greatest improvements in fibrinolytic activity occurred in individuals with the lower amounts of fibrinolysis (i.e., highest levels of PAI-1 activity). This adds to the growing body of literature evidencing a beneficial effect of exercise on fibrinolysis. Combined with the other studies of similar outcomes, these data suggest that serious consideration should be given to exercise interventions as a treatment option in cardiovascular patients.

In 2002, Wannamethee et al. examined the relations between physical activity and hemostatic variables in a large population based study (140). In 3810 adult men, physical activity showed a significant inverse dose response relationship with many hemostatic variables, including fibrinogen, t-PA antigen, and CRP. In this case, physical activity was collected by interview with a score assigned and used to categorize partcipants into one of six groups: (1) “No activity,” (2) “Occasional

Activity," (3) "Light Activity," (4) "Moderate Activity," (5) "Moderate to Vigorous Activity," and (6) "Vigorous Activity." As expected, the diseased men presented consistently higher values of these blood markers in every activity group, but the inverse relationships were similar between men with and without cardiovascular disease. This supports the notion that the benefit of physical activity on cardiovascular disease may be, at least partly, due to the positive effect on fibrinolysis (140).

In the past twenty years, research has illustrated the positive influence of regular aerobic exercise in fibrinolysis (14,37,136). Although more research can more clearly define a dose-response effect of exercise, the benefits on cardiovascular disease may be, at least partly, due to the positive effect on fibrinolysis (140). Moreover, the tendency of decreased PA activity with increasing age may be related to the high incidence of thrombosis in older persons.

Fibrinolysis and other clinical conditions

There is a well defined association between fibrinolysis and known diseases, such as cardiovascular disease (75), diabetes (37), and components of metabolic syndrome (4,28,140). Early development of atherosclerotic plaques has also been shown to impair fibrinolytic activity (119). In 1995, a cross-sectional case-control study with 457 pairs of subjects found that t-PA and PAI-1 were higher ($p \leq 0.001$) in patients above the 90^{th} percentile of intima-media thickness of carotid arteries compared to those having a thickness below the 75^{th} percentile of the Atherosclerotic

Risk in Communities (ARIC) Study (119). These findings led to the notion that thrombosis and fibrinolysis may play a role at the early stage of the atherosclerotic process.

Hypertension is an established risk factor for acute coronary events that is also being associated with impaired fibrinolysis (25,53,103,128). In a cross-sectional investigation, the relations of systolic and diastolic blood pressures (SBP and DBP) to levels of plasminogen activator inhibitor antigen, tissue plasminogen activator antigen, fibrinogen, were examined in 1193 men and 1459 women of the Framingham Offspring Study (103). In both sexes, levels of plasminogen activator inhibitor and tissue plasminogen activator antigen were positively related to systolic and diastolic blood pressures, even after adjusting for age, body mass index, smoking, diabetes, total cholesterol, HDL, triglycerides, alcohol intake, and estrogen use in women ($p < 0.001$). However, there was no association between systolic and diastolic blood pressure in either sex. These data provides another potential mechanism by which hypertension contributes to the pathogenesis of cardiovascular disease in hypertensive patients.

The negative influences of hypertension on fibrinolysis have been alleviated by exercise (36). Specifically, hypertensive subjects had a 172% increase in t-PA activity and a 25% decrease in PAI-1 activity after an acute bout of exercise (36). There are pharmacological treatments of hypertension that have an interfering role on fibrinolysis as well (103). As it is known that angiotension II increases PAI-1

activity (89,148), angiotension converting enzyme (ACE) inhibitors decrease PAI-1 levels and increase t-PA levels (103).

Numerous reports have also shown a link between impaired fibrinolysis and high cholesterol levels, another established risk factor of cardiovascular disease (93,105,106). Puccetti et al. compared individuals with hypercholesterolemia, hypertriglyceridemia and low HDL cholesterol levels in 75 males and females (105). Hypertriglyceridemia patients were found to have higher PAI-1 serum levels compared to hypercholesterolemia and control subjects ($p < 0.001$). Impaired fibrinolysis in subjects with hypertriglyceridemia or low HDL-cholesterol is associated with increased serum levels of PAI-1 whereas enhanced thrombin generation was the main finding in hypercholesterolemia. Such data may suggest the opportunity of evaluating several fibrinolytic factors when studied as prognostic factors in varying lipid profiles. Furthermore, Orem et al. showed that, after successful lipid lowering therapy, statin use improved global fibrinolytic capacity ($p = 0.003$), increased tissue plasminogen activator levels ($p = 0.04$) and decreased plasminogen activator inhibitor type-1 levels ($p = 0.02$) in dyslipidemia patients (93). Thus, pharmacological treatment may negate the negative effect of hypercholesterolemia on the fibrinolytic system.

The association between fibrinolysis and cigarette smoking, an established risk factor for cardiovascular disease, is less apparent than the relation between smoking and inflammation (35,38). One study showed that non-smokers had significantly higher ($p < 0.03$) levels of t-PA activity than current or former smokers

(91). Another study showed that there were no differences in fibrinogen levels between smokers and non-smoker (35). In contrast, a third investigation found that smokers had fibrinogen levels 0.34 g/L higher than non-smokers, showing a correlation between number of cigarettes smoked and plasma fibrinogen levels ($r = 0.21$, $P = 0.006$) (38). Collectively, these studies fail to clarify the association, if any, between fibrinolysis and smoking.

Another lifestyle factor that can influence fibrinolysis is alcohol consumption, showing that regular moderate alcohol intake can reduce coagulation and increase fibrinolysis (118,139). More specifically, Salem et al. found that individuals drinking 240 mL of red wine a day, showed increased levels of t-PA antigen and PAI-1 antigen, and lower levels of fibrinogen (118). The greatest benefit of alcohol consumption on fibrinolysis occurred in people following a low fat diet. Those ingesting diets of high fat content did not have improved fibrinolytic activity. Perhaps, this is another mechanism bridging a high fat diet to cardiovascular disease.

Impairments in fibrinolysis resulting from these clinical conditions present another potential mechanism that links traditional risk factors to the development of cardiovascular disease. Such claims support the notion that thrombosis and fibrinolysis may contribute to atherosclerotic development. However, traditional treatments (i.e., pharmaceutical or physical activity interventions) for these conditions do show a beneficial affect on fibrinolytic activity (36,93,103).

Summary

Chronic-low grade inflammation is becoming a well-recognized component of vascular disease pathology, as it instigates the breakdown of the inner walls of blood vessels (43,114,130). Components of the fibrinolytic system, more commonly associated with the coagulation process, are suggested to not only exacerbate existing vessel disease, but also to facilitate atherosclerotic development (45,131). As discussed throughout this chapter, much attention has been placed on identifying factors that affect inflammation or fibrinolytic activity.

In the past several years, the age-related changes occurring with these two conditions have been suspected to bridge aging and the increased prevalence of cardiovascular disease. However, paralleling changes in physical and clinical characteristics that occur with age (e.g., decreased physical activity levels, increased body fat, and an increased prevalence of other clinical conditions) make examining age-related changes in inflammation and fibrinolysis difficult. In fact, the failure to exclude, or at least statistically adjust for, these confounding conditions dilute the previous claims regarding the association between advancing age and hemostatic changes. Thus, we have yet to clearly define the existence of a primary, age-associated dysregulation of inflammatory cytokine production and thrombolytic degradation systems. Maybe there is no sole connection between these instigators of vascular disease and the unavoidable aging process. In order to clarify this relationship, it is crucial that such factors are considered when examining the age-related changes in inflammation and fibrinolysis.

CHAPTER THREE

METHODOLOGY

The primary aim of this study was to examine the independent relationship between age and blood levels of inflammatory and fibrinolytic markers. To isolate this relationship, the relationship between additional confounding factors (i.e., body composition and physical activity levels) and the concentrations of inflammatory and fibrinolytic markers were examined. The specific procedures and methods of this study to evidence these relationships are described in detail throughout this chapter.

Study Population

Males and females of any race between 18 and 90 years of age were recruited for this examination. The ultimate goal for recruitment into the study was set at 80 subjects with equal division among males and females. Recruitment of women and minorities into this protocol were a high priority to assess inflammatory markers, physical activity, and body composition among various demographic groups. This study was conducted on an outpatient basis, in the General Clinical Research Center (GCRC) on the University of Oklahoma Health Sciences Center (OUHSC) campus. The protocol was approved by the

GCRC Advisory Committee (Protocol #0103) (Appendix C) and the OUHSC Institutional Review Board (#11841) (Appendix D), and was supported by the OUHSC GCRC grant (M01-RR-14467) sponsored by the National Center for Research Resources from the National Institutes of Health.

To participate in this study, the inclusion criteria states that an individual must be between 18 and 90 years of age, ambulatory, and living independently at home. Subjects were excluded from the study if they presented with any of the following criteria:

1. Unable to perform physical activity: Non-ambulatory or other neuro-musculoskeletal limitations.
2. Non-independent living as determined by Impairments in Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADL)
3. History of atherosclerotic cardiovascular diseases (ACVD):
    a. Coronary artery disease (CAD): Angina pectoris, current or history of unstable angina, history of myocardial infarction, history of coronary angioplasty or stents, history of coronary artery bypass graft, acute coronary syndrome
    b. Peripheral arterial disease (PAD): Ankle-brachial index (ABI) = 0.9 or less, history of intermittent claudication, history of aorto-femoral or any other lower extremity bypass surgery for occlusive PAD, history of ischemic gangrene or amputation,

c. History of aortic aneurysm (thoracic or abdominal)
d. History of cerebral vascular disease: History of carotid stent, carotid endarterectomy, stroke or transient ischemic attack (TIA)
e. History of atherosclerotic renal artery disease
f. History of congestive heart failure (CHF)

4. Atherosclerotic cardiovascular risk factors (ACVRF):
    a. Having metabolic syndrome, defined as three or more of the following:
        i. Abdominal obesity: waist circumference > 40 in (102 cm) in men or > 35 in (88 cm) in women
        ii. Blood pressure ≥130/85 mm Hg
        iii. Fasting blood glucose ≥ 110 mg/dL
        iv. Fasting plasma high-density lipoprotein (HDL) cholesterol < 40 mg/dl (men) or < 50 mg/dL (women)
        v. Fasting plasma triglycerides ≥ 150 mg/dL
    b. Smoking: current or within past 12 months
5. Pulmonary diseases: chronic obstructive lung disease (COPD), asthma, reactive airway disease, bronchitis, pneumonia, pulmonary fibrosis,
6. Active renal disease
7. Rheumatologic diseases: Rheumatoid arthritis, systemic lupus erythematosis (SLE), scleroderma, or any other autoimmune disease

8. Endocrine diseases: Diabetes, hypo- or hyper-thyroidism, Cushing's syndrome, Adrenal diseases
9. Gastro-intestinal disease: Peptic ulcer disease, gastro-esophageal reflux disease, inflammatory bowel disease (Crohn's disease or Ulcerative colitis),
10. Liver diseases
11. Active Cancer or active chemo- or radio-therapy
12. Psychiatric impairments: Cognitive impairment (mini-mental status examination score = 23 or less), depression, psychosis, delusions
13. Substance abuse: Alcohol abuse current or within past 10 days, any other substance abuse
14. Recent vaccination: influenza, pneumovax, or others
15. Infectious diseases: Common cold or any other acute infection within 14 days
16. Medications: regular use of non-steroidal anti-inflammatory drugs (NSAIDs)
17. Surgery within past 3 months
18. Strenuous physical activity within 48 hours.

Prior to enrolling in the study, each subject underwent a brief telephone interview to reveal any potential exclusionary conditions. During this screening interview, over 80 individuals were excluded from participation due to regular medication use (e.g. anti-hypertensives, anti-inflammatory, cholesterol lowering drugs) or pre-existing medical conditions (e.g. known cardiovascular disease, arthritis, gastro-intenstinal disorders). If subjects declined to wear the physical

activity monitors, their participation in the study would have concluded at the end of the first visit. Additionally, study participation would have been terminated early if the subject declined to participate in any of the remaining tests, or if the test administrator believed that it was in the best interest of the subject not to participate. However, all subjects who qualified for participation in the study completed all tests.

Recruitment

Subjects of any race from 18 to 90 years of age were recruited for this examination. The goal for recruitment into the study was set at a minimum of 60 subjects and a maximum of 80 subjects with equal division among males and females. The subjects were recruited using newspaper advertisements, email announcements to OUHSC and OU faculty and staff, and media flyers. Recruitment of women and minorities into this protocol was a high priority to obtain measures of inflammatory markers, physical activity, vascular function, and body composition among various demographic groups. This study was conducted on an outpatient basis, in the General Clinical Research Center (GCRC) on the OUHSC campus. At the end of each visit, the subjects received a small meal. A report and an explanation of the results obtained was prepared for and given to all subjects after the tests were completed.

Research Design

This was a three-visit, cross-sectional study in which the levels of inflammatory and fibrinolytic markers were measured via blood samples in apparently healthy subjects. Additionally, tests were administered to assess body composition and monitors were provided to assess physical activity. The independent variable of this study is age of the participant. The dependent variables of this study are the blood levels of the inflammatory and fibrinolytic markers. The descriptive characteristics of the subjects were considered as potential covariates in the final analysis of the study.

Research Protocol

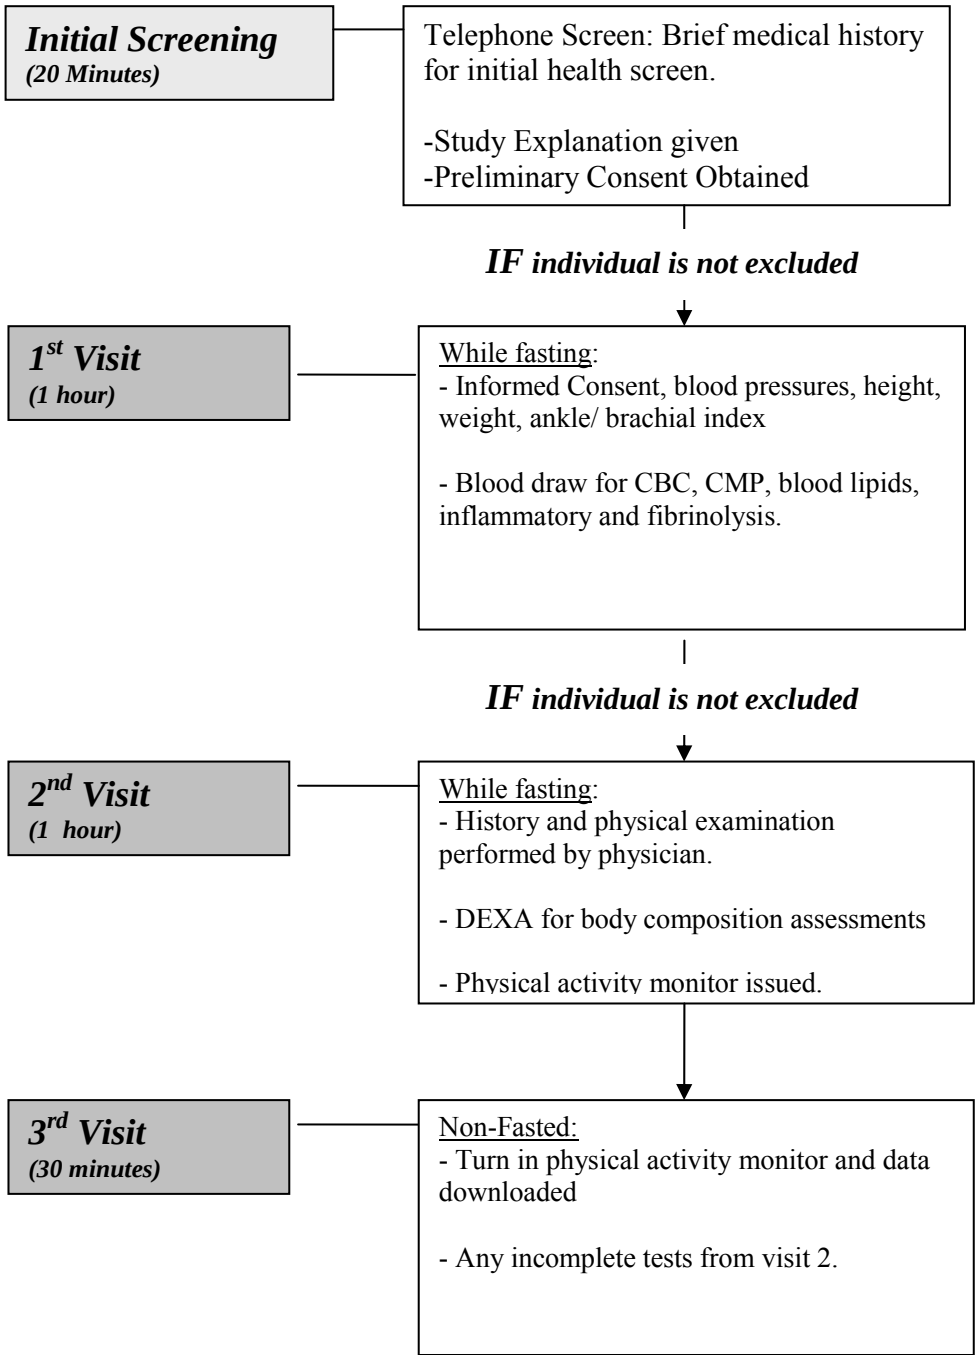
During this study, the subject completed three visits within one week, illustrated in Figure 1. During the first visit, the subject completed the informed consent (Appendix A) and HIPAA forms (Appendix B). Each subject also completed an initial screening to evaluate his or her health and medical history. Additionally, a blood draw was performed to obtain specimens for all blood tests. The first visit lasted approximately one hour.

On the second visit, the subjects completed a physician conducted health screening to ensure the subjects were healthy and free on all confounding conditions highlighted in the exclusion criteria. This screening was completed on the second visit so the attending physician could examine the blood chemistry

reports to identify any underlying exclusionary conditions. Physical activity monitors were given to the subject and they were instructed how to properly wear the device. Additionally, a dual energy X-ray absorptiometry (DEXA) scan was performed to assess body composition. The second visit lasted about one hour.

On the third and final visit, the subjects returned the physical activity monitor and any tests that were not conducted in the first two visits were completed. For example, if a subject was not fasting on the second visit, the testing was completed during the third visit. This visit could have lasted up to about one hour.

Figure 1. **Flow Chart of Subject Participation.**



Instruments and Measures

Health Screening Measurements

Prior to completing any of the tests in this study, preliminary information regarding health status was obtained. This included age, height, weight, blood pressure, sex, race, complete blood count (CBC), comprehensive metabolic profile (CMP), and blood lipid panels. In addition, a medical history and a physical examination was performed by the GCRC site physician to confirm that all participants in the study were free of any conditions in the exclusion criteria.

Physical Characteristics of the Subjects

The age and race of the subjects were obtained by self-report. The age was recorded to the nearest year. The race was recorded as: Caucasian, Asian, African American, American Indian, Hispanic, or Other.

Height was measured using a wall-mounted stadiometer (Accustat™ Genentech® Inc.; San Francisco, USA). All subjects were asked to remove their shoes and stand up straight against the stadiometer, with their feet flat on the floor. The height was measured as the distance from the floor to the top of the head and recorded to the nearest 0.1 cm. After removing any excess clothing, jewelry, and objects from their pockets, the subjects were then weighed by an electronic scale (Seca, Vogel & Halke; Germany). Weight was measured to the

nearest 0.1 kg. Body mass index (BMI) was calculated from the height and weight measurements, as follows: BMI = weight (kg) / height $(m)^2$.

Waist circumference was measured to ensure that all male subjects less than 102 cm and that all female subjects were less than 88 cm. The waist circumference was defined as the narrowest part of the torso (above the umbilicus and below the xiphoid process). A horizontal Gulick measuring tape (Creative Health Products; Plymouth, USA) was used to determine circumference, and the measurement was recorded to the nearest 0.1 cm.

Blood pressure and Pulse

Blood pressure and heart rate were measured with a Critikon automated Dinamap sphygmomanometer (Welch Allyn; Arden, USA) following 10 minutes of supine rest. Blood pressure readings were obtained in both arms to determine if systolic blood pressure (SBP) was less than 130 mmHg and diastolic blood pressure (DBP) was less than 85 mmHg. The resting heart rate was recorded as number of beats per minute.

Ankle-Brachial Index

An ankle-brachial index (ABI) test was performed using the Doppler ultrasound technique to rule out the presence of peripheral arterial disease, defined as an ABI of ≤ 0.90 (54). The brachial systolic pressures were obtained

as described above. The ankle systolic pressures were taken simultaneously with each brachial pressure. Specifically, a hand-held biodirectional Doppler machine (Hokanson; Bellevue, USA) was used to determine systolic pressure of the posterior tibialis and the dorsalis pedis arteries. After finding the resting pulses at each location, a blood pressure cuff (Hokanson; Bellevue, USA) was secured around the ankle and inflated to approximately 200 mmHg. The pressure in the cuff was slowly released at a rate of 2-4 mmHg per second. The pressure corresponding with the first sound of a pulse was recorded as the systolic pressure. The higher blood pressure of the two arteries was used as the ankle SBP. The ABI was then calculated by the following equation: ABI = Ankle SBP ÷ Brachial SBP.

Blood Markers

Sample Preparation

On the first visit of the study, venapuncture was used to obtain the blood specimen for analysis of the blood markers. Specifically, venous blood samples were collected from a vein in the antecubital space of either arm. The blood was ejected into two types of vacutainers: (1) a non-additive (red top) vacutainer for the CRP analysis and (2) a citrate anti-coagulant additive (1:9 vol of sample) siliconized (black top) vacutainer for the fibrinogen, t-PA, and PAI-1 analyses.

After the whole blood was collected into the vacutainer, the samples were centrifuged (Marathon 3200R; Fisher Scientific, USA) at 3000 X g for 15 minutes. The serum from the red top tubes (~10 mL of whole blood) was drawn and distributed into 1.0 ml aliquots in plastic microcentrifuge tubes. The plasma from the black top tubes (~9 mL of whole blood) was distributed into 0.5 ml aliquots in plastic microcentrifuge tubes. Care was taken to ensure a "platelet free" preparation, since platelets can release PAI-1. The samples were then stored in an ultra-low freezer at -80°C, where they were batched until all samples were collected for analysis.

C-Reactive Protein

A high-sensitivity Near Infrared Particles Immunoassay was used to quantify the concentration of C-reactive protein (CRP) from a serum sample of 300 µl, the optimum sample volume for this specific assay. A commercially available device, the SYNCHRON LX-20 (Beckman-Coulter; California, USA), was used to automatically perform the assay. Prior to performing each assay, the SYNCHRON system was calibrated and a calibration curve was established. To start the high-sensitivity assay, the SYNCHRON LX-20 combined one part of serum sample with 26 parts of the CRPH reagent, a pre-made solution consisting of an anti-CRP antibody-coated particle that causes a cloudy reaction when binding to CRP. The change in absorbance, directly proportional to the

concentration of CRP, was monitored by the SYNCHRON system at 940 nanometers and was used to calculate the CRP concentration based upon the pre-determined calibration curve. The "normal" reference range for concentrations of CRP using this high-sensitivity assay is 0.0 – 3.3 mg/L (16,76,129).

Fibrinogen

The ZYMUTEST Fibrinogen (DiaPharma) kit is a two site enzyme-linked immunosorbent assay (ELISA) for measuring human Fibrinogen in plasma, or in any fluid where Fibrinogen can be present. This specific ELISA is designed with rabbit polyclonal antibodies and is affinity purified. A standard curve, using the concentrations of 0, 5, 10, 25, and 50 ng/ml, was constructed on each microplate and was used for the assays. At the start of the process, 200 µl of the standard solutions or the tested samples were introduced into the corresponding microplate well. The microplate was mixed gently on a plate shaker and set to incubate for one hour at room temperature (18-25 °C). All plate shakes for each ELISA were set to 600 rpm, unless otherwise noted. After this first incubation period, the wells were emptied and subjected to five successive washings with the provided washing solution (20 fold diluted in distilled water).

Next, 200 µl of the Anti-Fibrinogen HRP immunoconjugate was introduced into the plate wells. Again, the plate was gently mixed on a plate shaker and allowed to incubate for 1 hour at room temperature (18-25 °C). The

microplate wells were washed another five times, as previously described. Immediately following the second wash, 200 µl of a tetramethylbenzidine (TMB) with hydrogen peroxide (H_2O_2) substrate was introduced into the wells. This was allowed to develop a blue color in the wells, and should take approximately five minutes. In the exact same fashion the TMB/H_2O_2 substrate was added, 50 µl of 0.45 M sulfuric acid was added to the wells to stop the color development. After letting the last step stabilize for 10 minutes, the microplate spectrophotometer analyzed the samples at 450 nm. Fibrinogen concentration in normal human plasma is in the range 1.5 to 5 mg/ml, in which greater than 5 mg/ml is associated with inflammation.

Tissue Plasminogen Activator

Biopool's Chromolize™ t-PA (DiaPharma Group, Inc; Ohio, USA) is a commercially available bio-functional immunosorbent assay (BIA) intended for the quantitative determination of human tissue plasminogen activator activity in plasma. All of the steps involved with this assay were performed at room temperature (18-25 °C). A standard curve was included with each plate analysis, using known concentrations of 0, 0.5, 1.0, 1.5, 2.0 IU/ml for the standards. A total of 100 µl of t-PA standards or 100 µl of sample to the microplate wells and the positions were recorded. The plate was allowed to incubate for 20 minutes on a plate shaker at ambient temperature. After this incubation period, the

supernatant was discarded by tapping onto an absorbent towel. Following this step, the wells were filled completely with Phosphate, NaCl, EDTA, and Tween 20 (PET) concentrate buffer and emptied to wash the wells 4 times.

After the first washes, 50 µl of Lyophilised H-D-But-CHT-Lys-pNA and poly-D-lysine (substrate reagent) were added to each well using a repeating pipette. Immediately following, 50 µl Lyophilised plasminogen and FDP (Plasminogen Reagent) were added to each well using the same technique, which was completed within 2 minutes. Again, the plate incubated for 90 minutes at ambient temperature on a microtest plate shaker at 600 rpm. Finally, 50 µl a stop solution (1.7 M acetic acid) was added to each well and allowed to mix on a microtest plate shaker for at least 15 seconds, forming a yellowish color.

The absorbance was set at 405 nm on the spectrophotometer, and a "blank" was run against air. Then, the absorbance in all wells was measured at 405 nm. A second measurement may be made at 492 nm and these subtracted from the readings at 405 nm. Paranitroanilide absorbs light at 405 nm, whereas the absorbance due to turbidity is approximately equal at 405 nm and 492 nm. Therefore, absorbance at 492 nm was measured and subtracted to correct for background due to turbidity. For healthy humans the basal level is between 0.2-2 IU/ml (38).

Plasminogen Activator Inhibitor – 1

Biopool Chromolize™ PAI-1 (DiaPharma Group, Inc; Ohio, USA) is a bio immunoassay (BIA) for the quantitative determination of active human plasminogen activator inhibitor, type 1 (PAI-1) in human plasma. With each assay, the PAI-1 standards were made for the PAI-1 concentrations of 0, 15, 30, and 50IU/ml and were used in the standard curve, which is used in the interpolation of PAI-1 activity in the patient's plasma specimen. After the standards were prepared, the wells in each microplate were reconstituted with 25 µl of the PET buffer. The plate was allowed to incubate on a microplate shaker at a speed of 600-800 r.p.m. for 2 minutes. Exactly 25 µl of plasma samples or the PAI-1 Standards was added to each well, and the positions were recorded. Immediately following (not to exceed 1 minute), 25 µl of Conjugate was added to each well. The plate then incubated for 30 minutes on a microplate shaker set at a speed of 600-800 r.p.m. Then the contents were discarded, washed with the PET buffer and emptied onto an absorbent towel. This washing process was repeated four times.

Next, 100 µl of the phosphate / citrate buffer with hydrogen peroxide (HRP) substrate to each well and the tray incubated for exactly five minutes on a shaker as described above. The reaction was stopped by adding 100 µl of 1.6 M sulphuric acid to each well in the same order and speed as the substrate was added. To quantify the PAI-1 in the specimen samples, the absorbance was set at

492 nm on the microplate spectrophotometer, with a "blank" against air being run first. Following, the absorbance in all wells were measured at 492 nm. The detection range for this specific assay is 2.0 to 50 IU/ml. Using this assay, the expected concentration of PAI-1 in plasma samples seen healthy adults should be around 5.15 ± 7.13 (SD) IU/ml (38).

Body Composition Assessment

Dual-energy X-ray absorptiometry (DXA) was used to measure body fat mass and fat-free mass during the second visit of the study. This DXA technique provides a body composition measurement, dividing the body into fat tissue, fat-free tissue, and bone mineral.

The Hologic QDR 4500 (Hologic Inc; Massachusetts, USA) DXA scanner is a fan beam scanner. Fan beam scanners perform one or more sweeps across the patient instead of the two-dimensional scan required by pencil beam geometry, resulting in decreased scan times and higher image resolution (15). There is an exposure to radiation during a whole body DXA scan is approximately 1.0 mrem. The x-ray tube is equipped with a filter to convert the polychromatic X-ray beam into low (100 keV) and high-energy peaks (140 keV). The scanning arm passes over the DXA bed and detects the x-ray energy that passes through the body in a posterior to anterior direction. The attenuation of the x-ray has a direct relationship with the mass of the tissue through which it passes. The QDR4500A

scanner has shown to be a highly reliable an accurate assessment of percent body fat (%BF), with a precision of <1 - 1.2 %BF (10,80).

Prior to each scan, all subjects were instructed to remove any metal or other interfering objects, such as jewelry, from their body. For all females, a human chorionic gonadotropin (HCG) test was completed to ensure they were not pregnant. Subjects underwent a total body scan with a fan beam X-ray in the array mode, after being properly situated in the supine position on the DXA bed. All scan analyses were performed by the same qualified technician. Quality Assurance and control phantom calibration scans were completed at the beginning of each test day.

Ambulatory Physical Activity Assessment

Ambulatory physical activity level was monitored for two to seven consecutive days (4.8 ± 1.0 days) by a StepWatch activity monitor (Cyma; Seattle, Washington) wrapped around the ankle using elastic straps above the lateral malleolus of the right leg. The StepWatch activity monitor measured strides and minutes of ambulatory activity accumulated per day for activity at a lower cadence (<15 strides per minute), activity at a moderate cadence (≥15 and < 30 strides per minute) and activity at a higher cadence (≥ 30 strides per minute), and total activity (the sum of activity at a lower, moderate, and a higher cadence).

Subjects were instructed to wear the device in this exact position, during their waking hours and to remove them before retiring to bed. Additionally, the subjects were instructed to carry out their usual activities through the monitored period. The activity monitor was issued on the first visit and returned on the second visit, at which time the data was downloaded and recorded. The step activity monitor is a highly reliable and validated method of quantifying of ambulatory physical activity (77,124).

Statistical Analysis

In an initial analysis of the study data, a summary description of the population was made by presenting the gender specific mean, standard deviation, maximum, and minimum values for each variable. All values were reported as the mean ± standard deviation (SD). The data were graphed as a first examination of relationships between variables to reveal any outliers in the data set. Outliers were checked as possible data entry errors. Errors were corrected or omitted. Outliers that were not errors were examined to determine their influence on the statistical results, by running the analyses with and without the outlier. Influential outliers were omitted from final analyses but noted and discussed.

To fully address the age associated changes in inflammation and fibrinolysis, subjects were grouped into one of three categories according to age: "Younger" = 20 – 39 years, "Middle Age" = 40 – 59 years, and "Older" = 60

years and greater. An analysis of variance was used to detect mean differences among the three groups for all measured variables.

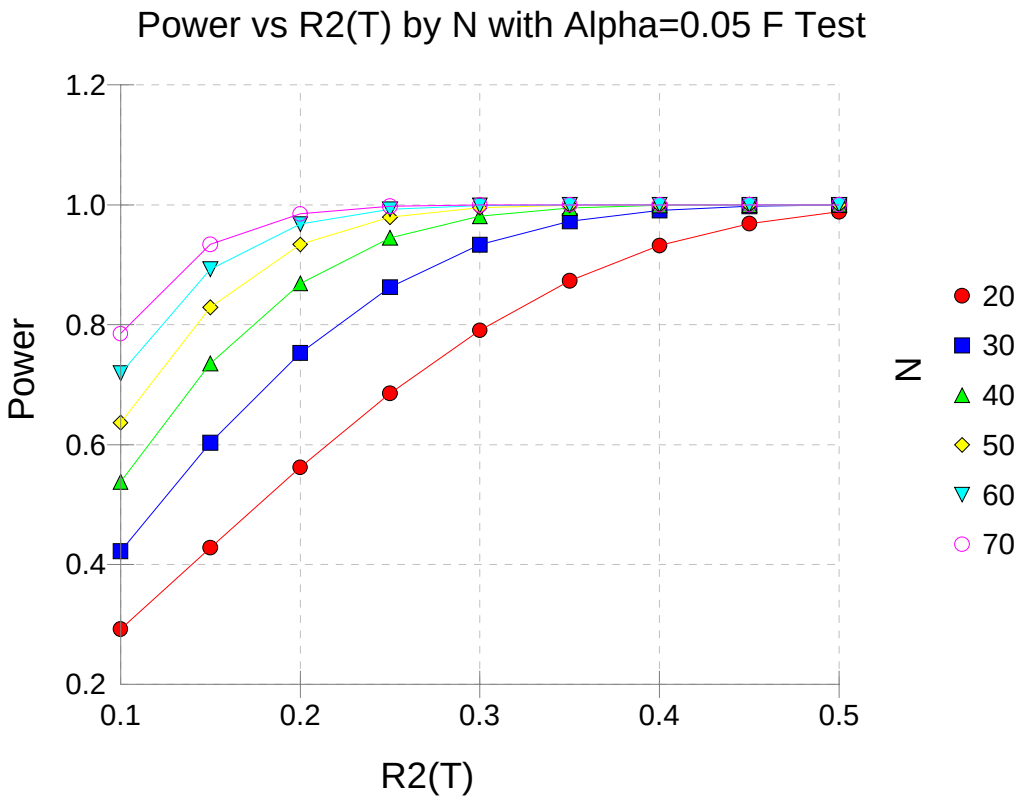
A correlation matrix correlating each variable with each other variable was constructed to examine pairwise relationships and dependencies between physical characteristics of the subjects, the blood concentrations of the inflammatory and fibrinolytic markers. In particular, correlations between the independent variables identified redundant characteristics. For example, if BMI and percent body fat are highly correlated, then we used the more descriptive variable (the larger absolute correlation) as a covariate in further statistical analyses.

Following these summary and investigational analyses, the primary analysis used a general linear model (GLM) to determine the significant predictors of levels for each marker of inflammation and fibrinolysis. The initial independent variable was age and the outcome (dependent) was the serum concentration of inflammatory or fibrinolysis marker. Physical characteristics (i.e., body composition, gender, and physical activity) found to significantly correlate with the concentration of each blood marker were entered as covariates into the statistical model to isolate the affect of age on inflammation and fibrinolysis. A p value was provided for each hypothesis test and an alpha = 0.05 was used to define significance. All statistical analyses were performed with the Statistical Package for the Social Sciences (SPSS, v. 11.5, Chicago, IL) software.

Statistical Power and Sample Size

Typically a relationship between an independent variable and a dependent variable is of interest if at least 25% of the variation in the dependent variable is attributable to variation in the independent variable, that is, $r^2 \geq 0.25$. A power analysis was performed using the NESS-PASS statistical software package to determine the number of subjects needed to detect relationships at the significance level (alpha) of 0.05. As shown in figure 2, it was determined that about 30 subjects were necessary to detect a relationship of $r^2 \geq 0.25$, ensuring a power of 80% ($\beta = 0.20$). Because there are two gender groups, at least 30 males and 30 females were needed. The study aimed to recruit and complete testing on a total of 80 subjects (40 males, 40 females) to allow for loss of participants and/or data from the study.

Figure 2. Results of the power calculations.



CHAPTER FOUR

RESULTS

The purpose of this study was to investigate the relationship between age, whole body and trunk fat mass, physical activity level and blood levels of CRP, fibrinogen, t-PA, and PAI-1. In order to accomplish this, 88 participants were enrolled in the study. Of the total enrolled, six individuals were excluded from participating, as one person reported regular use of non-steroidal anti-inflammatory drug, one person did not show up for the second visit, one person reported a recent influenza vaccination, and three people had hypercholesterolemia. Results of the remaining 82 participants are presented throughout the remainder of this chapter.

Group Characteristics and Comparisons

Comparing Men and Women Subjects. The means and standard deviations of the physical characteristics were calculated for the men and women and are presented in Table 1. Independent t-tests between gender groups showed that the men were taller than the women ($p < 0.001$) and weighed more than the women ($p < 0.001$). The females had a higher resting pulse compared to men ($p = 0.004$) and a higher high-density lipoprotein (HDL) level than men ($p = 0.013$). There were no differences ($p > 0.05$) between men and women on any other physical characteristic.

Table 2 presents the body composition data for men and women. The men had a greater waist circumference than the women ($p < 0.001$), but they had a lower percent fat in the trunk ($p < 0.001$) compared to the women. Additionally, the percent of whole body fat was lower in men than in women ($p < 0.001$), as was the whole body fat mass ($p < 0.001$). No differences were found between men and women in body mass index (BMI) or trunk fat mass ($p > 0.05$).

The ambulatory activity measurements were compared between men and women and are presented in Table 3. Overall, the women accumulated more total minutes of daily ambulatory activity than the men ($p = 0.046$), as well as more minutes of activity at a lower cadence ($p = 0.008$). The men were more sedentary than the women ($p = 0.046$). The remaining ambulatory activity measurements were not significantly different ($p > 0.05$) between the men and women.

The blood marker concentrations in the men and women are compared in Table 4. There was no difference in CRP values between the men and the women ($p = 0.504$). Additionally, no significant differences were found between men and women in blood levels of fibrinogen ($p = 0.700$), tissue plasminogen activator (t-PA) ($p = 0.984$), or plasminogen activator inhibitor – 1 (PAI-1) ($p = 0.453$).

Comparing Age Groups. To examine age-related differences in measurements, subjects were categorized into three groups according to age: "Younger" = 20 – 39 years, "Middle Age" = 40 – 59 years, and "Older" = 60 years and greater. The number of men and women in each group is shown in Figure 3, and the physical characteristics of each age group are presented in Table 5. One-way

ANOVAs revealed significant differences among the three age groups in systolic and diastolic blood pressure, total cholesterol, and low-density lipoprotein (LDL) level. More specifically, the older adults had a higher systolic blood pressure than the younger adults ($p < 0.001$) and middle age adults ($p < 0.001$), and a higher diastolic blood pressure than the younger adults ($p = 0.004$). The older adults also had a higher total cholesterol ($p<0.001$) and LDL level ($p<0.001$) than the younger and middle age adults.

Body composition measurements were also examined by age group, as shown in Table 6. Significant differences were found among the groups in waist circumference ($p = 0.012$), percent body fat ($p = 0.001$), body fat mass ($p = 0.016$), and the percent trunk fat ($p < 0.001$). The younger adults had a smaller waist circumference than the middle age ($p = 0.024$) and older adults ($p = 0.046$). Additionally, the older adults had a higher percent body fat ($p = 0.001$), higher body fat mass ($p = 0.014$), and a higher percentage of trunk fat ($p < 0.001$) compared to the younger adults. No significant differences were found in weight ($p = 0.442$), BMI ($p = 0.125$), or trunk fat mass ($p = 0.054$).

Table 7 shows the ambulatory activity measurements by age group. Overall, there were no significant differences in activity measures among the younger, middle age, and older adults ($p > 0.05$).

The blood marker concentrations among the younger, middle age, and older adults are presented in Table 8. Results from one-way ANOVA shows that the older age group had a significantly higher level of t-PA than the younger group ($p =$

0.042). No significant differences were found among age groups in the concentrations of CRP ($p = 0.413$), fibrinogen ($p = 0.231$), and PAI-1 ($p = 0.489$).

Correlations Among Blood Markers and Physical Characteristics

Age and Physical Characteristics. Pairwise correlations between age and physical characteristics are presented in Table 9. As shown, age was positively related to systolic blood pressure ($r = 0.573$, $p < 0.001$), diastolic blood pressure ($r = 0.406$, $p < 0.001$), total cholesterol ($r = 0.333$, $p = 0.002$), LDL level ($r = 0.286$, $p = 0.009$), and HDL level ($r = 0.231$, $p = 0.036$). The scatter plots examining age with physical characteristics to identify potential outliers in the data set are shown in Appendix I.

Age and Body Composition. Pairwise correlations between age and body composition also are presented in Table 9. Age was positively related to waist circumference ($r = 0.295$, $p = 0.007$), percent of whole body fat ($r = 0.401$, $p < 0.001$), whole body fat mass ($r = 0.335$, $p = 0.002$), percent trunk fat ($r = 0.430$, $p < 0.001$), and trunk fat mass ($r = 0.248$, $p = 0.025$). Body composition measurements were plotted against age (Appendix J) to identify potential outliers in the data set.

Age and Ambulatory Activity Measures. Pairwise correlations between age and ambulatory activity measures also are shown in Table 9. The only activity measures that were related to age were the number of strides per day at a moderate cadence ($r = 0.268$, $p = 0.016$) and the number of minutes per day at a moderate cadence ($r = 0.232$, $p = 0.037$). Physical activity measures were plotted against age

(Appendix K) to identify potential outliers in the data set. The data for age vs. total strides per day, strides of activity at a lower cadence, and strides of activity at a moderate cadence all showed one outlier in the scatter plots. After confirming that this was not a data entry error, the data point was removed from the data set and the correlations with age were repeated. The correlation coefficient remained consistent with our initial analyses, therefore the outlying data point was included in the data set. Later analyses for each blood marker were also done with and without the outlier to determine the influence, if any, on the blood marker concentrations.

Predictors of C-Reactive Protein. CRP values for the entire group ranged from 0.2 mg/L to 10.4 mg/L, and are presented across age in Figure 4. Upon reviewing the C-reactive protein (CRP) levels, one subject had a CRP value of 77.0 mg/L. This value lies nearly nine standard deviations above the mean CRP concentration for the sample (2.3 ± 8.5 mg/L). This extremely high value is indicative of an underlying infection that went undetected during screening (129), which is part of the exclusion criteria of the study. Thus, the data point was removed from the remaining analyses.

As shown in Table 9, CRP was not significantly correlated to age ($r = -0.073$, $p = 0.519$), but was correlated to total cholesterol ($r = -0.338$, $p = 0.002$) and HDL levels ($r = -0.255$, $p = 0.022$). CRP also was significantly correlated to the body composition measures: BMI ($r = 0.304$, $p = 0.006$), waist circumference ($r = 0.279$, $p = 0.012$), percent body fat ($r = 0.221$, $p = 0.048$), percent trunk fat mass ($r = 0.243$, p

= 0.029), and trunk fat mass (r = 0.234, p = 0.036). None of the ambulatory activity measures were related to CRP levels in the sample.

To reduce the number of covariates to be considered in a subsequent model, a correlation analysis was done between biologically correlated variables. This secondary correlation analysis showed that HDL and total cholesterol were significantly correlated (r = 0.449, $p < 0.001$). Therefore, HDL was used as a covariate in the GLM to assess the relationship between age and CRP. All of the body composition measures were significantly related ($p < 0.05$) with one another. BMI, percent body fat and trunk fat mass were selected as covariates between body composition and CRP, as they were the strongest correlates with CRP. All variables were entered one at a time into the GLM assessing the relation between age and CRP to determine which combination has the greatest confounding influence of CRP levels.

A general linear model (GLM) showed that CRP levels did not change with age ($R^2 = 0.011$, p = 0.641). BMI, percent body fat, trunk fat mass, and HDL were all entered separately into the general linear model (Appendix L) examining whether age was an independent predictor of CRP. Individually, BMI was the most powerful predictor (Sum of Squares [SS] = 28.896; $R^2 = 0.095$, p = 0.013) of all of the body composition measures. The model was not changed after adding trunk fat mass (SS = 28.926; $R^2 = 0.083$, p = 0.031) and percent body fat (SS = 29.344; $R^2 = 0.085$, p = 0.029). Thus, BMI and HDL were the covariates in the final CRP model. While the final model was significant (SS = 30.22; $R^2 = 0.077$, p = 0.050), BMI, not age or

HDL, was found to be the only significant predictor ($p = 0.036$) of CRP levels. Lastly, there was no significant age by gender interaction in the model.

Predictors of Fibrinogen. Fibrinogen values for the entire group averaged 4.2 ± 1.7 IU/mL and ranged from 2.16 IU/mL to 13.35 IU/mL. The fibrinogen value of 13.35 IU/ml was 5.4 standard deviations above the mean, and was removed from the data for the remaining analyses. After removing this outlier, the fibrinogen values for the group averaged 4.1 ± 1.4 IU/mL and ranged from 2.16 IU/ml to 9.72. These data are presented across age in Figure 5.

Fibrinogen was not significantly correlated to age ($r = -0.010$, $p = 0.951$) (Table 9). In contrast, fibrinogen concentration was related to strides per day of activity at a higher cadence ($r = -0.242$, $p = 0.029$), minutes per day of activity at a higher ($r = -0.223$, $p = 0.045$), and percent trunk fat ($r = 0.238$, $p = 0.031$). After removing the outlier, fibrinogen levels also were correlated to resting heart rate ($r = 0.306$, $p = 0.005$), percent body fat ($r = 0.257$, $p = 0.020$), body fat mass ($r = 0.239$, $p = 0.026$), percent trunk fat ($r = 0.307$, $p = 0.004$), trunk fat mass ($r = 0.297$, $p = 0.007$), and strides per day of activity at a higher cadence ($r = -0.225$, $p = 0.045$).

A secondary correlation analysis showed the percent body fat correlated with body fat mass ($r = 0.949$, $P < 0.001$) and percent fat correlated with trunk fat mass ($r = 0.761$, $p < 0.001$). To reduce the number of covariates, resting heart rate, percent body fat, percent trunk fat, and strides per day of activity at a higher cadence were selected as covariates for the GLM examining the relation between age and fibrinogen.

In the initial GLM, age was not an independent predictor of fibrinogen concentrations (SS = 117.15; R^2 = 0.131, p = 0.319) (Appendix M). There was no significant age by gender interaction in the model. Resting heart rate, percent body fat, percent trunk fat, and strides per day of activity at a higher cadence were all entered separately into the GLM (Appendix M). Individually, heart rate was the most influential covariate (Sum of Squares [SS] = 125.91; R^2 = 0.230, p = 0.117), however it was not significant. The model only slightly changed after adding percent body fat, percent trunk fat and strides per day of activity at a higher cadence (SS = 128.62; R^2 = 0.237, p = 0.226). The final GLM showed that age was not an independent predictor of fibrinogen levels (p = 0.236), and that there was no significant age by gender interaction (p = 0.825) in the model.

Predictors of Tissue Plasminogen Activator, Activity. The t-PA concentrations for the entire group (0.72 ± 0.44 IU/mL) ranged from 0.14 IU/mL to 2.61 IU/mL. Upon further review, one individual had a t-PA level of 2.61 IU/mL (4.3 standard deviations above the mean) and another had a t-PA level of 2.43 IU/ml (3.9 standard deviations above the mean). Therefore, these outliers were excluded from the analyses. The corrected t-PA concentrations for the entire group then averaged 0.68 ± 0.34 IU/mL and range from 0.14 IU/mL to 1.64 IU/mL. They are presented across age in Figure 6.

Initially, t-PA was correlated with age (r = 0.228, p = 0.042) (Table 9), and was negatively correlated with triglyceride level (r = -0.279, p = 0.012). Consequently, triglyceride concentration was used as a covariate in the GLM that

assessed the relationship between age and t-PA. None of the other physical characteristics, measures of body composition or measures of ambulatory activity were significantly related to t-PA concentrations ($p < 0.05$). These results were the same when examined with and without the outliers.

In contrast to the correlation analysis, the initial GLM showed that age was not a predictor of t-PA concentrations (SS = 6.38; $R^2 = 0.030$, $p = 0.567$) (Appendix N). The model was unchanged after adding triglyceride levels to the GLM (SS = 6.38; $R^2 = 0.079$, $p = 0.636$). There was no age by gender interaction ($p = 0.525$).

Predictors of Plasminogen Activator Inhibitor -1, Activity. The PAI-1 concentrations for the entire group (6.47 ± 9.39 IU/mL) ranged from 0.00 IU/mL to 40.03 IU/mL. The subject with a PAI-1 level of 40.03 IU/mL was removed from the analysis, as the value was 4.0 standard deviations above the mean. Thus, the corrected PAI-1 values for the group averaged 5.91 ± 7.58 IU/mL and ranged from 0.00 IU/mL to 29.13 IU/mL. The PAI-1 concentrations across age for the entire group are presented in Figure 7.

Before removing the outlier, PAI-1 concentrations were significantly correlated to triglyceride levels ($r = 0.310$, $p = 0.005$), HDL ($r = -0.218$, $p = 0.049$), BMI ($r = 0.277$, $p = 0.012$), waist circumference ($r = 0.53$, $p = 0.022$), and percent trunk fat ($r = 0.245$, $p = 0.026$). Once the outlier was removed, PAI-1 was significantly correlated to weight ($r = 0.262$, $p = 0.018$), systolic blood pressure ($r = 0.221$, $p = 0.047$), diastolic blood pressure ($r = 0.275$, $p = 0.013$), triglyceride level ($r = 0.334$, $p = 0.002$), HDL level ($r = -0.280$, $p = 0.011$), BMI ($r = 0.377$, $p = 0.001$),

waist circumference ($r = 0.334$, $p = 0.002$), percent body fat ($r = 0.236$, $p = 0.034$), body fat mass ($r = 0.248$, $p = 0.026$), percent trunk fat ($r = 0.307$, $p = 0.005$), and trunk fat mass ($r = 0.264$, $p = 0.017$). PAI-1 concentrations were not significantly correlated ($p > 0.05$) with age or any of the ambulatory activity measures.

A secondary correlation analysis between biologically correlated variables was done to further reduce the number of covariates to be considered in a subsequent model. Systolic blood pressure was highly correlated with diastolic blood pressure ($r = 0.715$, $p < 0.001$) and triglyceride level correlated with HDL level ($r = -0.440$, $p < 0.001$). BMI was significantly correlated with waist circumference ($r = 0.864$, $p < 0.001$), percent body fat ($r = 0.449$, $p < 0.001$), body fat mass ($r = 0.596$, $p < 0.001$), percent trunk fat ($r = 0.642$, $p < 0.001$), trunk fat mass ($r = 0.699$, $p < 0.001$). Percent body fat was correlated with body fat mass ($r = 0.932$, $p < 0.001$) and percent trunk fat was correlated with trunk fat mass ($r = 0.761$, $p < 0.001$). Therefore, diastolic blood pressure, triglyceride levels, body fat mass, and percent trunk fat were selected as covariates for the GLM, as they were the strongest correlates with PAI-1.

Age was not an independent predictor of PAI-1 concentrations in the initial GLM ($SS = 3199.94$; $R^2 = 0.158$, $p = 0.736$). Diastolic blood pressure, triglyceride levels, body fat mass, and percent trunk fat were all entered separately into the GLM (Appendix O). Diastolic blood pressure ($SS = 388.92$; $R^2 = 0.105$, $p = 0.012$), and percent trunk fat ($SS = 247.11$; $R^2 = 0.001$, $p = 0.051$) were the most influential factors in the GLM. Therefore, these variables were entered as covariates in the final

model to determine if age is an independent predictor of PAI-1 levels. The final model showed that age was not an independent predictor of PAI-1 concentrations (SS = 3654.78; R^2 = 0.137, p = 0.333). There was no significant age by gender interaction (p = 0.836) in the model.

Table 1 displays the physical characteristics of the male and female subjects. The p value represents the significance between the two groups.

CHAPTER 5

DISCUSSION AND CONCLUSIONS

The main purpose of this investigation was to determine if age is associated with blood concentrations of C-reactive protein (CRP), fibrinogen, tissue plasminogen activator (t-PA), and plasminogen activator inhibitor – 1 (PAI-1), independent of body fat and physical activity levels. The primary finding of the current study shows that age is not independently associated with blood concentrations of CRP, fibrinogen, t-PA or PAI-1. Additionally, this study revealed that BMI is a predictor of CRP levels, but not of markers of fibrinolysis.

Aging and Inflammation

These results show that CRP concentrations did not increase with advancing age, which conflicts with previous claims. Many studies conclude that aging is associated with increased plasma levels of CRP, TNF-α, and IL-6 (9,21,23). In one of the largest age ranges examined (20 to 102 years of age), CRP and IL-6 were found to be significantly higher in the age groups 65 years of age and older in both, males and females even after adjusting for the existing clinical conditions (i.e., hypertension, hypercholesterolemia) (48). But, the researchers failed to account for varying body size and physical activity status.

Another study comparing older and younger adults who were apparently healthy (9) carefully excluded for any disorders that could affect CRP levels. However, they did not account for blood pressure, cholesterol levels (or pertaining medications), physical activity levels, or body composition. The failure to control for such potential covariates limits the conclusion that there are age-association changes in inflammatory status. This study not only excluded subjects presenting with any co-existing clinical conditions, but also further adjusted for varying body size, body compositions, and physical activity levels. To date, this is one of the most complete examinations of the independent association between age and inflammation.

There also have been previous reports that did not shown an increase in inflammation with age. In the Framingham heart study, no differences were found in circulating TNF-α and IL1β between elderly adults and a younger, control group (115). The Framingham findings are consistent with the findings of this study that inflammatory activity does not change with age. Furthermore, the lack of an age-related change in inflammatory markers suggests that inflammation does not independently increase the risk of cardiovascular disease as people age. Instead, the prevention of atherosclerotic development should focus more on the increasing prevalence of co-morbid conditions (e.g. diabetes and hypertension) that occur with advancing age.

Aging and Fibrinolysis

The analysis between age groups did reveal significantly higher levels of t-PA in the older adults compared to younger adults ($p = 0.042$). Additionally, this study found a correlation between age and t-PA ($r = 0.228$, $p = 0.042$). Two previous reports show that t-PA release is blunted in older adults (36,127); however, they also reported the potential impact of habitual exercise on hemostatic conditions.

Age is associated with decreased physical activity, decreased t-PA levels, and a higher incidence of thrombosis (36). In this study, the older group had higher t-PA levels than expected and it was found that the strides and minutes of ambulatory activity at a moderate cadence per day increased with age. Higher levels of physical activity have the potential to blunt the decrease in t-PA that is normally associated with age (36,127). The higher levels of ambulatory physical activity measured among the older adults in this study also may help explain why the expected associations between age and inflammation and fibrinolysis were not present. Thus, the adverse age-associated impact on fibrinolysis, however great it may be, appears to be either attenuated or absent in highly physically active individuals.

A more in-depth analysis did not show a change in concentrations of fibrinogen, t-PA or PAI-1 with increasing age. These results contradict the positive correlation between age and the occurrence of thrombosis that has been presented over the past couple of decades (36,148). These studies showed a dramatic increase in PAI-1 and a decrease in t-PA activity with increasing age. As previously suggested, the lack of change in fibrinolytic activity with age that was found in this

study may be a consequence of the higher physical activity levels that were maintained by the older adults in this study.

While there could be a primary affect of aging, the data showing that increasing physical activity levels negate this affect introduce new factors that, at minimum, call this relation into question (36,127). These studies in combination with the findings of this study raise the question if there is truly an age effect on fibrinolytic activity, or whether fibrinolysis is more of a result of typical age-related declines in physical activity patterns.

Other Factors and Inflammation

Lipids. There were several factors found to be significantly related to CRP levels in this investigation. First, CRP levels were inversely related to total cholesterol ($r = -0.338$, $p = 0.002$) and HDL levels ($r = -0.255$, $p = 0.022$). HDL levels have previously been shown to be negatively correlated to CRP concentrations (100). Most likely, the correlation between HDL and CRP explain the negative association between total cholesterol and CRP, as HDL is a component of total cholesterol levels. This suggests that higher total cholesterol levels are probably not associated with lower levels of inflammation. However, this negative correlation between HDL & CRP may help explain the link between high HDL levels and the associated decrease in risk for cardiovascular disease.

Obesity and Body Composition. Obesity has been consistently associated with generalized, low-grade inflammation (29,86). In the current study, CRP levels

were also related to several measures of body composition. BMI and waist circumference were positively related to CRP concentrations. Overall, it was found that BMI is an independent predictor of CRP levels ($p = 0.038$) in healthy adults. Similar investigations have also shown CRP concentrations were significantly correlated with BMI, waist circumference, and waist-to-hip ratio (100,121,150,151).

Percent body fat, a more precise measure of body composition, also correlated positively with levels of CRP ($r = 0.221$, $p = 0.048$), as did percent trunk fat and trunk fat mass. These results are not surprising, as previous research has shown that adipocytes can produce CRP, TNF- and IL-6 (34,68,87,132). Furthermore, the age-associated increase in body fat (55,98) may be an important source of increased circulating levels of inflammatory markers in the older population (63). More importantly, this adds to the growing body of literature showing a link between obesity and inflammation, and strengthens the notion that inflammation may be the mechanistic link between obesity, and specifically abdominal obesity, and cardiovascular disease.

Other Factors and Fibrinolysis

Lipids. Individuals with high triglyceride and low HDL levels were found to have high PAI-1 serum levels (93,106). The findings of this study support these results, showing that triglyceride levels were positively related to PAI-1 levels ($r = 0.334$, $p = 0.002$) and negatively related to t-PA levels ($r = -0.279$, $p = 0.012$). Additionally, HDL levels were negatively related to PAI-1 levels ($r = -0.280$, $p =$

0.011). As shown by Orem et al (93) , successful lipid lowering therapy can improve fibrinolytic activity by increasing t-PA and decreasing PAI-1, suggesting that correcting dyslipidemia can reduce the risk of thrombosis formation.

Blood Pressure. PAI-1 concentration was also positively related to systolic ($r = 0.221$, $p = 0.047$) and diastolic blood pressure ($r = 0.275$, $p = 0.013$). Hypertension, an established risk factor for acute coronary events, has been linked to impaired fibrinolysis in men and women (25,53,103,128). As impaired fibrinolysis can lead to thrombosis (25,53), these data collectively provide another potential mechanism by which hypertension contributes to the pathogenesis of cardiovascular disease in hypertensive patients.

Obesity and Body Composition. As expected, BMI was directly related to PAI-1 levels ($r = 0.377$, $p = 0.001$), which indicates a decrease in fibrinolytic activity with increasing BMI. Furthermore, these results show that fibrinogen and PAI-1 were elevated with increases in more specific measures of whole body fatness, such as percent body fat and body fat mass. The results of the current study agree with numerous previous studies (78,81,133), suggesting that the bridge between obesity and cardiovascular disease is becoming better defined. From a clinical perspective, it is encouraging to learn that acute weight loss in obese individuals has been shown to improve fibrinolytic activity (29,78) and, in turn, decrease the risks of thrombus related accidents.

PAI-1 levels were also positively associated with waist circumference ($r = 0.334$, $p = 0.002$). More specifically, it was found that fibrinogen and PAI-1 levels

were positively related to percent trunk fat and trunk fat mass. This suggests that abdominal adiposity may contribute to increased levels of PAI-1, the major inhibitor of fibrinolysis. While fat distribution has been suggested to influence fibrinolytic activity (78,81,134), more studies are needed to clarify to the association between abdominal adiposity and fibrinolytic activity.

Study Limitations

This study is not without its limitations. This study used a cross-sectional design which does not allow for a causal link to be established between aging and inflammation or fibrinolysis. The participants in this study, particularly the older adults, were extremely healthy volunteers and, thus, may not be representative of the general population around the Oklahoma City metropolitan area, which in other studies may be considered a limitation. However, the rigor of the exclusion criteria was necessary to isolate the effect of age rather than other confounding factors commonly associated with age. The sample was largely Caucasian. Because of this, the results can not be generalized to adults from minority populations.

Another limitation is that the StepActivity Monitor is not waterproof and it is worn on the ankle, so water and upper body activity were not quantified throughout the monitoring period. All subjects were questioned about their physical activity regimen, however, and only one participant engaged in water activity during the monitoring time period. The most serious limitation related to the measurement of physical activity is that it is likely that a selection bias exists in this study, as only the

high-active elderly may have agreed to participate whereas low/moderate active younger subjects may not have volunteered.

Also, the dietary intake of subjects was not monitored in this study. It has been shown that people on low fat diets have significantly improved fibrinolytic activity (118). All of our subjects were tested in a fasted state, but the long-term dietary habits, including regular fat intake, is unknown. By excluding for high cholesterol and high blood pressure, we also may have excluded for poor dietary habits as well.

Conclusions

In summary, study results show that age is not independently associated with blood concentrations of CRP, fibrinogen, t-PA or PAI-1. It can therefore be concluded that aging is not associated with inflammation and impaired fibrinolysis in subjects carefully screened for co-morbid conditions and cardiovascular risk factors. While blood pressure, cholesterol levels and measures of body composition were significantly related to markers of inflammation and fibrinolysis, BMI was found to be an independent predictor of only CRP, not of fibrinolytic markers. Finally, it is speculated that previous observations of age-related changes in inflammation (9,21,22,23) and fibrinolysis (36,148) resulted from the variance in body composition, physical activity and co-existing clinical conditions that occur with aging.

Clinical Significance

This study indicates that inflammatory and fibrinolytic activity does not change with increasing age. However, it was observed that inflammation and fibrinolysis were associated with high blood pressure, high cholesterol levels, and measures of body fatness, which provides a possible explanation for the discrepancy between our findings and those of previous studies which did not control for such factors.

Furthermore, the maintenance of physical activity levels across the age range found in this sample suggests that physical activity may provide a protective effect against the age-related changes in inflammatory and fibrinolytic activity previously shown. Regardless, blood pressure, cholesterol, body composition and physical activity levels are all manageable. These results suggest that improving these problems will reduce the risk of developing cardiovascular disease by reducing inflammation and increasing fibrinolytic activity. Combined with existing research, this study ultimately suggests that the risks associated with atherosclerotic disease are modifiable, not inevitable.

APPENDIX A

Informed Consent Form

Version 4, October 26, 2006

INFORMED CONSENT FORM
for research being conducted at the
University of Oklahoma Health Sciences Center

Study Title: The age-related influences on inflammatory markers: a pilot study.

Principal Investigator: Andrew W. Gardner, Ph.D.

This is a research study. Research studies involve individuals who choose to participate. Please take your time to make your decision. Discuss this with your family and friends.

Why Is This Study Being Done?

This study will determine if natural substances in your blood stream, involved in blood clotting and fighting off infections, are related to age. Secondly, this study will see how physical activity, health status, body composition, and physical function affect this relationship.

How Many People Will Take Part In The Study?

A total of 100 people will complete this study in the General Clinical Research Center at the University of Oklahoma Health Sciences Center.

What Is Involved In The Study?

MEASUREMENTS

Health Status. We will obtain some information regarding your health. This will include recording your age, height, weight, sex, race, smoking habits, education level, physical ailments, and your self-assessment of your overall level of health. It will take approximately 20 minutes to obtain this information.

Questionnaires. Your physical activity level will be measured with a questionnaire, and your health-related quality of life will be measured with a questionnaire that asks about various aspects pertaining to your physical and mental health. The questionnaires will take approximately 15 minutes to complete.

Blood Tests. We will measure the levels of natural substances in your blood stream. These substances are made by cells in the body to fight off infections or injuries, and help in clotting of the blood. A small amount of blood, about 20 ml, will be taken from a vein in your forearm by trained personnel. This procedure will take approximately five minutes to complete.

Body Composition. A total body scan to determine body composition will be performed using dual energy x-ray absorptiometry (DEXA). This test is similar to an X-ray but only exposes you to approximately 1/10 of the radiation of a normal X-ray. This test is non-invasive and requires only that you lie still for the test to be completed. The DEXA scan lasts approximately 15 minutes.

Vascular Tests. You will be measured on these tests to assess your blood flow, blood pressure, and heart rate. These tests will require approximately 30 minutes to perform and will include the following:

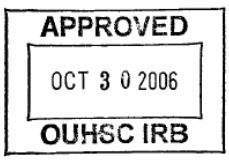
You will lie down for 10 minutes, after which leg blood flow, blood pressure in your arms and legs will be assessed at rest. The measurement of leg blood flow will be done by placing a small rubber band object around your leg calf muscle and inflating blood pressure cuffs around your thigh and ankle. Both blood pressure cuffs will be deflated after the resting measurement is obtained. Your arm blood pressure and heart rate will be measured automatically by a blood pressure machine. At the same time, your ankle blood pressure will be measured in the arteries in your foot by a Doppler machine.

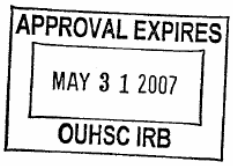
Following the resting measurements, we will perform a reactive hyperemia test. This test assesses the increase of blood flow occurring in the leg after the thigh blood pressure cuff is fully inflated for three minutes while you are lying down. After three minutes, the thigh blood pressure cuff is deflated and blood flow, blood pressure, and heart rate measurements will be measured as described above.

Following this test, a thigh blood pressure cuff will be fully inflated while you stand and perform heel-raises. The thigh blood pressure cuff will then be immediately deflated and you will lie down. Maximal leg blood flow, arm blood pressure, and heart rate will then be measured.

Functional Tests. You will perform functional tests which consist of walking, balancing, standing from a chair, and daily physical activity level. These tests will take approximately 30 minutes to complete. Your walking will be evaluated by a 4-meter walk test (about 12 feet). Your balance will be assessed by attempting to maintain your feet in a side-by-side, semi-tandem (heel of one foot beside the big toes of the other foot), and tandem (heel of one foot directly in front of the other foot) positions for 10 seconds each while you stand. Additionally, the time that you can stand on one foot with the other foot several inches off of the ground and your arms held loosely at your sides will be measured. Your ability to rise from a chair will be measured by having you fold your arms across your chest and stand up from a chair and sit down five times as quickly as possible.

To measure your physical activity level, you will wear two small (about the size of a pager) activity monitoring devices for at least two days. One device will be worn close to your waist (i.e., attached to your belt) and will measure the number of calories that you burn, while the other device will be fastened by elastic bands around your ankle and will measure the number of steps that you take. These devices will not restrict you from any activity; however, they should not be worn while sleeping or bathing.





How Long Will I Be In The Study?

During this study, you will make three visits within about two weeks. The visits will be the following:

- Visit 1: You will complete an initial screening to evaluate your health and medical history and a blood sample will be collected. This visit will take about one hour.
- Visit 2: Your second visit will be within one week after visit 1. You will complete a physician screening, questionnaires, body composition and vascular measurements described above. You will also have physical activity monitors placed around your waist and ankle for you to wear until Visit 3. This visit will take about two hours.
- Visit 3: Your third visit will be within one week after Visit 2. You will return the monitors, and complete the functional tests described above. This visit will take about one hour.

You have the option to decline any test or questionnaire that is part of the evaluation in this study. If you chose to not wear the activity monitors, then you will only have one visit during this study.

What Are The Risks of The Study?

RISKS / DISCOMFORTS There are minimal risks and discomforts involved during your participation in this research study. All research procedures will be conducted by trained clinical research personnel. The potential risk and discomforts associated with each test in this research study are listed below:

Health Status. There are no risks or discomforts associated with obtaining this information through an interview.

Questionnaires. There are no risks associated with obtaining information through the questionnaires.

Radiation. If you participate in this research you will receive radiation exposure from a DEXA scan (a type of x-ray) that you will not receive if you choose not to participate. The amount of additional radiation to which you will be exposed is approximately 1/5000th of the amount of radiation that an x-ray technologist is permitted to receive in one year.

Blood Draws. There is a minimal risk of having local discomfort, bruising, swelling, and in rare instances infection and fainting from the needle stick to obtain about 10 tablespoons of blood to measure the blood profiles.

Vascular Tests. There are no risks associated with the leg blood flow test. However, several minutes of discomfort can be expected during the leg blood flow test.

due to inflation of the blood pressure cuffs on your leg. Furthermore, there may be minor discomfort during the measurement of arm blood pressure due to the inflation of the blood pressure cuff on your arm.

Functional Tests. There are minimal risks associated with performing the functional tests. The test administrator may decide to not conduct any test that you may have trouble completing.

Physical Activity Monitors. There are no risks associated with wearing the physical activity monitors, nor will they affect your day-to-day activities. The only potential discomfort is the inconvenience of wearing a small device around your ankle.

Pregnancy / Reproductive Risks For Women and Men:

Pregnant women should not be exposed to radiation. If you become pregnant or suspect that you are pregnant during this study, you should immediately inform the study personnel and a pregnancy test will be done. If pregnancy is confirmed, you may be withdrawn from the study. As previously stated, there is a minimal risk for exposure to radiation. However, besides pregnancy, this risk is not detrimental to the reproductive system in either males, or females.

Are There Benefits to Taking Part in The Study?

If you agree to take part in this study, there may or may not be direct medical benefit to you. You will receive information about your cardiovascular function, health status, physical activity, physical function, and body composition at the end of the testing. Additionally, your participation will make a contribution to science because the information obtained will help us understand what factors are related to cardiovascular function in men and women of various ages. This information may be used in future studies aimed at improving cardiovascular function. Finally, you will have the opportunity to interact with investigators and ask questions regarding your measurements.

What Other Options Are There?

Instead of being in this study, you have the option to not participate.

What About Confidentiality?

Efforts will be made to keep your personal information confidential. You will not be identifiable by name or description in any reports or publications about this study. We cannot guarantee absolute confidentiality. Your personal information may be disclosed if required by law.

There are organizations that may inspect and/or copy your research records for quality assurance and data analysis. These organizations include the General Clinical Research Center (GCRC), the US Food & Drug administration, the National Institutes of Health, and the OUHSC Institutional Review Board. You will be asked to sign a separate authorization form for use or sharing of your protected health information.

What Are the Costs?

Transportation will be your only cost. Parking is free, as are all medical tests.

Will I Be Paid For Participating in This Study?

You will not be paid for participating in this study.

What if I am Injured or Become Ill While Participating in this Study?

In the case of injury or illness resulting from this study, emergency medical treatment is available. However, you or your insurance company may be expected to pay the usual charge for this treatment. No funds have been set aside by The University of Oklahoma Health Sciences Center or the Department of Health and Exercise Science to compensate you in the event of injury.

What Are My Rights As a Participant?

Taking part in this study is voluntary. You may choose not to take part or may leave the study at any time. If you agree to take part and then decide against it, you can withdraw for any reason. Please be sure to discuss leaving the study with the principal investigator or your regular physician. Leaving the study will not result in any penalty or loss of benefits that you would otherwise receive.

We will tell you about any new information that may affect your health, welfare or willingness to stay in this study.

You understand that you have the right to access the medical information that has been collected about you as a part of this research study. However, you agree that you may not have access to this medical information until the entire research study has completely finished and you consent to this temporary restriction.

Whom Do I Call If I have Questions or Problems?

If you have questions about the study, Muhammed Firdaus, M.D. is available to be contacted 24 hours a day at 405-271-3050. For questions about your rights as a research subject, contact the OUHSC Director, Human Research Participant Protection Program at 405-271-2045.

Signature:

In the future, researchers involved with this project may need more information about you, or may ask you if you are willing to participate in other research studies. Please check below to indicate whether or not you may be contacted within the next few years by the investigators conducting this study. If you agree to be re-contacted, you may still change your mind about providing additional information, or in participating in other research studies in the future.

_____ I may be re-contacted for information or a future study.

_____ I may not be re-contacted for information or a future study.

Subject Signature:_____ Date: _____

By signing this form, you are agreeing to participate in this research study under the conditions described. You have not given up any of your legal rights or released any individual or institution from liability for negligence. You have been given an opportunity to ask questions. You will be given a copy of this consent document.

I agree to participate in this study:

Research Subject: _____ Date:_____

Subject's Printed Name _____

Person Obtaining
Informed Consent:_____ Date:_____

APPENDIX B

Health Insurance Portability and Accountability Act (HIPAA)
Participant Form

AUTHORIZATION TO USE or DISCLOSE
PROTECTED HEALTH INFORMATION FOR RESEARCH

An additional Informed Consent Document for Research Participation may also be required. Form 2 must be used for research involving psychotherapy notes.

Title of Research Project: **The age-related influences on inflammatory markers: a pilot study.**

Leader of Research Team: **Andrew W. Gardner, Ph.D.**

Address: **General Clinical Research Center, University of Oklahoma Health Sciences Center**

1122 N.E. 13th Street, ORI-W 1400. Oklahoma City, OK 73117

Phone Number: **(405)325-1371**

If you decide to join this research project, University of Oklahoma Health Sciences Center (OUHSC) researchers may use or share (disclose) information about you that is considered to be protected health information for their research. Protected health information will be called private information in this Authorization.

Private Information To Be Used or Shared. Federal law requires that researchers get your permission (authorization) to use or share your private information. If you give permission, the researchers may use or share with the people identified in this Authorization any private information related to this research from your medical records and from any test results. Information, used or shared, may include all information relating to any tests, procedures, surveys, or interviews as outlined in the consent form, medical records and charts, name, address, telephone number, date of birth, race, and government-issued identification number.

Purposes for Using or Sharing Private Information. If you give permission, the researchers may use your private information to help evaluate the most important factors that are related to chronic inflammation and physical activity.

Other Use and Sharing of Private Information. If you give permission, the researchers may also use your private information to develop new procedures or commercial products. They may share your private information with the research sponsor, the OUHSC Institutional Review Board, auditors and inspectors who check the research, and government agencies such as the Food and Drug Administration (FDA) and the Department of Health and Human Services (HHS). The researchers may also share your private information with family members.

Confidentiality. Although the researchers may report their findings in scientific journals or meetings, they will not identify you in their reports. The researchers will try to keep your information confidential, but confidentiality is not guaranteed. Any person or organization receiving the information

based on this authorization could re-release the information to others and federal law would no longer protect it.

YOU MUST UNDERSTAND THAT YOUR PROTECTED HEALTH INFORMATION MAY INCLUDE INFORMATION REGARDING ANY CONDITIONS CONSIDERED AS A COMMUNICABLE OR VENEREAL DISEASE WHICH MAY INCLUDE, BUT ARE NOT LIMITED TO, DISEASES SUCH AS HEPATITIS, SYPHILIS, GONORRHEA, AND HUMAN IMMUNODEFICIENCY VIRUS ALSO KNOWN AS ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS).

Voluntary Choice. The choice to give OUHSC researchers permission to use or share your private information for their research is voluntary. It is completely up to you. No one can force you to give permission. However, you must give permission for OUHSC researchers to use or share your private health information if you want to participate in the research and if you revoke your authorization, you can no longer participate in this study.

Refusing to give permission will not affect your ability to get routine treatment or health care from OUHSC.

Revoking Permission. If you give the OUHSC researchers permission to use or share your private information, you have a right to revoke your permission whenever you want. However, revoking your permission will not apply to information that the researchers have already used, relied on, or shared.

End of Permission. Unless you revoke it, permission for OUHSC researchers to use or share your private information for their research will never end. You may revoke your permission at any time by writing to:

RE: The Age-Related Influences on Inflammatory Markers: A Pilot Study

Dear Dr. Gardner:

The University of Oklahoma Health Sciences Center's Institutional Review Board (IRB) reviewed the above-referenced research protocol at its regularly scheduled meeting on October 25, 2004. It is the IRB's judgement that the rights and welfare of the individuals who may be asked to participate in this study will be respected; that the proposed research, including the process of obtaining informed consent, will be conducted in a manner consistent with the requirements of 45 CFR 46 or 21 CFR 50 & 56, as amended; and that the potential benefits to participants and to others warrant the risks participants may choose to incur.

On behalf of the IRB, I have verified that the specific changes requested by the convened IRB have been made. Therefore, on behalf of the Board, I have granted final approval for this study.

This letter documents approval to conduct the research as described:

Survey Instrument Dated: October 05, 2004 Physical Activity Scale
Survey Instrument Dated: October 05, 2004 MOS-36 Questionnaire
Radiation Safety CA Ltr Dated: January 18, 2005
IRB Application Dated: December 14, 2004
Consent form - Subject Version : 3 Dated: January 28, 2005
Priv - Research Auth 1 Dated: January 06, 2005
Protocol Version : 3 Dated: January 28, 2005

As principal investigator of this protocol, it is your responsibility to make sure that this study is conducted as approved by the IRB. Any modifications to the protocol or consent form, initiated by you or by the sponsor, will require prior approval, which you may request by completing a protocol modification form.

It is a condition of this approval that you report promptly to the IRB any serious, unanticipated adverse events experienced by participants in the course of this research, whether or not they are directly related to the study protocol. These adverse events include, but may not be limited to, any experience that is fatal or immediately life-threatening, is permanently disabling, requires (or prolongs) inpatient hospitalization, or is a congenital anomaly, cancer or overdose. For multi-site protocols, the IRB must be informed of serious adverse events at all sites.

The approval granted expires on September 30, 2005. Should you wish to maintain this protocol in an active status beyond that date, you will need to provide the IRB with an IRB Application for Continuing Review (Progress Report) summarizing study results to date. The IRB will request a progress report from you approximately three months before the anniversary date of your current approval.

If you have questions about these procedures, or need any additional assistance from the IRB, please call the IRB office at (405) 271-2045 or send an email to irb@ouhsc.edu. Finally, please review your professional liability insurance to make sure your coverage includes the activities in this study.

Sincerely yours,

Martina Jelley, M.D., M.S.P.H.
Chair, Institutional Review Board

RE: The Age-Related Influences on Inflammatory Markers: A Pilot Study

Dear Dr. Gardner:

Thank you for completing and returning the IRB Application for Continuing Review (Progress Report) for the above-referenced study. You have indicated that the study is still active. At the meeting held August 29, 2005 the Institutional Review Board (IRB) reviewed and approved the Progress Report and determined that this study was appropriate for continuation.

This letter documents approval to conduct the research as described in:
Cont Review Form Dated: July 14, 2005
Protocol Dated: July 14, 2005
Consent form - Subject Version : 3 Dated: January 28, 2005
Priv - Research Auth 1 Dated: January 06, 2005

Please remember that any change in the protocol, consent document or other recruitment materials (adverstisements, etc.) must be approved by the IRB prior to its incorporation into the study procedures. Submit a completed Protocol Modification form to the IRB office. Any serious, unanticipated adverse events involving participants enrolled in this study at OUHSC must be reported within four working days on the IRB Adverse Event Report form. Any event which involves the death of a participant must be reported no later than the next working day. All other adverse events (from outside sites) must be forwarded to the IRB office within 14 working days of receipt.

Approximately three months prior to the expiration date of this approval, you will be contacted by the IRB staff about procedures necessary to maintain this approval in an active status. Although every attempt will be made to notify you when a study is due for review, it is the responsibility of the investigator to assure that their studies receive review prior to expiration.

The approval of this study expires on July 31, 2006 and must be reviewed by the convened IRB prior to this time if you wish to remain in an active status. Federal regulations do not allow for extensions to be given on the expiration date.

If we can be of further assistance, please call the IRB office at (405) 271-2045 or send an email to irb@ouhsc.edu.

Sincerely yours,

Martina Jelley, M.D., M.S.P.H.

RE: IRB No. 11841: The Age-Related Influences on Inflammatory Markers: A Pilot Study

Dear Dr. Gardner:

On behalf of the Institutional Review Board (IRB), I have reviewed your protocol modification form. It is my judgement that this modification allows for the rights and welfare of the research subjects to be respected. Further, it has been determined that the study will continue to be conducted in a manner consistent with the requirements of 45 CFR 46 or 21CFR 50 56 as amended; and that the potential benefits to subjects and others warrant the risks subjects may choose to incur.

This letter documents approval to conduct the research as described in:

Amend Form Dated: October 26, 2006
Protocol Version : 4 Dated: October 26, 2006
Consent form - Subject Version : 4 Dated: October 26, 2006
Recruitment flyer Dated: October 26, 2006 Cardiovascular Study

Amendment Summary:
1. Addition of new media flyer.
2. Revised exclusion criteria to define metabolic syndrome as having 3 or more characteristics of metabolic syndrome.
3. Revise protocol to move blood draw for the inflammatory markers and physician examination to the second visit.
4. Revised consent to update the order of the tests listed in the outline of each visit.

This letter covers only the approval of the above referenced modification. All other conditions, including the original expiration date, from the approval granted June 26, 2006 are still effective.

Any proposed change in approved research including the protocol, consent document, or other recruitment materials cannot be initiated without IRB approval except when necessary to eliminate immediate hazards to participants. Changes in approved research initiated without IRB approval to eliminate immediate hazards to the participant must be promptly reported to the IRB. Completion of approved research must be reported to the IRB.

If consent form revisions are a part of this modification, you will be provided with a new stamped copy of your consent form. Please use this stamped copy for all future consent documentation. Please discontinue use of all outdated versions of this consent form.

If you have any questions about these procedures or need additional assistance, please do not hesitate to call the IRB office at (405) 271-2045 or send an email to irb@ouhsc.edu.

Sincerely yours,

Vicki Lampley, M.D., M.P.H.

Re: The Age-Related Influences on Inflammatory Markers: A Pilot Study

Dear Dr. Gardner:

The above referenced protocol was reviewed and approved at the December GCRC Advisory Committee meeting. It is imperative that the GCRC is notified of any modifications in this protocol.

All correspondence to the IRB regarding this protocol must be copied and sent to the GCRC. Before any subjects can be seen for this protocol, it is your responsibility as the Principal Investigator to:

- Ensure the GCRC has copies of current consent forms, HIPAA authorization forms and IRB approval letters related to the protocol.
- Contact Melissa Hackney, Patient Care Manager, to schedule an in-service for the GCRC clinical staff.
- Ensure orders have been written for the protocol and signed off by the protocol M.D. and the GCRC Patient Care Manager.
- Contact John Eckmann to discuss data management issues.

In order to secure continuing funding of our GCRC, it is necessary to apprise reviewing bodies of our research accomplishments. Accordingly, it is essential that all manuscripts submitted for publication contain the following acknowledgment and a copy of the manuscript forwarded to the GCRC:

> "This work supported in part by the University of Oklahoma Health Sciences Center General Clinical Research Center grant M01-RR14467, National Center for Research Resources, National Institutes of Health."

If you have any questions or need assistance, please don't hesitate to contact me at 271-4272 or email philip-comp@ouhsc.edu.

Sincerely,

Philip C. Comp, MD
GAC Chairman

Cardiovascular Study

The University of Oklahoma, Health and Exercise Sciences Department, is performing a study to investigate the effects of age, physical function, blood vessel function, and body fat on inflammatory substances in the blood stream in healthy adults.

Healthy men and women volunteers, between the ages of 20 and 90 years, are needed to complete this study. You will receive information regarding your cardiovascular health and percent body fat.

If interested, please contact: Luke Acree
(405)325-6839

TO: All OUHSC Faculty and Staff
Subject Line: Cardiovascular Study

Volunteers who are 20 to 90 years of age and healthy are needed for a research study being conducted at the General Clinical Research Center. The purpose of the study is to examine the effects of aging on naturally occurring markers of inflammation in the blood stream. You will receive a report that includes information including basic cardiovascular measurements as well as a percent body fat assessment, after your participation is complete. If interested, contact Luke Acree at (405) 325-6839 or lacree@ou.edu for more information.
