## ACKNOWLEDGMENTS

The author wishes to express her appreciation to the Agronomy Department for the use of its facilities.

Special recognition and appreciation is due Dr. Lester W. Reed, thesis adviser and chairman of the graduate committee for guidance, patience, and encouragement during this study. My appreciation also goes to Dr. Dale E. Weibel and Dr. J. Q. Lynd, for their invaluable assistance and efforts as members of the graduate committee.

Deepest appreciation is extended to my husband, Mohsen, for his encouragement, understanding and love during this study. I am also indebted to my son, Wail, for his understanding during this period of study.

To the typist, Mrs. Diane Monn, I also wish to record my appreciation.

## CHAPTER I

### INTRODUCTION

About twenty-five percent of the earth's surface is sufficiently arid for salt accumulation in the soil. In the United States a large area, especially in the Western states may contain soil areas classified as saline soils. Near Altus, Oklahoma, there is a large area of irrigated soils known as the Tillman-Hollister Complex. Small acreages of these soils are beginning to show significant accumulation of soluble salts. These saline soils appear to be growing in areal extent and the need for leaching and subsurface drainage appears to be increasing. There are two hypotheses to explain the origin of soluble salts in these soils. Irrigation water from the Altus-Lugert Reservoir has a soluble salt burden in excess of 1500 ppm soluble salts and if these salts accumulate in the soil excess salinity is possible. A second source of soluble salts may be found in the soil itself, that is, these soils were developed from Permian Redbed parent material and old alluvium and most Permian geological formations in Oklahoma contain some soluble salts, therefore soluble salts in these soils may be inherited from the parent material. In addition to these two possible sources of soluble salts in these soils there may be other sources of minor nature such as municipal refuse, etc. These other sources are considered to be minor.

The research reported here is an attempt to study the mineralogy and the chemistry of irrigated Tillman-Hollister soil to provide some information concerning the extent of the salinity problem and to make some estimate of the change in soluble salt content of a saline or potentially saline area.

## CHAPTER II

### LITERATURE REVIEW

In arid and semiarid areas the vertical and horizontal expansion of cultivated soils meet some difficulties as a result of soil salinity.

Among the soil formation factors which affect soil salinity are:

- (1) the parent material, igneous rocks and sedimentary parent rock;
- (2) the climate, arid and semiarid weather including the amount of precipitation and the temperature daily and annually; and (3) the vegetation, as a result of non-vegetation, humus content is low.

Some salts more or less soluble in water are the result of the weathering processes on rocks. The predominant salts are chlorides, sulphates, and carbonates of calcium, magnesium and sodium, while the minor salts are nitrates.

These salts are classified according to their water solubility to:

- (1) salts of low solubility, calcium and magnesium carbonates;
- (2) salts of medium solubility, calcium sulphate; and (3) salts of high solubility, sodium carbonate, sodium and magnesium sulphate, and calcium, magnesium and sodium chloride.

The U.S. Salinity Laboratory (1953) proposed a simple classification separating the salted soils into three groups: (1) Saline soils: These soils contain a relatively high concentration of soluble salts. The sodium makes up more than one-half of the soluble cations. The pH

value is 8.5 or less, and the exchangeable sodium percent is less than 15. These soils were designated as Solonchak in the Russian classification; (2) Saline-alkali soils: These soils are distinguished by a high concentration of soluble salts, but the exchangeable sodium percent is greater than 15. The pH value exceeds 8.5. It is the Solonetz in the Russian classification; and (3) Non-saline-alkali soils: These soils contain a low concentration of soluble salts, but they have a larger amount of adsorbed sodium, the exchangeable sodium percent exceeds 15. The pH values range between 8.5 and 10. These soils are the Solod in the Russian classification.

The presence of large amounts of exchangeable sodium and soluble salts leads to the lack of structure and swelling of material when moist, to retarded development of soil in drying, to limited mobility of moisture, low rate of air exchange, and to strong compression of the soil and its resistance to tillage. Harris (1931) studied the relation between soil permeability and replaceable Na and concluded that the permeability decreases exponentially as the Na concentration increases.

Sources of saline salts are: (1) from the sedimentary parent material during the process of rock's deposition at the bottom of a sea or a salt lake where the salts are accumulated; (2) translocation of salts by wind or by precipitation as may happen around coastal maritime areas where a continuous evaporation of sea water results in precipitated salts that may be carried by wind to other areas; (3) the saline ground water as a result of igneous rocks weathering accompanied by soluble salt formation; and (4) irrigation water can bring salts to the soil especially when river water is strongly mineralized in arid areas.

### Formation of Saline Soils Concepts

The formation of saline soils is associated with the introduction of salts by the mineralized groundwater and their accumulation in the superficial horizons of the soil due to the evaporation of groundwater at the surface. The nature of the salt accumulation and saline formation is determined by the vegetation and the depth and the composition of groundwater.

Polynov introduced the concept of the critical depth of groundwater, meaning the maximal water table depth for which salinization of the superficial soil horizon is possible. The critical depth for soils and subsoils of various mechanical composition is within the limits of 1.5 to 3.5 m. It is less on heavy clay and sand, and greater on loamy and loess subsoil.

The degree of salt accumulation, for equal depth of groundwater, increases with the increase in their mineralization, primarily associated with aridity of the climate. When mineralization is small, bicarbonates and carbonates of alkalis predominate in the salt composition. When the degree of mineralization increases, an accumulation of sulphates occurs, mostly in the form of gypsum and due to this, sodium carbonate disappears.

The soil is characterized by the accumulation of sodium sulphate ( $\text{Na}_2\text{SO}_4$ ), and at the same time by the deposition of gypsum ( $\text{CaSO}_4$ ) and calcium carbonate ( $\text{CaCO}_3$ ).

Sodium chloride begins to predominate over all the other salts in very high mineralization of groundwater.

Due to the great differences in salt solubilities in the groundwater and soil solution, maximum accumulations of individual salts occur in different horizons of salt profile of the saline soil. The most readily soluble salts, particularly chlorides, accumulate on the surface. The less soluble gypsum, lying below, and calcium carbonate, still lower.

The processes which lead to the formation of saline soils have been summarized by Magistad (1945) as follows: (1) Salinization: the process of salt accumulation in soils and concentration by water evaporation. Sodium salts usually predominate in the early stages of salinization. Calcium carbonate and calcium sulphate are less soluble, so they accumulate more slowly and precipitate as the process of evaporation and concentration proceed; (2) Alkalization: as salts accumulate in soils there is an equilibrium established between the positively charged ions in solution, and those adsorbed on the colloid. As sodium salts become more concentrated in the soil solution, greater quantities are adsorbed. As the percentage of exchangeable sodium is increased, the soil becomes more alkaline in reaction, and for this reason the process is termed alkalization; (3) Desalinization: this is the process of leaching away soluble salts from soils which have had large accumulation. When the salts are largely removed, the colloids tend to disperse and permeability decreases; and (4) Degradation: if a soil undergoing desalinization does not contain gypsum or calcium carbonate, there are few bases to replace sodium after the soluble salts have been removed. Exchangeable sodium then tends to hydrolize

and form sodium hydroxide with hydrogen being added to the clay. The NaOH results in a dispersion of organic matter, sometimes called a "black alkali" condition. The sodium hydroxide reacts readily with carbon dioxide from the soil air to form sodium carbonate.

With extensive leaching, the sodium carbonate is gradually removed, and the hydrogen exchange for sodium is brought to near completion with a resulting drop in the soil pH.

#### Effect of Saline Irrigation Water on Soil Characteristics

Kelley et al. (1940) reported that the soluble salts of irrigation water are very important due to its effect on the concentration and composition of the soil solution, and their effect on the absorbed bases of the soil. With a given irrigation water, the former is greatly influenced, and the latter to some extent, by the inherent properties of the soil, its permeability and profile characteristics, the climatic conditions, and the amount of the water applied. They added that sodium salt solutions react with soils by base exchange with resulting absorption of Na by the soil. This effect increases with increasing concentration of solution and also as the ratio of Na:Ca increases. The presence of absorbed Na soils tends to affect their physical properties adversely.

Although agricultural science has shown that saline water can be used, within limits, for the successful cultivation of certain salt-resistant plants, as described by Kearney and Scofield (1936) and by Foaden (1897), two factors must be considered; namely, the direct effect of saline water on the soil, which in turn will affect the growth of plants. Puffeles (1939) investigated the effect of saline water on the loess soils of the Beersheba area (southern Palestine). This type of soil is highly permeable to air and water and possesses good physical properties but the soil is poor in nutrients. He found that if the very saline water that is available is used for irrigation, under favorable climatic and drainage conditions, such as obtained in this area, the salts will not accumulate, but instead an alkaline salt will, in time, be formed by base exchange and this will lead the soil to be useless for agricultural purposes.

Doneen (1954, p. 944) states:

When nonsaline soils, irrigated for some years, gradually develop a high salt concentration, it is usually due to the accumulation of soluble salts brought in with the irrigation water. Under high water-table conditions, the concentration of salts occasionally may be due to soluble salts from the deep subsoils coming to or near the soil surface with the rise of the water table, and some salts may be dissolved from the soil by the water table. This dissolving of the soil minerals is probably a minor source in salt accumulation for a short period of time, and most of the salt increase may be directly attributed to the irrigation water. In the absence of a high water table, the irrigation water would be the main source of salts in the development of a saline soil.

Some investigators show that the soil solution in well-drained soil to be more concentrated than the irrigation water used. Under this condition Scofield (1935) found that the soil solution in heavily leached soil may be twice as concentrated as the irrigation water; and

under less severe leaching where the water is used sparingly, the difference is much greater, often eight times or more the concentration of the irrigation water. This concentration of salts in the soil is due to two factors, evaporation from the soil surface and water used by the plants in transpiration. Plants usually remove only a small percentage of the total salt occurring in the irrigation water.

Harper and Stout (1950) studied the effect of ten years of irrigation of cotton with water which had a Ca:Na ratio of 1:2 from the S.W. Oklahoma Cotton Station at Tipton. They showed that the pH of an irrigated soil rose as compared with nonirrigated soil. Exchangeable Na was higher in the irrigated soil, but exchangeable K was similar for both soils. Very little soluble K was found in either soil. Exchangeable calcium was much lower in the irrigated soil.

McGeorge et al. (1952) found that two years of irrigation with a water containing a conductance of 6 millimhos and a sodium percentage of about 83 increased the exchangeable sodium percentage of soil on the Arizona Safford Experiment Farm from about 10 to near the equilibrium value of 25. These results indicate that many effects of irrigation water are established in relatively short periods of time.

Thorne and Thorne (1954) found that the salt content of the soils was closely related to the salt content of the irrigation waters. They also found that the percentages of exchangeable sodium in the soils had significant regressions on sodium percentages, weighted sodium percentages, sodium adsorption ratios and the theoretical exchangeable sodium percentages for the irrigation waters in their study.

Plice (1949, p. 278) states:

Salt (sodium chloride) injures soil by dispersing it, at the time causing organic matter and exchangeable material to be lost. The extent of the damage it does is not entirely proportional to the amount of salt present. The maximum physical injury done to soils seems to occur at the time the soil again has about the same amount of total sodium it originally had, or even less.

The movement of water through the soil profile is an important mechanism in soil development. During irrigation, additional waters with chemical compositions different from that of rainfall are applied to the soil. River and ground waters often acquire significant quantities of mineral salts between the time the water falls as rain and the time it is intercepted for irrigation. Under intensive irrigation these dissolved salts have certain influences on the soil.

In irrigated areas, some soil problems such as decreased soil permeability, development of saline or alkali soils, and increased requirements for specific soil amendments, are traceable to the influence of irrigation water.

Chapman and Kelley (1930), Kelley et al. (1949), Bushnell (1949), and Hosking (1948) have shown that relatively insoluble constituents, such as the carbonates and sulfates of calcium and the soils' minerals themselves, have a great influence on chemical equilibriums established in soils.

Irrigation waters containing an excess of carbonates and bicarbonates may precipitate much of the calcium and magnesium and thus cause sodium to become the predominant cation in the soil solution. This theory has been postulated by Eaton (1950), and corrective measures have been suggested (Eaton, 1954). In a study of this high bicarbonate factor, Wilcox et al. (1954) concluded that bicarbonate

would have to exceed a concentration of 1.25 me per liter of water before it could be considered important.

Lewis and Juve (1956) studied the effects of irrigation water quality on soil characteristics in Idaho soils. They found that: (1) soluble salts were evenly distributed throughout the profiles of the irrigated soils; (2) the soluble calcium content of the soil was reduced in general, with increasing depth in the profile; (3) there was a correlation between the sodium-adsorption ratio of the irrigation water and that of the saturation extract of the soil; (4) there was a good correlation between the sodium-adsorption ratio of the saturation extract and the exchangeable sodium percentage of soil; (5) saturation extracts from soils approach the chemical composition of irrigation water applied to them; and (6) the calcium carbonate content of the soil showed an increase when irrigation water high in calcium and bicarbonate ions are used.

#### Influence of Exchangeable Cations on Soil Properties

Among the important cations which can affect the physical and chemical properties of soils are sodium (Na), calcium (Ca), potassium (K), and magnesium (Mg).

The dispersion of soil colloids and resultant breakdown of aggregation as a result of the adsorption of high percentages of Na ions by the soil exchange complex is widely noted (Gedroix, 1931; Chang and Dregne, 1955; and DeSigmond, 1927).

Gedroix (1931) by artificially saturating Chernozems with various cations reports increasing deflocculation with increasing degree of Na

saturation of the exchange complex. Also noted was the fact that Mg reacts in a manner similar to Na when the exchange complex is completely saturated with either cation. The work of Veihmeyer and Hendrickson (1937) is in agreement with Gedroix's results as pertaining to the rate of Na in deflocculation.

The effects of exchangeable calcium on the physical properties of soils are better understood than the effects of exchangeable potassium and magnesium. Most of the literature indicates that the role of exchangeable potassium and magnesium is controversial.

Shawrguin (1935), Joffe and Zimmerman (1945) and others have concluded that exchangeable magnesium has an effect similar to that of exchangeable sodium. Others believe that magnesium has an effect similar to that of calcium. Few, if any, investigators have given satisfactory reasons for the poor soil physical conditions sometimes associated with the high exchangeable magnesium. Baver and Hall (1937, p. 18) pointed out that "the low flocculating power of the magnesium ion with respect to organic matter suggests a possible explanation of the formation of magnesium solonetz soils." Gill and Sherman (1952) have associated the poor physical properties of some Hawaiian soils with their high contents of exchangeable magnesium. They suspected that the reason for the low permeability and high plasticity was that the hydration of the exchangeable magnesium ion is greater in the presence of certain humates and that this hydration results in a dispersion of the clay and organic matter.

## CHAPTER III

### METHODS AND MATERIALS

All soil samples for this study were collected from the Altus Irrigation Station, (Oklahoma Agricultural Experiment Station), Altus, Oklahoma. The soil studied was the Tillman-Hollister clay loam (fine mixed, thermic Typic-Pachic Paleustoll). The soil samples were air-dried in the laboratory and ground and screened to pass through 20-mesh sieve, for physical, chemical, and mineralogical analyses.

#### Physical Analyses

Particle size distribution analyses (mechanical analyses) were determined by the Hydrometer Method (Day, 1956). The method used was as follows: weigh out 50.0 grams of soil for analyses and add 50 ml of distilled water, shake for one hour, centrifuge, decant and the extraction solution was kept for chemical analyses, the remaining soil was transferred to 1000 ml sedimentation cylinder. Add 10 ml of sodium carbonate solution, and bring to the 1000 ml mark with distilled water. Move cylinder into constant temperature room.

When the suspension has reached constant temperature, insert the plunger and move it up and down to mix the contents thoroughly. Material trapped at the bottom will require strong upward strokes of the plunger to lift them into suspension. When the suspension has been

thoroughly mixed, note the time and remove the plunger, tipping it slightly to remove adhering drops of suspension.

Lower the hydrometer carefully into the suspension and, at the end of 30 seconds, read the scale at the top of the meniscus. Without removing, read again at the end of one minute. Remove carefully, wipe clean with a soft towel, and be ready to repeat at the end of three minutes.

Subsequent hydrometer measurements should be made at three minutes, 10 minutes, 30 minutes, 90 minutes, 4 hours, 8 hours, and 12 hours, or at other conveniently spaced intervals. Each time a measurement is to be made, the hydrometer should be lowered carefully into the suspension 20 seconds before the desired time and removed carefully after reading.

#### Chemical Analyses

The chemical analyses consisted of the determination of the total soluble salts, the electric conductivity (EC), the chlorine (Cl), and the extractable sodium, calcium and magnesium. The extractable cations were determined with the atomic absorption spectrophotometer as described in U.S.D.A. Handbook No. 60 (1954).

#### Mineralogical Analyses

The total clay suspension was saved for x-ray diffraction analyses. After 24 hours the clay suspension (at depth of 30 cm) was siphoned off and saved. The hydrometer cylinder was refilled to 1000 ml with distilled water, shaken, allowed to stand for 24 hours, and then siphoned off again. Siphoning was repeated until the suspension (after setting 24 hours) was essentially clear. All horizons for profile No. 1

were analyzed by x-ray. In these analyses, coarse clay and fine clay were the only fractions analyzed.

The preparation and x-ray examination of samples were described by Black et al. (1965). A dilute suspension of clay, containing approximately 25 mg clay, was added to the surface of a porous ceramic plate after Ca-saturation, ethylene glycole, and K-saturation. The samples were air-dried and x-rayed. The K-saturated samples were heated to 550 C for four hours and then x-rayed again.

## CHAPTER IV

### RESULTS AND DISCUSSION

#### Physical Analyses

The particle size distribution in the nine profiles of Altus irrigated soil studied are reported in Tables I to IX. The sand and silt were subfractioned to coarse, fine, and very fine sand for the sand group, and coarse silt and fine silt for the silt group. The relative percentage of fine to coarse sand, generally decreased by depth except in profiles 4, 5, and 7, where the decrease was in the B horizon then the percentage increased, while in profile 9, the percentage of fine to coarse sand increased with depth (Table IX). The percentage of fine to coarse sand in all profiles ranged between 13 and 50. Profile 9 contains the lowest percentage (19) of f/c sand in the A horizon, while profile 8 contains the highest percentage in the same layer (31%).

The percentage of very fine sand generally decreased with depth in all profiles and its values were generally less than that of the fine to coarse sand ratio. The relative percentages of the silt group where the ratio of coarse silt to fine silt were less than sand and clay percentages in all profiles. The percentage of coarse silt was double or more than the fine silt, however, the coarse silt generally decreased with depth. The silt is distributed through the profiles with very little change from horizon to horizon.

The percentage of clay in all profiles increased substantially in the B horizon and then decreased in the C horizon. The dominance of clay in the B horizon is probably due to illuviation.

#### Mineralogical Analyses

Profile No. 1 was studied by x-ray diffraction for identification and differentiation of clay minerals.

##### K-saturated Air-dried Samples

This treatment allowed the separation of vermiculite from hydrous micas (illite) where hydrous mica was observed as the  $10\text{\AA}$  diffraction peak, and vermiculite did not tend to collapse.

##### K-saturation and then Heating of Samples to 550C

This treatment aids in identification of clay minerals. First, it causes the collapse of vermiculite and other 2:1 micaceous minerals which may contain non-exchangeable interlayer aluminum hydroxy complexes. Second, it destroys the kaolin minerals. When chlorite is present in the sample, it normally yields a second-order peak maximum at nearly the same position as the first-order maximum of kaolinite (7.15A). If a 7.15A spacing is obtained from an unheated sample, or disappears or is decreased in intensity after heating to 550C, the presence of kaolinite is confirmed.

##### Ca-saturated Air-dried Samples

A diffraction spacing of approximately 14A obtained from Ca-saturated preparations indicates the following clay minerals:

vermiculite, chlorite, montmorillonite (smutite), or a mixture of these species.

#### Ca-saturated and Ethylene Glycol-solvated Samples

These treatments give a diffraction spacing of 17-18A which may indicate the presence of montmorillonite which expands from 14 to 17 or 18A upon ethylene glycol solvation of Ca-saturated samples.

The results of the x-ray mineralogical analyses for the fine and coarse clay are presented in Table X.

#### Fine Clay

Mica, kaolinite and quartz were dominant in all horizons of these profiles. Montmorillonite, vermiculite and chlorite were present to a lesser extent in the surface layer where more of the total clay of the A horizon may be in the coarse fraction (2.0 - 0.2 $\mu$ ). Jackson (1956) noted that the coarse clay (<2 $\mu$ ) may be abundant in hydrous mica (illite) and that large amounts of poorly crystallized hydrous micas with poorly resolved basal spacings may not be detected in the presence of large amounts of montmorillonite or kaolinite. In the B and C horizons where the fine clay was abundant, montmorillonite, vermiculite, chlorite, mica, kaolinite and quartz all gave strong diffraction patterns. The presence of quartz in all profiles may have been enhanced by quartz in the ceramic slides used as mounts for the clay samples. The presence of kaolinite in the fine clay was not completely understood. Some small crystals of calcite were also found in the fine clay. Calcite was found in the fine clay at depth of 180-225 cm.

Weak = m, v, cl, Mi, K, Q

Strong = M, V, Cl, Ca

M = montmorillonite

V = vermiculite

Cl = chlorite

Ca = calcite

K = kaolin

Q = quartz

Mi = hydrous mica

### Coarse Clay

Mica, quartz and calcite were dominant in the A, B and C horizons. Montmorillonite, vermiculite and chlorite gave weak diffraction patterns in the A and B horizons which may have been due to the dominance of quartz and mica in the coarse clay. With depth, all these minerals gave strong diffraction patterns. As mentioned in the discussion of the x-ray mineralogy of the fine clay, kaolinite was usually present. However, in some of the coarse clay samples, kaoline was not present which was unexpected and no explanation can be given at this time for a satisfactory explanation of the absence of kaolinite.

### Chemical Analyses

The soluble salts composition of all soils are reported in Tables XI to XIX.

### Electrical Conductivity (EC)

The salt content of the soil can be estimated roughly from an electrical conductivity measurement on a saturated soil paste or in a 1:1 water extract of the soil. The  $EC_{250C}/cm$  of soil samples, generally, increased with depth. This increase of  $EC_{250C}/cm$  by depth may be due to the leaching process of the irrigation water. While the majority of the profiles showed an increase of EC with depth and then a decrease in the C horizon, profile No. 1 showed a gradual increase in the EC until the C horizon, while it showed a decrease in the B horizon. Most of the profiles showed a negligible salinity effect in the A horizon, except profile 1 and 8 where the EC ranged from 4700 to

35000  $\mu\text{mho/cm}$ . This high value of EC in these profiles could restrict the yield of many crops. Profile 8 shows a decrease of EC with depth and this can be attributed to the accumulation of soluble salts on the soil surface as shown in Table XVIII where the EC was 35000  $\mu\text{mho/cm}$  in the layer 0 - 1.25 cm, and the TDS (Total Dissolved Solids) were 46730 ppm in the same layer.

#### Total Dissolved Solids (TDS)

The amount of soluble salts (TDS) showed a large variation in the increase or decrease in each profile. Generally the soluble salts increased in the B horizon and then decreased in the C horizon, except in profile 1 where the soluble salts increased from the surface down to the C horizon. Profile 8 was an exception for all of the profiles, due to an accumulation of soluble salts on the soil surface as in the 0 - 125 cm layer as shown in Table XVIII.

#### Soluble Cations and Anions

The soluble cations determined were sodium (Na), calcium (Ca), and magnesium (Mg). The chlorine (Cl) was the only anion determined and both cations and chlorine are reported in Tables XI to XIX.

The chlorine (Cl) ion, generally increased with depth and then decreased in the C horizon except in profiles 1, 2, and 9. In profile 8 the surface layer (0 - 1.25 cm) contained a very high amount of Cl (10937.00 ppm) and this was mentioned previously in the discussion and was due to an accumulation of soluble salts on the soil surface.

The dominant cation was sodium (Na) and it usually increased with depth in the B horizon and then decreased in the C horizon except in profile 9 where it increased with depth into the profile.

Calcium (Ca) showed less tendency to increase with depth probably due to lower solubility and accumulation at the upper layers of the profile.

Magnesium (Mg) increased with depth through the B horizon and then decreased in the C horizon.

#### Exchangeable Sodium Percentage (ESP)

The ESP for the soils studied ranged between 0.15 to 10.27 as is shown in Tables XI to XIX. It is known that the structural deterioration of soil results only indirectly from the use of high Sodium Absorption Ratio (SAR) irrigation water. The ESP, a function of SAR, may be used as an indication of the extent of structural breakdown in irrigated soils. While 15% exchangeable Na is generally considered to be the point at which structural breakdown begins, it is logical to assume that soils of low clay content may tolerate higher exchangeable Na percentages than do fine textured soils.

The Sodium Absorption Ratio (SAR) did not exceed 8.81 in any of these soil samples. The SAR of these soils was very well correlated with the ESP with an "r" of .96. Both SAR and ESP increased with depth except for profile 8 where the surface layer (0 - 1.25 cm) had an SAR of 8.81 and an ESP of 10.27 and these results were probably due to the accumulation of soluble salts on the soil surface. The increase of ESP by depth can be explained by the role of irrigation water in leaching soluble salts downward into the soil profile. It is suggested that the

irrigation water should be analyzed to determine the principal source of salinity. Another explanation for the increase of SAR and ESP with depth may be due to the local soluble salts from the parent material in the profile.

## CHAPTER V

### SUMMARY AND CONCLUSIONS

Nine profiles from an irrigated Tillman-Hollister soil were investigated for their mineralogical, physical, and chemical characteristics.

The percentage of fine to coarse sand generally decreased with depth. The percentage of very fine sand also decreased with depth. The percentage coarse and fine silt were present in lower percentages than sand and clay, and both the coarse and fine silt decreased with depth. The percentage of clay increased substantially into the B horizon and then decreased in the C horizon. The dominance of clay in the B horizon may be due to illuviation.

Mineralogical determinations by x-ray diffraction of these profiles showed that mica, kaolinite and quartz were dominant in the fine clay fraction of all profiles, whereas mica, quartz and calcite were dominant in the coarse clay fractions. Montmorillonite, vermiculite and chlorite were present to a lesser extent in the fine clay fraction from the surface layers. Weak diffraction patterns for these minerals were observed in the A and B horizons for the coarse clay fractions. It was found that kaolinite was present in the fine clay fraction but did not exist in the coarse clay fraction. This phenomenon was not completely understood. Small crystals of calcite were found in the fine clay at depths of 185 - 225 cm.

The chemical analyses of these soils showed that the EC increased with depth and decreased in the C horizon. All profiles showed low EC values except profile No. 8 where the EC varied from 4700-35000  $\mu\text{mho/cm}$  but it decreased with depth. The total soluble salts generally showed an increase in the B horizon and then decreased in the C horizon.

The chlorine content increased with depth but decreased in the C horizon except for profile No. 8 where the accumulation of soluble salts was very high in the surface area.

The dominant cation was sodium which increased with depth and decreased in the C horizon except for profile No. 9 where it increased with depth through all the profile. Magnesium concentration was similar to sodium, while the calcium decreased with depth.

The ESP and SAR showed an increase with depth and this was probably due to the role of irrigation water in leaching the soluble salts downward into the soil profile.

It is suggested that the irrigation water may be one of the causes of salinity in these soils plus the effect of the local salts in the parent material.

VITA<sup>~</sup>

Hoda Abbas Ahmed El-Shayeb Selfo

Candidate for the Degree of

Master of Science

Thesis: MINERALOGY AND CHEMISTRY OF AN IRRIGATED TILLMAN-HOLLISTER SOIL

Major Field: Agronomy

Biographical:

Personal Data: Born in El-Batanoun, Minufia, Egypt, March 29, 1948, the daughter of Mr. and Mrs. Abbas Ahmed El-Shayeb.

Education: Graduate from Al-Horia High School, Shebin El-Kom, Minufia, Egypt, in 1966; received the Bachelor of Science in Chemistry degree, with a major in Chemistry and Physics, from Faculty of Science, Ain Shams University, Cairo, Egypt in 1970; completed requirements for the Master of Science degree, with a major in Agronomy in 1976.

Professional Experience: Employed by the Ministry of Education, Sayeda Esha Junior High School, El-Batanoun, Minufia, Egypt, 1971; graduate assistant at Oklahoma State University, 1974-1976.
