SOUTH DAKOTA

Corn Performance Tests, 1951

By G. E. NACHTIGAL and D. B. SHANK[1]

Corn yield trials were conducted again in 1951 by the Agronomy department of the South Dakota State College Experiment Station to supply farmers with information on popular hybrids which are planted extensively in the various agricultural areas of the state. The information obtained in the 1951 yield tests reflects the relative performing abilities of the different hybrids in a cool season. Throughout the season, temperatures averaged several degrees below normal, while moisture was generally excessive. This resulted in a corn crop that was soft and immature. The results are presented in the tables which follow.

Location of the 1951 Tests

Eight agricultural areas have been set up in the state and corn tests were conducted in each of these areas (Fig. 1). In establishing these areas, consideration was given to the effects which various soil types, rainfall, temperature, and elevation have on crop production. At least one corn performance test was located in each area while two performance tests were planted in Areas 1, 3 and 8. The exact location of each test, the cooperator, and the soil type are given in Table 1. Anyone evaluating and selecting a hybrid variety should consult the results of the tests conducted nearest to his farm.

Table 1. Location of the 1951 Tests

District	County	Cooperator	Post Office	Soil Type	Date Planted	Date Harvested

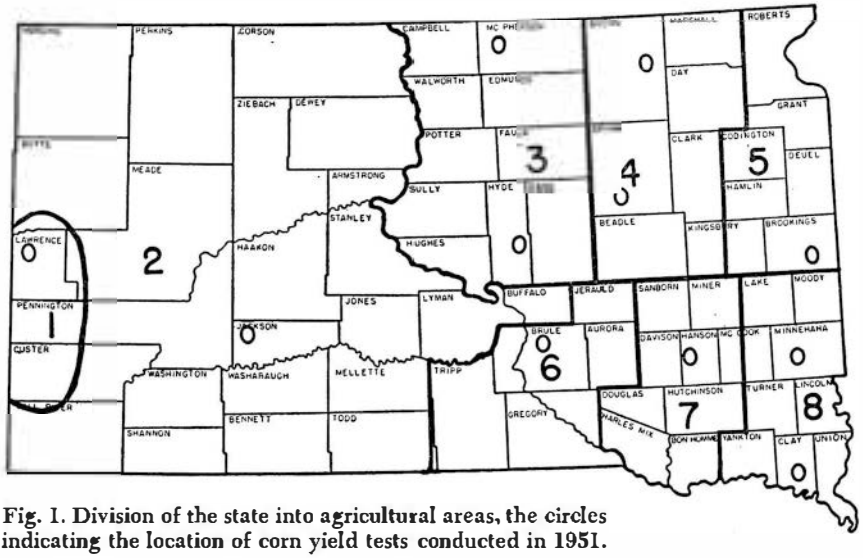

Fig. 1. Division of the state into agricultural areas, the circles indicating the location of corn yield tests conducted in 1951.

Temperature and Rainfall

Temperature and rainfall data are presented in Table 2. Where information was not available for the immediate vicinity of each test plot, reports from the closest station were used. In 1951 the temperature was consistently below average while rainfall was high, resulting in very soft corn. Briefly, month by month the weather for the state was as follows:

May: Temperature and precipitation was about average. Cool, showery weather delayed corn planting in many places.

June: The mean temperature for the state was 6.4 degrees[2] below the average. Snow occurred in the Black Hills on June 1. Precipitation was 1.01 inches above average over the state. Corn developed slowly, especially in late planted fields.

July: Temperatures were below the weekly mean the first seven days and slightly above the rest of the month, resulting in 2.7 degrees below average for the whole month. Precipitation was above average the first two weeks and below, the rest of the month. Corn grew slowly the first part of July because of the cool weather.

August: The first two weeks were warm while the last two were cool. Temperatures for the month were 2.7 degrees below average while rainfall was 1.64 inches above average. Brookings had the most rain with 8.29 inches for the month. Corn grew fairly well during this month.

[2]Figures and monthly climatological information were obtained from the same Weather Bureau reports used in setting up Table 2.

*Information presented was taken from Monthly Climatological Data, U. S. Dept. of Commerce, Weather Bureau, Huron, South Dakota.

†Number of days between 32°, or below, in the spring and 32°, or below, in the fall.

‡No figures available.

September: Temperatures for the month averaged the second lowest since 1890. Killing frosts occurred in the central part of the state on September 24 and over most of the state on September 28. During the last week the state average temperature was 15 degrees below the mean. Cool temperatures throughout May, June, July, August and early September delayed corn development. The frosts in September killed the corn, much of which was not yet dented in many fields.

October continued to have below-average temperatures and above-average precipitation. November also had temperatures 3.5 degrees below average. These lower temperatures reduced the drying of corn after frost had killed it.

Selection of Entries

In order to select entries for the tests, a survey was conducted to ascertain those hybrids which were purchased most by farmers in the agricultural area represented by each test. Information was obtained on the hybrids of those companies which registered their corns with the South Dakota State Department of Agriculture. The survey included recommendations by representatives of the corn companies producing and registering the hybrids, and lists submitted by county agents located in the areas where the tests were conducted. Facilities permitted testing only the most widely used hybrids.

Method of Planting and Harvesting

Planting. Each group of entries was planted in four or five replications. Within these replications, plots of individual hybrids were located at random. Each plot consisted of two rows, 10 hills long, or the equivalent if the corn was drilled rather than checked. Planting was done at the rate of three kernels per hill for the check plots, one per hill for the drilled plots. Where tests were located with farmer cooperators they received the same fertilizer applications and cultural treatments as did their corn. Planting dates are given in Table 1.

Harvesting. The tests were picked at the time general harvesting was going on in the surrounding area. The corn from each plot was picked separately and weighed. After weighing, samples for moisture determination were taken on three replications of the plots. This was accomplished by selecting 12 ears at random, taking a one-inch cross section from the middle of each ear by means of a machine built for this purpose, and placing the 12 cross sections in a paper bag. The samples were weighed when taken in the field, then they were oven-dried at 105 degrees C. in the laboratory, reweighed and the moisture percentages determined. Harvesting dates are given in Table 1.

Measuring Performance

Yield. The yield reported for each hybrid or variety in each test is the average obtained for all replications, expressed in bushels per acre on the basis of 15.5 percent moisture. All yields were computed from the field weights which had been corrected according to the moisture content of the individual entries. At the bottom of each table of results (Tables 3-14 inclusive) is given the minimum amount for the 1951 tests by which two entries must differ in yield in order for that difference to be considered statistically significant.

A slight amount of variation can occur between entries of equal performance potential because of field conditions such as variations in soil type, stand, and slope. Therefore, mathematical determinations have been made to establish what difference it is necessary to have between two entries before it can be said that there is a true difference between them rather than a chance variation. For example, in Brookings County (Table 10), a difference of 4.4 bushels per acre in the yield of two entries is required before it can be said that one has a superior yielding ability over the other. This difference, required for significance, varies from test to test, depending upon amount of chance variation within each.

Also, at the bottom of the yield column in each table appears the average yield of all entries.

Moisture content. The moisture content at harvest is given for each entry in the tables. This is the amount of moisture in the ear corn expressed in percentage. At the bottom of the moisture percentage column in each table appears the average moisture content of all entries. Moisture content is directly related to maturity, and because maturity is of primary consideration in South Dakota, these figures are very important when an evaluation of the various entries is made.

Performance score. Each entry in the various tables is ranked on the basis of a performance score. This score was computed for each entry from its 1951 performance record, expressed as a percentage of the average of all entries. In such calculations, yield was weighted 60 percent and dry matter (100 minus percent moisture) 40 percent.

Stand. A reduction in the number of hills below 100 percent is taken to mean that either the seed of an entry is unable to produce a good stand under the environmental conditions prevailing for the test, or that something destroyed either the kernels before germination or the young plants. Thin stands reduce yields and since this work is designed primarily to test yielding potential of the various entries, rather than germination, corrections in yield were made for missing hills according to the formula:

$$CW = FW \left(\frac{H - 0.3M}{H - M} \right)$$

where CW = corrected weight, FW = field weight, H = number of hills per plot and M = number of missing hills. No yield corrections were made

for minor variations in stand, that is, less than three stalks per hill. Also, no corrections were attempted for poor stands in drilled plots.

Lodging. In the Brookings County test, stalk and root lodging figures for 1951 are presented. Stalk lodging is expressed as the percentage of stalks which were broken below the ear at the time of harvest. Root lodging is the percentage of stalks which lodged 30 degrees or more from the perpendicular at the time of harvest.

Results over a period of years. Many of the entries included in the 1951 trials were also tested in previous years. This makes possible the calculation of two-, three-, four- and five-year averages in some cases, and such data are included in many of the tables which follow. These averages are more useful than the results obtained in a single year for determining the value of any hybrid or variety, for in any one year an entry may fluctuate in its relative value because of specific environmental conditions under which the test was conducted. Averages for a period of several years will iron out these environmental variations. A hybrid or variety was included in the averages only when it was the same variety each year and was secured from the same source.

Black Hills Area

Lawrence County. Two tests were planted on farms of Walter Tetrault just northwest of Spearfish. One was on dry land; the other was under irrigation. The irrigated test was so immature that it was used for silage. In the dry-land plots both stands and moisture contents at harvest were quite variable. Damage caused by deer also caused yield reductions for some entries. The dry-land test was planted May 15 and harvested October 24.

West River Area

Jackson County. The test in this county was located on the Range Field Station at Cottonwood. Yields obtained were low while moistures were high. One variety, Gehu, gave no yield at all. The others, however, yielded some corn in 1951 which they were unable to do in 1949 and 1950. The test was planted May 16 and harvested October 25.

North Central Area

McPherson County. A test is conducted each year on the North Central Station located at Eureka, South Dakota. This is the northernmost test and the corn in 1951 was extremely wet, running up to 70 percent moisture for some entries at harvest time. The plots were planted May 29 and harvested October 23.

*Differences in yield of less than 5.4 bushels per acre are not statistically significant.
†No test was harvested in 1949. Therefore, the three-year averages are for 1951, 1950, and 1948, the four-year averages are for 1951, 1950, 1948, and 1947; the five-year averages are for 1951, 1950, 1948, 1947, and 1946.

North James River Area

Brown County. Ellis Barnes continued to be the cooperator in this area. His farm is located three or four miles west of Claremont. Planting was done May 29 and harvesting on October 22.

North James River Area

Spink County. Two tests were conducted on the Redfield Development Farm in cooperation with the Bureau of Reclamation. This farm is about six miles east of Redfield. One experiment was on dry land, the other under irrigation. The dry-land plot was fertilized with 10 tons of manure and 100 pounds of 10-20-0 per acre. It was planted May 24 and harvested October 17. The irrigated test received 20 tons of manure and 200 pounds of 10-20-0 per acre. It was planted May 17 and harvested October 16.

South Central Area

Brule County. The test in area 6 was conducted in Brule County in 1951 on the farm of Dale Cook which is three to four miles east of Chamberlain on U. S. Highway 16. In previous years the test in this area has been in Tripp County. Therefore, there are no averages covering periods of two or more years. The test was planted June 5 and harvested October 19.

Southeast Area

Minnehaha County. In 1951 this test was moved from its previous location near Garretson to the farm of John Muchow which is nine miles west of Sioux Falls on U. S. Highway 16 and one mile north. The test was planted May 25, quite late because of the wet spring. This coupled with the cool season resulted in excessively high moisture in the fall. Harvesting took place October 29.

*Differences in yield of less than 5.7 bushels per acre are not statistically significant.

Southeast Area

Clay County. Leo Trudeau was again the cooperator for the Clay County test. He lives about six miles north of Vermillion on State Highway 19. Corn in these plots were the driest of any harvested in 1951 and yields were quite good for this year. Planting was done May 26 and harvesting was completed on October 31.
